The 1–18 group labels are recommended by the International Union of Pure and Applied Chemistry (IUPAC). The group labels below those with numerals and letters (1A, 2A, etc.) follow the common North American convention, as we do in this text.

A value in parentheses is the mass number of the isotope of the longest half-life.

Permanent names are not yet assigned for elements 113, 115, 117, and 118. These elements are assigned temporary names based on their atomic numbers. See [www.webelements.com](http://www.webelements.com) for more information.

# TABLE OF ATOMIC NUMBERS AND ATOMIC WEIGHTS

Name	Symbol	Atomic Number	Atomic Weight	Name	Symbol	Atomic Number	Atomic Weight
Actinium	Ac	89	(227)	Mendelevium	Md	101	(258)
Aluminum	Al	13	26.9815386	Mercury	Hg	80	200.592
Americium	Am	95	(243)	Molybdenum	Mo	42	95.95
Antimony	Sb	51	121.760	Neodymium	Nd	60	144.242
Argon	Ar	18	39.948	Neon	Ne	10	20.1798
Arsenic	As	33	74.921596	Neptunium	Np	93	(237)
Astatine	At	85	(210)	Nickel	Ni	28	58.6934
Barium	Ba	56	137.328	Niobium	Nb	41	92.90637
Berkelium	Bk	97	(247)	Nitrogen	N	7	14.007
Beryllium	Be	4	9.0121832	Nobelium	No	102	(259)
Bismuth	Bi	83	208.98040	Osmium	Os	76	190.23
Bohrium	Bh	107	(272)	Oxygen	O	8	15.999
Boron	B	5	10.81	Palladium	Pd	46	106.42
Bromine	Br	35	79.904	Phosphorus	P	15	30.973761999
Cadmium	Cd	48	112.414	Platinum	Pt	78	195.085
Calcium	Ca	20	40.078	Plutonium	Pu	94	(244)
Californium	Cf	98	(251)	Polonium	Po	84	(209)
Carbon	C	6	12.011	Potassium	K	19	39.0983
Cerium	Ce	58	140.116	Praseodymium	Pr	59	140.90766
Cesium	Cs	55	132.90545197	Promethium	Pm	61	(145)
Chlorine	Cl	17	35.45	Protactinium	Pa	91	231.03588
Chromium	Cr	24	51.9962	Radium	Ra	88	(226)
Cobalt	Co	27	58.933194	Radon	Rn	86	(222)
Copernicium	Cn	112	(285)	Rhenium	Re	75	186.207
Copper	Cu	29	63.546	Rhodium	Rh	45	102.90550
Curium	Cm	96	(247)	Roentgenium	Rg	111	(280)
Darmstadtium	Ds	110	(281)	Rubidium	Rb	37	85.4678
Dubnium	Db	105	(262)	Ruthenium	Ru	44	101.07
Dysprosium	Dy	66	162.500	Rutherfordium	Rf	104	(267)
Einsteinium	Es	99	(252)	Samarium	Sm	62	150.36
Erbium	Er	68	167.259	Scandium	Sc	21	44.955909
Europium	Eu	63	151.964	Seaborgium	Sg	106	(271)
Fermium	Fm	100	(257)	Selenium	Se	34	78.972
Flerovium	Fl	114	(289)	Silicon	Si	14	28.085
Fluorine	F	9	18.998403164	Silver	Ag	47	107.8682
Francium	Fr	87	(223)	Sodium	Na	11	22.98976928
Gadolinium	Gd	64	157.25	Strontium	Sr	38	87.62
Gallium	Ga	31	69.723	Sulfur	S	16	32.06
Germanium	Ge	32	72.631	Tantalum	Ta	73	180.94788
Gold	Au	79	196.966570	Technetium	Tc	43	(98)
Hafnium	Hf	72	178.49	Tellurium	Te	52	127.60
Hassium	Hs	108	(270)	Terbium	Tb	65	158.92535
Helium	He	2	4.002602	Thallium	Tl	81	204.38
Holmium	Ho	67	164.93033	Thorium	Th	90	232.0377
Hydrogen	H	1	1.008	Thulium	Tm	69	168.93422
Indium	In	49	114.818	Tin	Sn	50	118.711
Iodine	I	53	126.90447	Titanium	Ti	22	47.867
Iridium	Ir	77	192.217	Tungsten	W	74	183.84
Iron	Fe	26	55.845	Ununoctium	Uuo	118	(294)
Krypton	Kr	36	83.798	Ununpentium	Uup	115	(288)
Lanthanum	La	57	138.90548	Ununseptium	Uus	117	(294)
Lawrencium	Lr	103	(262)	Ununtrium	Uut	113	(284)
Lead	Pb	82	207.2	Uranium	U	92	238.02891
Lithium	Li	3	6.941	Vanadium	V	23	50.9415
Livermorium	Lv	116	(293)	Xenon	Xe	54	131.294
Lutetium	Lu	71	174.9668	Ytterbium	Yb	70	173.055
Magnesium	Mg	12	24.305	Yttrium	Y	39	88.90584
Manganese	Mn	25	54.938044	Zinc	Zn	30	65.38
Meitnerium	Mt	109	(276)	Zirconium	Zr	40	91.224

A value in parentheses is the mass number of the isotope of longest half-life.

# 5 REASONS

to buy your textbooks  
and course materials at

# CENGAGE **brain**.com

- 1 SAVINGS:**  
Prices up to 75% off, daily coupons, and free shipping on orders over \$25
  - 2 CHOICE:**  
Multiple format options including textbook, eBook and eChapter rentals
  - 3 CONVENIENCE:**  
Anytime, anywhere access of eBooks or eChapters via mobile devices
  - 4 SERVICE:**  
Free eBook access while your text ships, and instant access to online homework products
  - 5 STUDY TOOLS:**  
Study tools\* for your text, plus writing, research, career and job search resources  
\*availability varies

# Contents

Essays	xv
Preface	xvi
A Note to Students	xx
About the Authors	xxi

## 1 Chemistry and Measurement 1

### An Introduction to Chemistry 2

- 1.1 Modern Chemistry: A Brief Glimpse 3
- 1.2 Experiment and Explanation 4
- A CHEMIST LOOKS AT** The Birth of the Post-it Note® 5
- 1.3 Law of Conservation of Mass 6
- 1.4 Matter: Physical State and Chemical Composition 8

**INSTRUMENTAL METHODS** Separation of Mixtures by Chromatography 13

### Physical Measurements 15

- 1.5 Measurement and Significant Figures 15
- 1.6 SI Units 18
- 1.7 Derived Units 21
- 1.8 Units and Dimensional Analysis (Factor-Label Method) 25

A Checklist for Review • Summary of Facts and Concepts • Learning Objectives • Important Terms • Key Equations • Questions and Problems • Self-Assessment and Review Questions • Concept Explorations • Conceptual Problems • Practice Problems • General Problems • Strategy Problems • Capstone Problems

## 2 Atoms, Molecules, and Ions 31

### Atomic Theory and Atomic Structure 32

- 2.1 Atomic Theory of Matter 33
- 2.2 The Structure of the Atom 35
- 2.3 Nuclear Structure; Isotopes 38
- 2.4 Atomic Weights 40
- 2.5 Periodic Table of the Elements 43

**A CHEMIST LOOKS AT** The Discovery of New Elements 45

### Chemical Substances: Formulas and Names 46

- 2.6 Chemical Formulas; Molecular and Ionic Substances 46
- 2.7 Organic Compounds 51
- 2.8 Naming Simple Compounds 52

### Chemical Reactions: Equations 63

- 2.9 Writing Chemical Equations 63
- 2.10 Balancing Chemical Equations 64

A Checklist for Review • Summary of Facts and Concepts • Learning Objectives • Important Terms • Questions and Problems • Self-Assessment and Review Questions • Concept Explorations • Conceptual Problems • Practice Problems • General Problems • Strategy Problems • Capstone Problems

### 3 Calculations with Chemical Formulas and Equations 70

#### Mass and Moles of Substance 71

- 3.1 Molecular Weight and Formula Weight 71
- 3.2 The Mole Concept 73

#### Determining Chemical Formulas 78

- 3.3 Mass Percentages from the Formula 78
- 3.4 Elemental Analysis: Percentages of Carbon, Hydrogen, and Oxygen 80
- 3.5 Determining Formulas 82

#### INSTRUMENTAL METHODS Mass Spectrometry and Molecular Formula 83

#### Stoichiometry: Quantitative Relations in Chemical Reactions 88

- 3.6 Molar Interpretation of a Chemical Equation 88
- 3.7 Amounts of Substances in a Chemical Reaction 89
- 3.8 Limiting Reactant; Theoretical and Percentage Yields 93

A Checklist for Review • Summary of Facts and Concepts • Learning Objectives • Important Terms • Key Equations • Questions and Problems • Self-Assessment and Review Questions • Concept Explorations • Conceptual Problems • Practice Problems • General Problems • Strategy Problems • Capstone Problems

### 4 Chemical Reactions 102

#### Ions in Aqueous Solution 103

- 4.1 Ionic Theory of Solutions and Solubility Rules 103
- 4.2 Molecular and Ionic Equations 108

#### Types of Chemical Reactions 111

- 4.3 Precipitation Reactions 111
- 4.4 Acid–Base Reactions 114
- 4.5 Oxidation–Reduction Reactions 122
- 4.6 Balancing Simple Oxidation–Reduction Equations 129

#### Working with Solutions 131

- 4.7 Molar Concentration 131
- 4.8 Diluting Solutions 133

#### Quantitative Analysis 135

- 4.9 Gravimetric Analysis 135
- 4.10 Volumetric Analysis 137

A Checklist for Review • Summary of Facts and Concepts • Learning Objectives • Important Terms • Key Equations • Questions and Problems • Self-Assessment and Review Questions • Concept Explorations • Conceptual Problems • Practice Problems • General Problems • Strategy Problems • Capstone Problems

**5 The Gaseous State 143****Gas Laws 144**

5.1 Gas Pressure and Its Measurement 144

5.2 Empirical Gas Laws 146

**A CHEMIST LOOKS AT** Nitrogen Monoxide Gas and Biological Signaling 154

5.3 The Ideal Gas Law 155

5.4 Stoichiometry Problems Involving Gas Volumes 160

5.5 Gas Mixtures; Law of Partial Pressures 162

**Kinetic-Molecular Theory 166**

5.6 Kinetic Theory of an Ideal Gas 167

5.7 Molecular Speeds; Diffusion and Effusion 170

5.8 Real Gases 175

**A CHEMIST LOOKS AT** Carbon Dioxide Gas and the Greenhouse Effect 178

A Checklist for Review • Summary of Facts and Concepts • Learning Objectives • Important Terms • Key Equations • Questions and Problems • Self-Assessment and Review Questions • Concept Explorations • Conceptual Problems • Practice Problems • General Problems • Strategy Problems • Capstone Problems

**6 Thermochemistry 182****Understanding Heats of Reaction 183**

6.1 Energy and Its Units 184

6.2 First Law of Thermodynamics; Work and Heat 186

6.3 Heat of Reaction; Enthalpy of Reaction 190

6.4 Thermochemical Equations 194

6.5 Applying Stoichiometry to Heats of Reaction 196

**A CHEMIST LOOKS AT** Lucifers and Other Matches 197

6.6 Measuring Heats of Reaction 198

**Using Heats of Reaction 202**

6.7 Hess's Law 202

6.8 Standard Enthalpies of Formation 206

6.9 Fuels—Foods, Commercial Fuels, and Rocket Fuels 210

A Checklist for Review • Summary of Facts and Concepts • Learning Objectives • Important Terms • Key Equations • Questions and Problems • Self-Assessment and Review Questions • Concept Explorations • Conceptual Problems • Practice Problems • General Problems • Strategy Problems • Capstone Problems

**7 Quantum Theory of the Atom 215****Light Waves, Photons, and the Bohr Theory 217**

7.1 The Wave Nature of Light 217

7.2 Quantum Effects and Photons 219

7.3 The Bohr Theory of the Hydrogen Atom 222

**A CHEMIST LOOKS AT** Lasers and CD and DVD Players 226**Quantum Mechanics and Quantum Numbers 228**

7.4 Quantum Mechanics 228

7.5 Quantum Numbers and Atomic Orbitals 231

**INSTRUMENTAL METHODS** Scanning Tunneling Microscopy 232

A Checklist for Review • Summary of Facts and Concepts • Learning Objectives • Important Terms • Key Equations • Questions and Problems • Self-Assessment and Review Questions • Concept Explorations • Conceptual Problems • Practice Problems • General Problems • Strategy Problems • Capstone Problems

## 8 Electron Configurations and Periodicity 239

**Electronic Structure of Atoms** 240

8.1 Electron Spin and the Pauli Exclusion Principle 240

**INSTRUMENTAL METHODS** Nuclear Magnetic Resonance (NMR) 242

8.2 Building-Up Principle and the Periodic Table 245

8.3 Writing Electron Configurations Using the Periodic Table 249

**INSTRUMENTAL METHODS** X Rays, Atomic Numbers, and Orbital Structure (Photoelectron Spectroscopy) 250

8.4 Orbital Diagrams of Atoms; Hund's Rule 253

**A CHEMIST LOOKS AT** Levitating Frogs and People 256

**Periodicity of the Elements** 256

8.5 Mendeleev's Predictions from the Periodic Table 256

8.6 Some Periodic Properties 258

8.7 Periodicity in the Main-Group Elements 265

A Checklist for Review • Summary of Facts and Concepts • Learning Objectives • Important Terms • Questions and Problems • Self-Assessment and Review Questions • Concept Explorations • Conceptual Problems • Practice Problems • General Problems • Strategy Problems • Capstone Problems

## 9 Ionic and Covalent Bonding 269

**Ionic Bonds** 270

9.1 Describing Ionic Bonds 270

**A CHEMIST LOOKS AT** Ionic Liquids and Green Chemistry 275

9.2 Electron Configurations of Ions 276

9.3 Ionic Radii 279

**Covalent Bonds** 281

9.4 Describing Covalent Bonds 282

9.5 Polar Covalent Bonds; Electronegativity 284

**A CHEMIST LOOKS AT** Chemical Bonds in Nitroglycerin 285

9.6 Writing Lewis Electron-Dot Formulas 287

9.7 Delocalized Bonding: Resonance 291

9.8 Exceptions to the Octet Rule 293

9.9 Formal Charge and Lewis Formulas 296

9.10 Bond Length and Bond Order 299

9.11 Bond Enthalpy 301

**INSTRUMENTAL METHODS** Infrared Spectroscopy and Vibrations of Chemical Bonds 305

A Checklist for Review • Summary of Facts and Concepts • Learning Objectives • Important Terms • Questions and Problems • Self-Assessment and Review Questions • Concept Explorations • Conceptual Problems • Practice Problems • General Problems • Strategy Problems • Capstone Problems

## 10 Molecular Geometry and Chemical Bonding Theory 309

### Molecular Geometry and Directional Bonding 311

- 10.1 The Valence-Shell Electron-Pair Repulsion (VSEPR) Model 311  
**A CHEMIST LOOKS AT** Left-Handed and Right-Handed Molecules 320  
 10.2 Dipole Moment and Molecular Geometry 321  
 10.3 Valence Bond Theory 325  
 10.4 Description of Multiple Bonding 331

### Molecular Orbital Theory 336

- 10.5 Principles of Molecular Orbital Theory 336  
 10.6 Electron Configurations of Diatomic Molecules of the Second-Period Elements 339  
 10.7 Molecular Orbitals and Delocalized Bonding 342  
**A CHEMIST LOOKS AT** Human Vision 344  
**A CHEMIST LOOKS AT** Stratospheric Ozone (An Absorber of Ultraviolet Rays) 345  
 A Checklist for Review • Summary of Facts and Concepts • Learning Objectives • Important Terms • Questions and Problems • Self-Assessment and Review Questions • Concept Explorations • Conceptual Problems • Practice Problems • General Problems • Strategy Problems • Capstone Problems

## 11 States of Matter; Liquids and Solids 349

- 11.1 Comparison of Gases, Liquids, and Solids 350

### Changes of State 351

- 11.2 Phase Transitions 351  
 11.3 Phase Diagrams 361

### Liquid State 363

- 11.4 Properties of Liquids; Surface Tension and Viscosity 363  
**A CHEMIST LOOKS AT** Removing Caffeine from Coffee 364  
 11.5 Intermolecular Forces; Explaining Liquid Properties 367  
**A CHEMIST LOOKS AT** Gecko Toes, Sticky But Not Tacky 375

### Solid State 376

- 11.6 Classification of Solids by Type of Attraction of Units 376  
 11.7 Crystalline Solids; Crystal Lattices and Unit Cells 380  
**A CHEMIST LOOKS AT** Liquid-Crystal Displays 384  
 11.8 Structures of Some Crystalline Solids 385  
 11.9 Calculations Involving Unit-Cell Dimensions 390  
 11.10 Determining Crystal Structure by X-Ray Diffraction 393

### INSTRUMENTAL METHODS Automated X-Ray Diffractometry 395

- A CHEMIST LOOKS AT** Water (A Special Substance for Planet Earth) 396

A Checklist for Review • Summary of Facts and Concepts • Learning Objectives • Important Terms • Key Equation • Questions and Problems • Self-Assessment and Review Questions • Concept Explorations • Conceptual Problems • Practice Problems • General Problems • Strategy Problems • Capstone Problems

## 12 Solutions 401

### Solution Formation 402

12.1 Types of Solutions 402

12.2 Solubility and the Solution Process 404

**A CHEMIST LOOKS AT** Hemoglobin Solubility and Sickle-Cell Anemia 409

12.3 Effects of Temperature and Pressure on Solubility 410

### Colligative Properties 413

12.4 Ways of Expressing Concentration 413

# Preface

In the preface to the first edition, we wrote, “Scientists delve into the molecular machinery of the biological cell and examine bits of material from the planets of the solar system. The challenge for the instructors of introductory chemistry is to capture the excitement of these discoveries [of chemistry] while giving students a solid understanding of the basic principles and facts. The challenge for the students is to be receptive to a new way of thinking, which will allow them to be caught up in the excitement of discovery.” From the very first edition of this text, our aims have always been to help instructors capture the excitement of chemistry and to teach students to “think chemistry.” Here are some of the features of the text that we feel are especially important in achieving these goals.

## Clear, Lucid Explanations of Chemical Concepts

We have always placed the highest priority on writing clear, lucid explanations of chemical concepts. We have strived to relate abstract concepts to specific real-world events and have presented topics in a logical, yet flexible, order. With succeeding editions we have refined the writing, incorporating suggestions from instructors and students.

## Coherent Problem-Solving Approach

With the first edition, we presented a coherent problem-solving approach that involved worked-out *Examples* coupled with in-chapter *Exercises* and corresponding end-of-chapter *Problems*. This approach received an enormously positive response, and we have continued to refine the pedagogical and conceptual elements in each subsequent edition.

In the ninth edition, we revised every Example, dividing the problem-solving process into a *Problem Strategy*, a *Solution*, and an *Answer Check*. By doing this, we hoped to help students develop their problem-solving skills: *think* how to proceed, *solve* the problem, and *check* the answer. This last step is one that is often overlooked by students, but it is critical if one is to obtain consistently reliable results.

In the tenth edition, we added yet another level of support for students in this problem-solving process. In every Example, we added what we call the *Gaining Mastery Toolbox*. We based this Toolbox on how we as instructors might help a student who is having trouble with a particular problem. We imagine a student coming to our office because of difficulty with a particular problem. We begin the help session by pointing out to the student the “big idea” that one needs to solve the problem. We call this the *Critical Concept*. But suppose the student is still having difficulty with the problem. We now ask the student about his or her knowledge of prior topics that will be needed to approach the problem. We call these needed prior topics the *Solution Essentials*. Each *Gaining Mastery Toolbox* that we have added to an Example begins by pointing out the Critical Concept involved in solving the problem posed in that Example. Then, under the heading of Solution Essentials, we list the topics the student needs to have mastered to solve this problem. We hope the Gaining Mastery Toolbox helps the student in much the way that an individual office visit can. Over several Examples, these Toolboxes should help the student develop the habit of focusing on the Critical Concept and the Solution Essentials while engaged in general problem solving.

While we believe in the importance of this coherent example/exercise approach, we also think it is necessary to have students expand their understanding of the concepts. For this purpose, we have a second type of in-chapter problem, *Concept Checks*. We have written these to force students to think about the concepts involved, rather than to focus on the final result or numerical answer—or to try to fit the problem to a memorized algorithm. We want

students to begin each problem by asking, “What are the chemical concepts that apply here?” Many of these problems involve visualizing a molecular situation, since visualization is such a critical part of learning and understanding modern chemistry. Similar types of end-of-chapter problems, the *Conceptual Problems*, are provided for additional practice.

A major focus of this edition was to perform a thorough integration of the text with the host of digital instructional materials available from Cengage Learning, including the MindTap digital version and the OWLv2 online learning solution. However, of particular note for this edition is a revision to how each of the Example Problems have been formatted to provide a clearer path for student learning. Additionally, new Capstone Problems have been added to a number of chapters. Essays have been added, updated, and revised to reflect our current understanding of a variety of relevant topics.

### Extensive Conceptual Focus

A primary goal of recent editions has been to strengthen the conceptual focus of the text. To that end we have three types of end-of-chapter problems, *Concept Explorations*, *Strategy Problems*, and *Self-Assessment Questions*. While we have included them in the end-of-chapter material, *Concept Explorations* are unlike any of the other end-of-chapter problems. These multipart, multistep problems are structured activities developed to help students explore important chemical concepts—the key ideas in general chemistry—and confront common misconceptions or gaps in learning. Often deceptively simple, *Concept Explorations* ask probing questions to test student’s understanding. Because we feel strongly that in order to develop a lasting conceptual understanding, students must think about the question without jumping quickly to formulas or algorithms (or even a calculator); we have purposely not included their answers in the *Student Solutions Manual*. As *Concept Explorations* are ideally used in an interactive classroom situation, we have reformatted them into workbook style in-class handouts with space for written answers and drawings to facilitate their use in small groups. In the *Instructor’s Resource Manual*, we provide additional background on the literature and theories behind their development, information on how Steve Gammon has implemented them into his classroom and suggestions for integration, and a listing of the concepts (and common misconceptions thereof) that each *Concept Exploration* addresses.

We recognize a need to challenge students to build a conceptual understanding rather than simply memorizing the algorithm from the matched pair and then applying it to a similar problem to get a solution. The *Strategy Problems* were written to extend students’ problem-solving skills beyond those developed in the *Practice* and *General Problems*. With this edition, we have nearly doubled the number of these problems. To work a *Strategy Problem*, students will need to think about the problem (which might involve several concepts or problem-solving skills from the chapter), then solve it on their own without a similar problem from which to model their answer. For this reason, we have explicitly chosen not to include their answers in the *Student Solutions Manual*.

On the basis of student feedback, we developed conceptually focused multiple-choice questions to provide students with a quick opportunity for self-assessment. As they are intended primarily for self-study, these questions have been included with the Review Questions, in the retitled *Self-Assessment and Review Questions* section. As an instructor, you know that a student may answer a multiple-choice question correctly but still use incorrect reasoning to arrive at the answer. You would certainly like to know whether the student has used correct reasoning. In this edition, we have explored using *two-tier questions* to address whether the student’s learning of a concept has depth or is superficial. The first tier of a question might be fairly straightforward. For example, we might begin a question by listing a number of formulas of compounds and ask the student to classify each one as an ionic compound or a molecular compound. The student might give correct answers, but we want to draw him or her out as to the reasoning used by adding a further question (the second tier), such as, “Which of the following is the best statement regarding molecular compounds?” By seeing how the student answers the second tier of a two-tier question, we can learn whether

he or she may have a misconception of the material. In other words, we learn whether the student has a complete and correct understanding of an important concept.

### An Illustration Program with an Emphasis on Molecular Concepts

Most of us (and our students) are highly visual in our learning. When we see something, we tend to remember it. As in the previous edition, we went over each piece of art, asking how it might be improved or where art could be added to improve student comprehension. We continue to focus on the presentation of chemistry at the molecular level. The molecular “story” starts in Chapter 1, and by Chapter 2, we have developed the molecular view and have integrated it into the problem-solving apparatus as well as into the text discussions. The following chapters continue to use the molecular view to strengthen chemical concepts. We have introduced electrostatic potential maps where pedagogically relevant to show how electron density changes across a molecule. This is especially helpful for visually demonstrating such things as bond and molecular polarity and acid–base behavior.

### Chapter Essays Showcasing Chemistry as a Modern, Applicable Science

We continue our *A Chemist Looks at . . .* essays, which cover up-to-date issues of science and technology. We have chosen topics that will engage students’ interest while at the same time highlight the chemistry involved. Icons are used to describe the content area (materials, environment, daily life, frontiers, and life science) being discussed. The essays show students that chemistry is a vibrant, constantly changing science that has relevance for our modern world. The essay “Gecko Toes, Sticky But Not Tacky,” for example, describes the van der Waals forces used by gecko toes and their possible applications to the development of infinitely reusable tape or robots that can climb walls!

Also, with this edition, we continue our *Instrumental Methods* essays. These essays demonstrate the importance of sophisticated instruments for modern chemistry by focusing on an instrumental method used by research chemists, such as mass spectroscopy or nuclear magnetic resonance. Although short, these essays provide students with a level of detail to pique the students’ interest in this subject.

We recognize that classroom and study times are very limited and that it can be difficult to integrate this material into the course. For that reason, we include end-of-chapter essay questions based on each *A Chemist Looks at . . .* and *Instrumental Methods* essay. These questions promote the development of scientific writing skills, another area that often gets neglected in packed general chemistry courses. It is our hope that having brief essay questions ready to assign will allow both students and instructors to value the importance of this content and make it easier to incorporate into their curriculums.

### Additions and Changes Made in This Edition

- Changed formatting of Example Problems to facilitate student learning.
- Throughout the text, we adopted the terms atomic weight, molecular weight, and formula weight in place of corresponding terms atomic mass, and so on.
- Throughout the text, we adopted IUPAC periodic table conventions.
- Revisions throughout reflect recent work showing that the *d* hybrid orbitals are not dominant in bonding.
- Several “A Chemist Looks At” essays, including “Carbon Dioxide Gas and the Greenhouse Effect,” “Nuclear Magnetic Resonance (NMR),” “Acid Rain,” “Limestone Caves,” and “Superconductivity,” were updated. New essays on “The Discovery of New Elements” and “Lithium-Ion Batteries” were added.
- The mass spectrometer was added to Figure 3.8.
- In Chapter 6, the explanation of conversion factors used in stoichiometry calculations was clarified and the discussion of the NASA space program updated.
- In Chapter 7, figures relating to the electron microscope and scanning tunneling microscope were updated.
- In Chapter 8, the discussion on main-group elements was updated.

- In Chapter 9, we improved the discussion of electrostatic potential maps and the application of formal charge.
- In Chapter 10, a new subsection was added explaining the modern view of bonding in central atoms having more than eight valence electrons.
- The discussion of graphite in Chapter 11 was updated to include the recent discovery of graphene, the Nobel Prize for its discovery, and the lubricating ability of graphite by adsorption of water molecules to the layer structure.
- Chapter 18 was revised in several areas to clarify the discussion of the laws of thermodynamics.
- In Chapter 19, major revisions were made to the discussion of commercial voltaic cells to include modern battery types.
- In Chapter 23, a mention of the “E-Z system” for naming geometric isomers was added.

## ▶ Acknowledgments

---

The successful revision of a text depends upon the knowledge, skills, and dedication of a large number of individuals at Cengage Learning. This revision was initiated and led by Lisa Lockwood. Content developers provide invaluable guidance in performing the revision. Alyssa White and Peter McGahey were invaluable in this role. Our content product manager, Teresa Trego, ensured that we had the perfect content asset to meet our instructional needs. Art direction was provided by Sarah Cole. Her work created the new interior and cover designs. Ensuring that the 11th edition gets into the hands of students is our marketing manager, Janet Del Mundo. Product assistance was provided by Margaret O’Neil. Margaret prepared all of our permission and art logs. The media developer is Lisa Weber. Lisa works with content developers and vendors to ensure the seamless integration of technology with the text. Christine Myakovsky, permissions specialist, worked tirelessly to acquire photo permissions, kept us on track with the photo budget, and led the photo research team. Our IP project manager, Farah Fard, managed the photo researcher in order to provide the best possible photographic choices.

In addition to those people at Cengage, a number of people from other vendors were key players in this revision. These include Lynn Lustberg, at MPS Limited. Lynn was the production manager who ensured that everything came together when preparing the final product. Vikram Jayabala, at Lumina Datamatics, performed all of the photo research and permissioning. Our new chemistry photographs were due to the work of Jean Smolen (chemist) and Melissa Kelly (photographer) at St. Joseph’s University.

David Shinn, at the U.S. Merchant Marine Academy, performed the revisions to end-of-chapter problems and provided new problems. Accuracy reviews and pre-revision reviews were performed by Don Neu at St. Cloud State University. Over the numerous editions of the text, we have been grateful for the insights and suggestions of the reviewers. They have played a critical role in the continuous improvements that are a hallmark of this text. For this edition, we would like to give a special thank you to Mark Blankenbuehler at Morehead State University and Mathilda Doorley at Southwest Tennessee Community College, who played the most critical role in the current revision.

Darrell wishes to thank his wife Jean and their children, Julie, Linda, and Russell, for their continued support and encouragement over many years of writing. Steve thanks his wife Jodi and their two children, Katie and Andrew, and his parents, Judy and Dick, for their support and for helping him keep a perspective on the important things in life.

# A Note to Students

Having studied and taught chemistry for some years, we are well aware of the problems students encounter. We also know that students don't always read the Preface, so we wanted to remind you of all the resources available to help you master general chemistry.

## Read the book

Each individual learns in a different way. We have incorporated a number of features into the text to help you tailor a study program that meets your particular needs and learning style.

## Practice, practice, practice

Problem solving is an important part of chemistry, and it only becomes easier with practice. We worked hard to create a consistent three-part problem-solving approach (*Problem Strategy*, *Solution*, and *Answer Check*) in each in-chapter *Example*. Try the related *Exercise* on your own, and use the corresponding end-of-chapter *Practice Problems* to gain mastery of your problem-solving skills.

In every Example, we have also added what we call the *Gaining Mastery Toolbox*. We based this Toolbox on how we as instructors might help a student who is having trouble with a particular problem. We imagine a student coming to our office because of difficulty with a particular problem. We begin the help session by pointing out to the student the "big idea" that one needs to solve the problem. We call this the *Critical Concept*. But suppose the student is still having difficulty with the problem. We now ask the student about his or her knowledge of prior topics that will be needed to approach the problem. We call these needed prior topics the *Solution Essentials*. Each Gaining Mastery Toolbox that we have added to an Example begins by pointing out the Critical Concept involved in solving the problem posed in that Example. Then, under the heading of Solution Essentials, we list the topics the student needs to have mastered to solve this problem. We hope the Gaining Mastery Toolbox helps the student in much the way that an individual office visit can. Over several Examples, these Toolboxes should help the student develop the habit of focusing on the Critical Concept and the Solution Essentials while engaged in general problem solving.

## Get help when you need it

Don't hesitate to ask your instructor or teaching assistant for help. You can also take advantage of the following helpful aids available at your school bookstore or at [www.cengagebrain.com](http://www.cengagebrain.com):

- The **Student Solutions Manual** contains detailed solutions to textbook problems.
- The **Study Guide** reinforces concepts and further builds problem-solving skills.

We have put a lot of time and thought into how to help you succeed. We hope you take advantage of all the technology and resources available with *General Chemistry*, Eleventh Edition. Best of luck in your study!

Darrell D. Ebbing  
Steven D. Gammon

# About the Authors

## DARRELL D. EBBING

Darrell Ebbing became interested in chemistry at a young age when he tried his hand at doing magic tricks for friends, such as turning water to wine and having (nitrated) handkerchiefs disappear in a poof. Soon, however, his interests turned to the chemistry behind the magic and he even set up a home laboratory. After briefly becoming interested in botany in high school (having gathered several hundred plant specimens), his interest in chemistry was especially piqued when he managed to isolate white crystals of caffeine from tea. From that point, he knew he would go on to major in chemistry. During college, he helped pay his expenses by working at the USDA lab in Peoria, Illinois, as an assistant to a carbohydrate chemist, where he worked on derivatives of starch. As a graduate student at Indiana University, his interests gravitated to the theoretical—to understand the basis of chemistry—and he pursued a PhD in physical chemistry in the area of quantum chemistry.

Professor Ebbing began his professional career at Wayne State University where he taught courses at the undergraduate and graduate level and was for several years the Head of the Physical Chemistry Division. He soon became especially involved in teaching general chemistry, taking the position of Coordinator of General Chemistry. In his teaching, he used his knowledge of “chemical magic” to do frequent lecture demonstrations. He has written a book for introductory chemistry as well as this one for general chemistry (where you will see many of those lecture demonstrations). Although retired from active teaching, he retains a keen interest in frontier topics of science and in the history and philosophy of physical science, interests he hopes to turn into another book.

Having grown up in farm country, surrounded by fields and woods, Professor Ebbing has always maintained a strong interest in the great outdoors. He enjoys seeing nature up close through hiking and birding. His interests also include concerts and theater, as well as world travel.

## STEVEN D. GAMMON

Steve Gammon started on his path to becoming a chemist and science educator in high school where he was captivated by a great instructor. After receiving a PhD in inorganic chemistry and chemical education from the University of Illinois-Urbana, he worked for two years at the University of Wisconsin-Madison, serving as the General Chemistry Laboratory Coordinator and becoming immersed in the field of chemical education. Professor Gammon then went on to join the faculty at the University of Idaho as the Coordinator of General Chemistry. In this role, he taught thousands of students, published instructional software, directed federally funded projects involving K-12 teachers, and began his work on *General Chemistry* (then going into its sixth edition). During his 11 years at the University of Idaho, he was honored with both university and national (Carnegie Foundation) teaching awards.

Throughout his career, while working at a number of colleges and universities, Professor Gammon has been involved with science education and has maintained a keen interest in the learning and teaching of introductory chemistry. In all of his endeavors, his desire is to create materials and methods that inspire his students to be excited about learning chemistry and science.

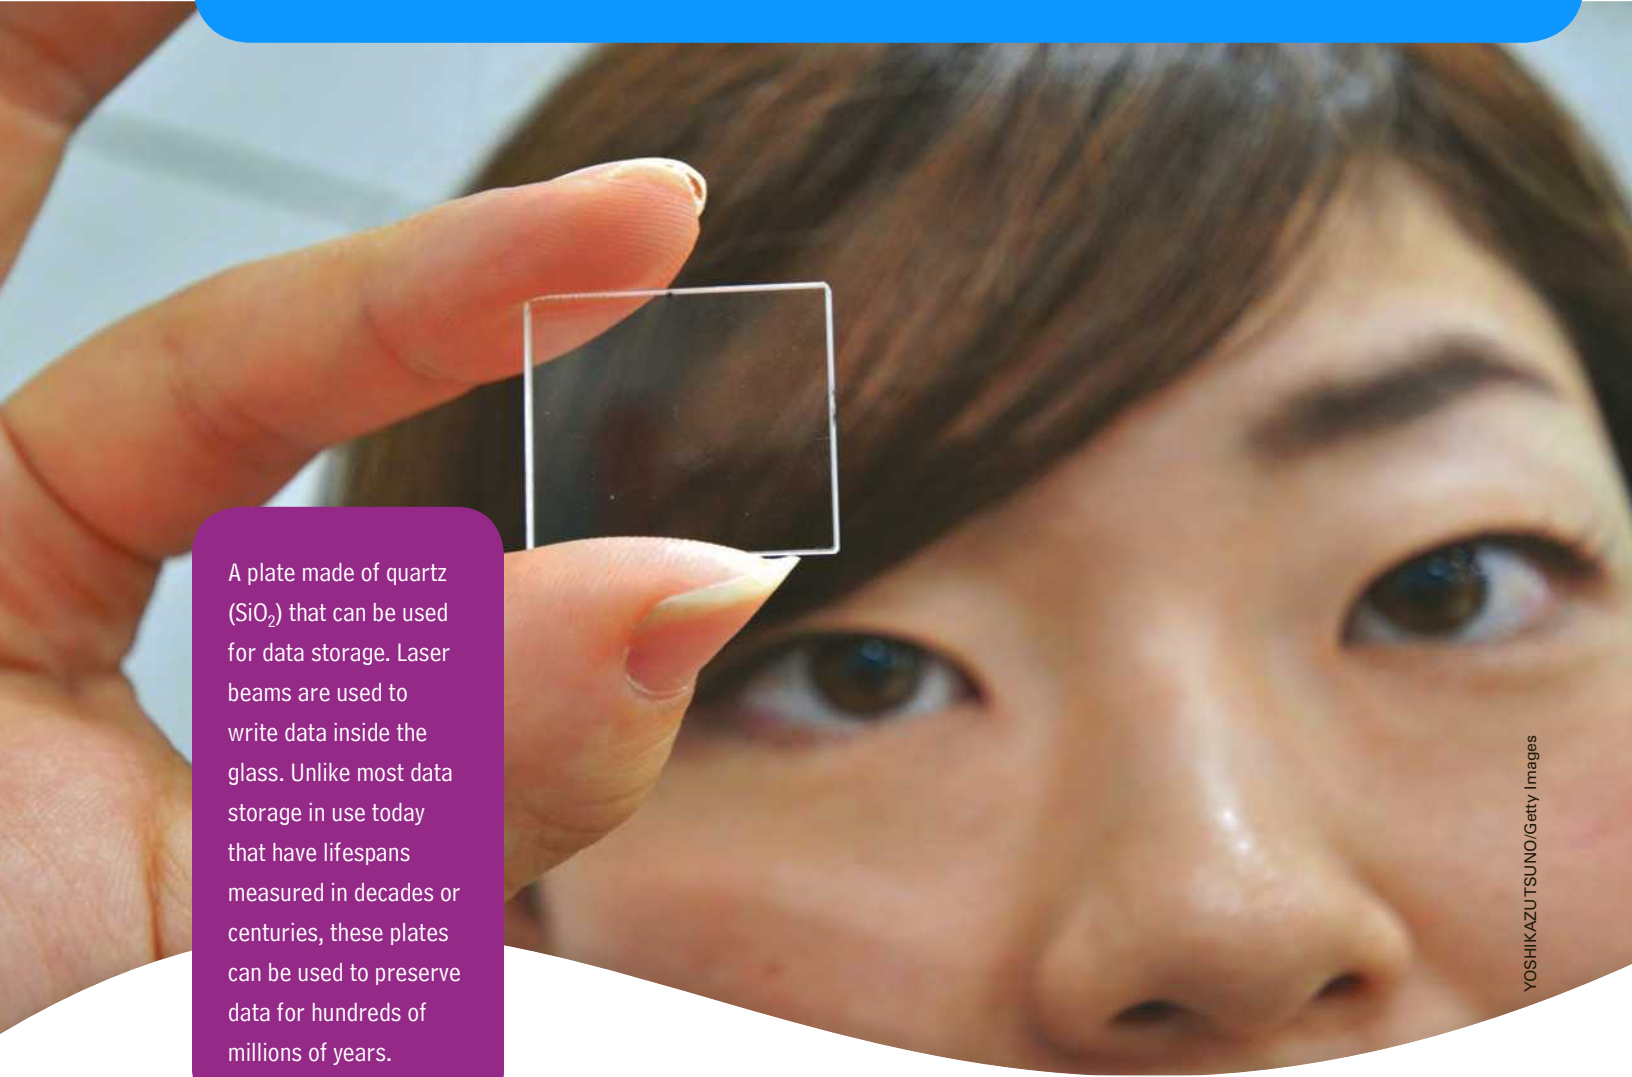

When Professor Gammon isn't thinking about the teaching and learning of chemistry, he enjoys doing a variety of activities with his family, including outdoor pursuits such as hiking, biking, camping, gold panning, and fishing. Scattered throughout the text you might find some examples of where his passion for these activities is used to make connections between chemistry and everyday living.

## CONTENTS AND CONCEPTS

### An Introduction to Chemistry

We start by defining the science called chemistry and introducing some fundamental concepts.

- 1.1** Modern Chemistry: A Brief Glimpse
- 1.2** Experiment and Explanation
- 1.3** Law of Conservation of Mass
- 1.4** Matter: Physical State and Chemical Composition

### Physical Measurements

Making and recording measurements of the properties and chemical behavior of matter is the foundation of chemistry.

- 1.5** Measurement and Significant Figures
- 1.6** SI Units
- 1.7** Derived Units
- 1.8** Units and Dimensional Analysis (Factor-Label Method)

In 1964 Barnett Rosenberg and his coworkers at Michigan State University were studying the effects of electricity on bacterial growth. They inserted platinum wire electrodes into a live bacterial culture and allowed an electric current to pass. After 1 to 2 hours, they noted that cell division in the bacteria stopped. The researchers were very surprised by this result, but even more surprised by the explanation. They were able to show that cell division was inhibited by a substance containing platinum, produced from the platinum electrodes by the electric current. A substance such as this one, the researchers thought, might be useful as an anticancer drug, because cancer involves runaway cell division. Later research confirmed this view, and the platinum-containing substances, *cisplatin*, *carboplatin*, and *oxaliplatin* are all current anticancer drugs. (Figure 1.1).

This story illustrates three significant reasons to study chemistry. First, chemistry has important practical applications. The development of lifesaving drugs is one, and a complete list would touch upon most areas of modern technology.

Second, chemistry is an intellectual enterprise, a way of explaining our material world. When Rosenberg and his coworkers saw that cell division in the bacteria had ceased, they systematically looked for the chemical substance that caused it to cease. They sought a chemical explanation for the occurrence.

Finally, chemistry figures prominently in other fields. Rosenberg's experiment began as a problem in biology; through the application of chemistry, it led to an advance in medicine. Whatever your career plans, you will find that your knowledge of chemistry is a useful intellectual tool for making important decisions.

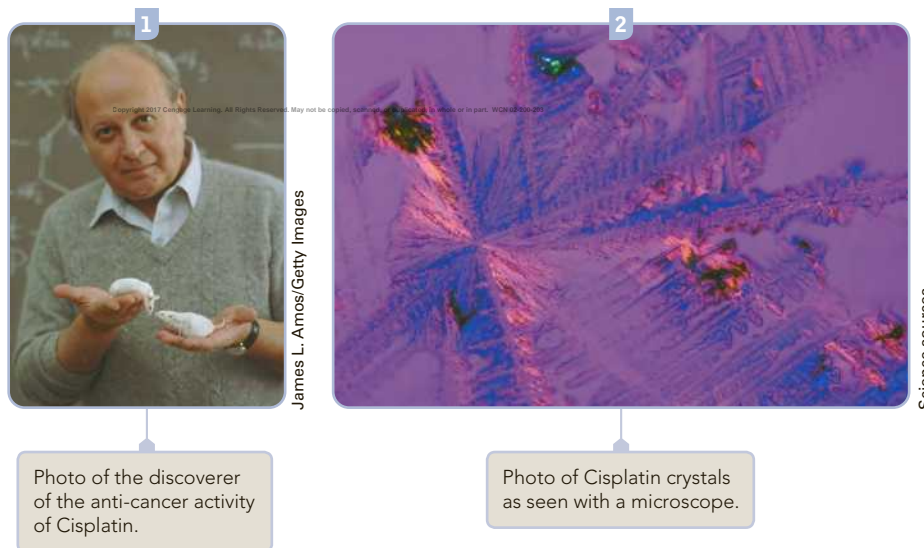

## ► An Introduction to Chemistry

All of the objects around you—this book, your pen or pencil, and the things of nature such as rocks, water, and plant and animal substances—constitute the *matter* of the universe. Each of the particular kinds of matter, such as a certain kind of paper or plastic or metal, is referred to as a *material*. We can define chemistry as the science of the composition and structure of materials and of the changes that materials undergo.

One chemist may hope that by understanding certain materials, he or she will be able to find a cure for a disease or a solution for an environmental ill. Another chemist may simply want to understand a phenomenon. Because chemistry deals with all materials, it is a subject of enormous breadth. It would be difficult to exaggerate the influence of chemistry on modern science and technology or on our ideas about our planet and the universe. In the section that follows, we will take a brief glimpse at modern chemistry and see some of the ways it has influenced technology, science, and modern thought.

Figure 1.1 ►

Barnett Rosenberg and Cisplatin

## 1.1 Modern Chemistry: A Brief Glimpse

For thousands of years, human beings have fashioned natural materials into useful products. Modern chemistry certainly has its roots in this endeavor. After the discovery of fire, people began to notice changes in certain rocks and minerals exposed to high temperatures. From these observations came the development of ceramics, glass, and metals, which today are among our most useful materials. Dyes and medicines were other early products obtained from natural substances. For example, the ancient Phoenicians extracted a bright purple dye, known as Tyrian purple, from a species of sea snail. One ounce of Tyrian purple required over 200,000 snails. Because of its brilliant hue and scarcity, the dye became the choice of royalty.

Although chemistry has its roots in early technology, chemistry as a field of study based on scientific principles came into being only in the latter part of the eighteenth century. Chemists began to look at the precise quantities of substances they used in their experiments. From this work came the central principle of modern chemistry: the materials around us are composed of exceedingly small particles called *atoms*, and the precise arrangement of these atoms into *molecules* or more complicated structures accounts for the many different characteristics of materials. Once chemists understood this central principle, they could begin to fashion molecules to order. They could *synthesize* molecules; that is, they could build large molecules from small ones. Tyrian purple, for example, was eventually synthesized from the simpler molecule aniline; see Figure 1.2. Chemists could also correlate molecular structure with the characteristics of materials and so begin to fashion materials with special characteristics.

The liquid-crystal displays (LCDs) that are used on everything from watches and cell phones to computer monitors and televisions are an example of an application that depends on the special characteristics of materials (Figure 1.3). The liquid crystals used in these displays are a form of matter intermediate in characteristics between those of liquids and those of solid crystals—hence the name. Many of these liquid crystals are composed of rodlike molecules that tend to align themselves something like the wood matches in a matchbox. The liquid crystals are held in alignment in layers by plates that have microscopic grooves. The molecules are attached to small electrodes or transistors. When the molecules are subjected to an electric charge from the transistor or electrode, they change alignment to point in a new direction. When they change direction, they change how light passes through their layer. When the liquid-crystal layer is combined with a light source and color filters, incremental changes of alignment of the molecules throughout the display allow for images that have high contrast and millions of colors. ▶ Figure 1.4 shows a model of one of the molecules that forms a liquid crystal; note the rodlike shape

**Figure 1.3** ▶

Scott Camazine/Alamy

**Figure 1.6** ▲

**A side view of a fragment of a DNA molecule** DNA contains the hereditary information of an organism that is passed on from one generation to the next.

of the molecule. Chemists have designed many similar molecules for liquid-crystal applications.

Chemists continue to develop new materials and to discover new properties of old ones. Electronics and communications, for example, have been completely transformed by technological advances in materials. Optical-fiber cables have replaced long-distance telephone cables made of copper wire. Optical fibers are fine threads of extremely pure glass. Because of their purity, these fibers can transmit laser light pulses for miles compared with only a few inches in ordinary glass. Not only is optical-fiber cable cheaper and less bulky than copper cable carrying the same information, but through the use of different colors of light, optical-fiber cable can carry voice, data, and video information at the same time (Figure 1.5). At the ends of an optical-fiber cable, devices using other new materials convert the light pulses to electrical signals and back, while computer chips constructed from still other materials process the signals.

Chemistry has also affected the way we think of the world around us. For example, biochemists and molecular biologists—scientists who study the molecular basis of living organisms—have made a remarkable finding: all forms of life appear to share many of the same molecules and molecular processes. Consider the information of inheritance, the genetic information that is passed on from one generation of organism to the next. Individual organisms, whether bacteria or human beings, store this information in a particular kind of molecule called deoxyribonucleic acid, or DNA (Figure 1.6).

DNA consists of two intertwined molecular chains; each chain consists of links of four different types of molecular pieces, or bases. Just as you record information on a page by stringing together characters (letters, numbers, spaces, and so on), an organism stores the information for reproducing itself in the order of these bases in its DNA. In a multicellular organism, such as a human being, every cell contains the same DNA.

One of our first projects will be to look at this central concept of chemistry, the atomic theory of matter. We will do that in the next chapter, but first we must lay the groundwork for this discussion. We will need some basic vocabulary to talk about science and to describe materials; then we will need to discuss measurement and units, because measurement is critical for quantitative work.

## 1.2 Experiment and Explanation

Experiment and explanation are the heart of chemical research. A chemist makes observations under circumstances in which variables, such as temperature and amounts of substances, can be controlled. An **experiment** is *an observation of natural phenomena carried out in a controlled manner so that the results can be duplicated and rational conclusions made*. In the chapter opening, it was mentioned that Rosenberg studied the effects of electricity on bacterial growth. Temperature and amounts of nutrients in a given volume of bacterial medium are important variables in such experiments. Unless these variables are controlled, the work cannot be duplicated, nor can any reasonable conclusion be drawn.

After a series of experiments, perhaps a researcher sees some relationship or regularity in the results. For instance, Rosenberg noted that in each experiment in which an electric current was passed through a bacterial culture by means of platinum wire electrodes, the bacteria ceased dividing. If the regularity or relationship is fundamental and we can state it simply, we call it a law. A **law** is *a concise statement or mathematical equation about a fundamental relationship or regularity of nature*. An example is the law of conservation of mass, which says that the mass, or quantity of matter, remains constant during any chemical change.

At some point in a research project, a scientist tries to make sense of the results by devising an explanation. Explanations help us organize knowledge and predict future events. A **hypothesis** is *a tentative explanation of some regularity of nature*. Having seen that bacteria ceased to divide when an electric current from platinum wire electrodes passed through the culture, Rosenberg was eventually able to propose the hypothesis that certain platinum compounds were responsible. If a hypothesis

## Daily Life

## A CHEMIST Looks at . . .

## The Birth of the Post-it Note®

Have you ever used a Post-it and wondered where the idea for those little sticky notes came from? You have a chemist to thank for their invention. The story of the Post-it Note illustrates how the creativity and insights of a scientist can result in a product that is as common in the office as the stapler or pen.

In the early 1970s, Art Fry, a 3M scientist, was standing in the choir at his church trying to keep track of all the little bits of paper that marked the music selections for the service. During the service, a number of the markers fell out of the music, making him lose his place. While standing in front of the congregation, he realized that he needed a bookmark that would stick to the book, wouldn't hurt the book, and could be easily detached. To make his plan work, he required an adhesive that would not *permanently* stick things together. Finding the appropriate adhesive was not as simple as it may seem, because most adhesives at that time were created to stick things together permanently.

Still thinking about his problem the next day, Fry consulted a colleague, Spencer Silver, who was studying adhesives at the 3M research labs. That study consisted of conducting a series of tests on a range of adhesives to determine the strength of the bond they formed. One of the

adhesives that Silver created for the study was an adhesive that always remained sticky. Fry recognized that this adhesive was just what he needed for his bookmark. His first bookmark, invented the day after the initial idea, consisted of a strip of Silver's tacky adhesive applied to the edge of a piece of paper.

Part of Fry's job description at 3M was to spend time working on creative ideas such as his bookmark. As a result, he continued to experiment with the bookmark to improve its properties of sticking, detaching, and not hurting the surface to which it was attached. One day, while doing some paperwork, he wrote a question on one of his experimental strips of paper and sent it to his boss stuck to the top of a file folder. His boss then answered the question on the note and returned it attached to some other documents. During a later discussion over coffee, Fry and his boss realized that they had invented a new way for people to communicate: the Post-it Note was born. Today the Post-it Note is one of the top-selling office products in the United States.

■ See Problems 1.143 and 1.144.

is to be useful, it should suggest new experiments that become tests of the hypothesis. Rosenberg could test his hypothesis by looking for the platinum compound and testing for its ability to inhibit cell division.

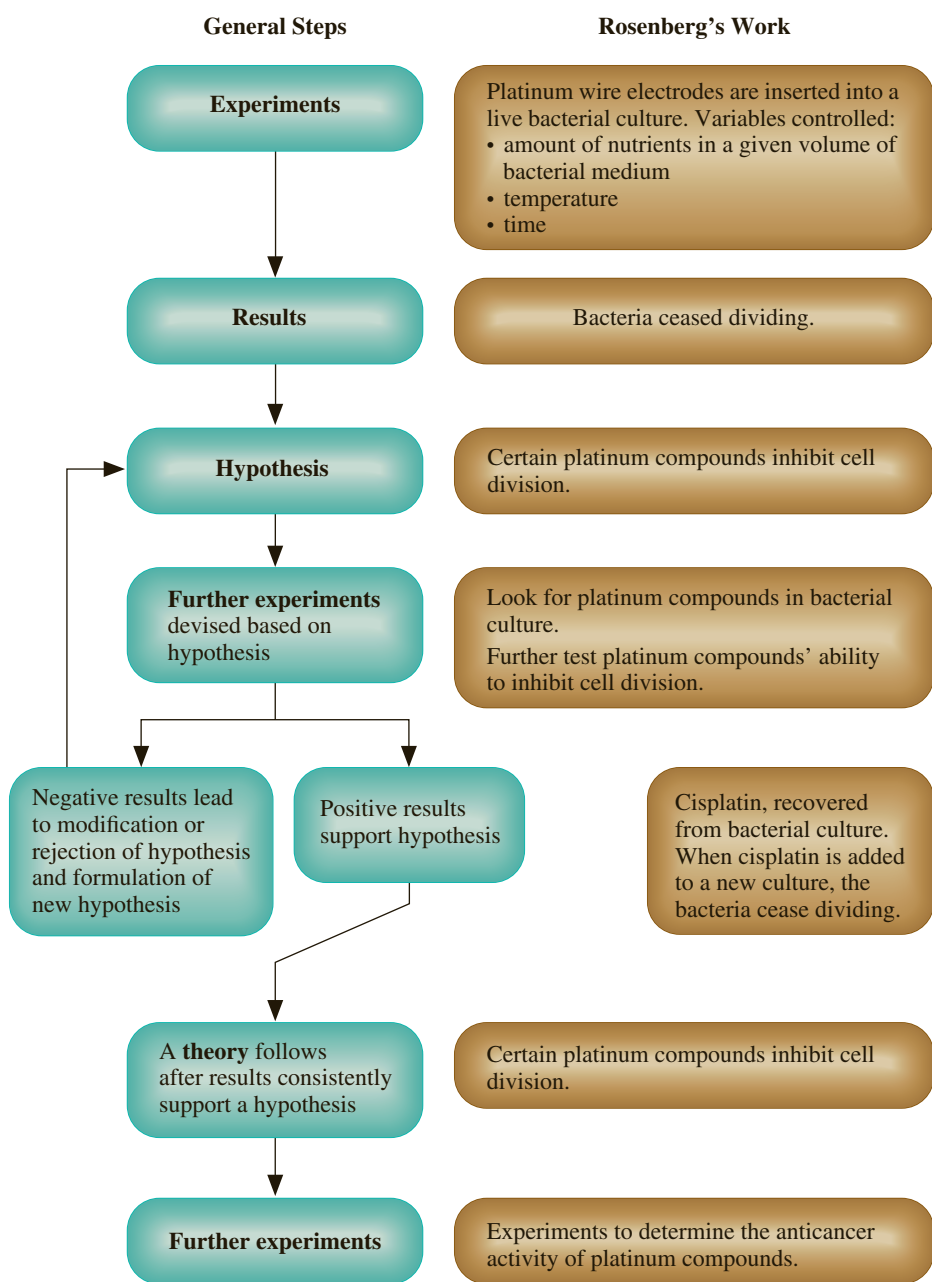

If a hypothesis successfully passes many tests, it becomes known as a theory. A **theory** is a *tested explanation of basic natural phenomena*. An example is the molecular theory of gases—the theory that all gases are composed of very small particles called molecules. This theory has withstood many tests and has been fruitful in suggesting many experiments. Note that we cannot prove a theory absolutely. It is always possible that further experiments will show the theory to be limited or that someone will develop a better theory. For example, the physics of the motion of objects devised by Isaac Newton withstood experimental tests for more than two centuries, until physicists discovered that the equations do not hold for objects moving near the speed of light. Later physicists showed that very small objects also do not follow Newton's equations. Both discoveries resulted in revolutionary developments in physics. The first led to the theory of relativity, the second to quantum mechanics, which has had an immense impact on chemistry.

The two aspects of science, experiment and explanation, are closely related. A scientist performs experiments and observes some regularity; someone explains this regularity and proposes more experiments; and so on. From his experiments, Rosenberg explained that certain platinum compounds inhibit cell division. This explanation led him to do new experiments on the anticancer activity of these compounds.

The *general* process of advancing scientific knowledge through observation; the framing of laws, hypotheses, or theories; and the conducting of more experiments

Figure 1.7 ▶

Figure 1.8 ▲

**Laboratory balance** A modern single-pan balance. The mass of the material on the pan appears on the digital readout.

Chemical reactions may involve a gain or loss of heat and other forms of energy. According to Einstein, mass and energy are equivalent. Thus, when energy is lost as heat, mass is also lost, but such small changes in mass in chemical reactions (billionths of a gram) are too small to detect.

is called the *scientific method* (Figure 1.7). It is not a method for carrying out a *specific* research program, because the design of experiments and the explanation of results draw on the creativity and individuality of a researcher.

### 1.3 Law of Conservation of Mass

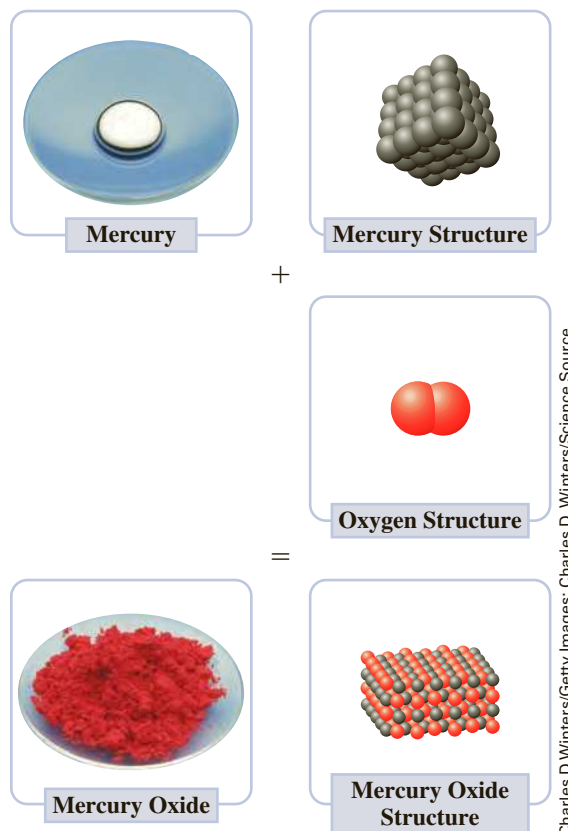

Modern chemistry emerged in the eighteenth century, when chemists began to use the balance systematically as a tool in research. Balances measure **mass**, which is *the quantity of matter in a material* (Figure 1.8). **Matter** is the general term for the material things around us; we can define it as *whatever occupies space and can be perceived by our senses*.

Antoine Lavoisier (1743–1794), a French chemist, was one of the first to insist on the use of the balance in chemical research. By weighing substances before and after chemical change, he demonstrated the **law of conservation of mass**, which states that *the total mass remains constant during a chemical change (chemical reaction)*. ◀

**Figure 1.9** ▶**Heating mercury metal in**

**air** Mercury metal reacts with oxygen to yield mercury(II) oxide. The color of the oxide varies from red to yellow, depending on the particle size.

In a series of experiments, Lavoisier applied the law of conservation of mass to clarify the phenomenon of burning, or combustion. He showed that when a material burns, a component of air (which he called oxygen) combines chemically with the material. For example, when the liquid metal mercury is heated in air, it burns or combines with oxygen to give a red-orange substance, whose modern name is mercury(II) oxide. We can represent the chemical change as follows:

The arrow means “is changed to.” See Figure 1.9.

By strongly heating the red-orange substance, Lavoisier was able to decompose it to yield the original mercury and oxygen gas (Figure 1.10). The following example illustrates how the law of conservation of mass can be used to study this reaction.

© Cengage Learning

**Figure 1.10** ▲

**Heated mercury(II) oxide** When you heat mercury(II) oxide, it decomposes to mercury and oxygen gas.

### Example 1.1 Using the Law of Conservation of Mass

#### Gaining Mastery Toolbox

##### Critical Concept 1.1

The law of conservation of mass applies to chemical reactions. Whenever a chemical reaction occurs, the mass of the substances before the reaction (reactants) is identical to the mass of the newly formed substances after the reaction (products).

##### Solution Essentials:

- Definition of mass
- Definition of matter
- Law of conservation of mass

You heat 2.53 grams of metallic mercury in air, which produces 2.73 grams of a red-orange residue. Assume that the chemical change is the reaction of the metal with oxygen in air.

What is the mass of oxygen that reacts? When you strongly heat the red-orange residue, it decomposes to give back the mercury and release the oxygen, which you collect. What is the mass of oxygen you collect?

**Problem Strategy** You apply the law of conservation of mass to the reaction. According to this law, the total mass remains constant during a chemical reaction; that is,

$$\text{Mass of substances before reaction} = \text{mass of substances after reaction}$$

(continued)

**Example 1.1** (continued)

**Solution** From the law of conservation of mass,

$$\begin{array}{r} \text{Mass of mercury} + \text{mass} \\ \text{of oxygen} \end{array} = \begin{array}{r} \text{mass of red-orange} \\ \text{residue} \end{array}$$

Substituting, you obtain

$$2.53 \text{ grams} + \text{mass of oxygen} = 2.73 \text{ grams}$$

or

$$\text{Mass of oxygen} = (2.73 - 2.53) \text{ grams} = \mathbf{0.20 \text{ grams}}$$

The mass of oxygen collected when the red-orange residue decomposes equals the mass of oxygen that originally reacted (**0.20 grams**).

**Answer Check** Arithmetic errors account for many mistakes. You should always check your arithmetic, either by carefully redoing the calculation or, if possible, by doing the arithmetic in a slightly different way. Here, you obtained the answer by subtracting numbers. You can check the result by addition: the sum of the masses of mercury and oxygen,  $2.53 + 0.20$  grams, should equal the mass of the residue, 2.73 grams.

**Exercise 1.1** You place 1.85 grams of wood in a vessel with 9.45 grams of air and seal the vessel. Then you heat the vessel strongly so that the wood burns. In burning, the wood yields ash and gases. After the experiment, you weigh the ash and find that its mass is 0.28 gram. What is the mass of the gases in the vessel at the end of the experiment?

See Problems 1.37, 1.38, 1.39, and 1.40.

Lavoisier set out his views on chemistry in his *Traité Élémentaire de Chimie* (*Basic Treatise on Chemistry*) in 1789. The book was very influential, especially among younger chemists, and set the stage for modern chemistry.

Before leaving this section, you should note the distinction between the terms *mass* and *weight* in precise usage. The weight of an object is the force of gravity exerted on it. The weight is proportional to the mass of the object divided by the square of the distance between the center of mass of the object and that of the earth. ◀ Because the earth is slightly flattened at the poles, an object weighs more at the North Pole, where it is closer to the center of the earth, than at the equator. The mass of an object is the same wherever it is measured.

The force of gravity  $F$  between objects whose masses are  $m_1$  and  $m_2$  is  $Gm_1m_2/r^2$ , where  $G$  is the gravitational constant and  $r$  is the distance between the centers of mass of the two objects.

## 1.4 Matter: Physical State and Chemical Composition

We describe iron as a silvery-colored metal that melts at  $1535^\circ\text{C}$  ( $2795^\circ\text{F}$ ). Once we have collected enough descriptive information about many different kinds of matter, patterns emerge that suggest ways of classifying it. There are two principal ways of classifying matter: by its physical state as a solid, liquid, or gas, and by its chemical composition as an element, compound, or mixture.

### Solids, Liquids, and Gases

Commonly, a given kind of matter exists in different physical forms under different conditions. Water, for example, exists as ice (solid water), as liquid water, and as steam (gaseous water) (Figure 1.11). The main identifying characteristic of solids is their rigidity: they tend to maintain their shapes when subjected to outside forces. Liquids and gases, however, are *fluids*; that is, they flow easily and change their shapes in response to slight outside forces.

What distinguishes a gas from a liquid is the characteristic of *compressibility* (and its opposite, *expansibility*). A gas is easily compressible, whereas a liquid is not. You can put more and more air into a tire, which increases only slightly in volume. In fact, a given quantity of gas can fill a container of almost any size. A small quantity would expand to fill the container; a larger quantity could be

compressed to fill the same space. By contrast, if you were to try to force more liquid water into a closed glass bottle that was already full of water, it would burst.

These two characteristics, rigidity (or fluidity) and compressibility (or expansibility), can be used to frame definitions of the three common states of matter:

**solid** *the form of matter characterized by rigidity; a solid is relatively incompressible and has fixed shape and volume.*

**liquid** *the form of matter that is a relatively incompressible fluid; a liquid has a fixed volume but no fixed shape.*

**gas** *the form of matter that is an easily compressible fluid; a given quantity of gas will fit into a container of almost any size and shape.*

The term *vapor* is often used to refer to the gaseous state of any kind of matter that normally exists as a liquid or a solid.

*These three forms of matter—solid, liquid, gas—comprise the common states of matter.*

### Elements, Compounds, and Mixtures

To understand how matter is classified by its chemical composition, we must first distinguish between physical and chemical changes and between physical and chemical properties. A **physical change** is a change in the form of matter but not in its chemical identity. Changes of physical state are examples of physical changes. The process of dissolving one material in another is a further example of a physical change. For instance, you can dissolve sodium chloride (table salt) in water. The result is a clear liquid, like pure water, though many of its other characteristics are different from those of pure water. The water and sodium chloride in this liquid retain their chemical identities and can be separated by some method that depends on physical changes.

*Distillation* is one way to separate the sodium chloride and water components of this liquid. You place the liquid in a flask to which a device called a *condenser* is attached (see Figure 1.12). The liquid in the

**Figure 1.11** ▲

**Molecular representations of solid, liquid, and gas** The top beaker contains a solid with a molecular view of the solid; the molecular view depicts the closely packed, immobile atoms that make up the solid structure. The middle beaker contains a liquid with a molecular view of the liquid; the molecular view depicts atoms that are close together but moving freely. The bottom beaker contains a gas with a molecular view of the gas; the molecular view depicts atoms that are far apart and moving freely.

**Figure 1.12** ◀

**Separation by distillation** You can separate an easily vaporized liquid from another substance by distillation.

© Cengage Learning

**Figure 1.13** ▲**Reaction of sodium with water**

Sodium metal flits around the water surface as it reacts briskly, giving off hydrogen gas. The other product is sodium hydroxide, which changes a substance added to the water (phenolphthalein) from colorless to pink.

flask is heated to bring it to a boil. (Boiling entails the formation of bubbles of the vapor in the body of the liquid.) Water vapor forms and passes from the flask into the cooled condenser, where the vapor changes back to liquid water. The liquid water is collected in another flask, called a *receiver*. The original flask now contains the solid sodium chloride. Thus, by means of physical changes (the change of liquid water to vapor and back to liquid), you have separated the sodium chloride and water that you had earlier mixed together.

A **chemical change**, or **chemical reaction**, is a change in which one or more kinds of matter are transformed into a new kind of matter or several new kinds of matter. The rusting of iron, during which iron combines with oxygen in the air to form a new material called rust, is a chemical change. The original materials (iron and oxygen) combine chemically and cannot be separated by any physical means. To recover the iron and oxygen from rust requires a chemical change or a series of chemical changes.

We characterize or identify a material by its various properties, which may be either physical or chemical. A **physical property** is a characteristic that can be observed for a material without changing its chemical identity. Examples are physical state (solid, liquid, or gas), melting point, and color. A **chemical property** is a characteristic of a material involving its chemical change. A chemical property of iron is its ability to react with oxygen to produce rust.

**Substances** The various materials we see around us are either substances or mixtures of substances. A **substance** is a kind of matter that cannot be separated into other kinds of matter by any physical process. Earlier you saw that when sodium chloride is dissolved in water, it is possible to separate the sodium chloride from the water by the physical process of distillation. However, sodium chloride is itself a substance and cannot be separated by physical processes into new materials. Similarly, pure water is a substance.

No matter what its source, a substance always has the same characteristic properties. Sodium is a solid metal having a melting point of 98°C. The metal also reacts vigorously with water (Figure 1.13). No matter how sodium is prepared, it always has these properties. Similarly, whether sodium chloride is obtained by burning sodium in chlorine or from seawater, it is a white solid melting at 801°C.

**Exercise 1.2** Potassium is a soft, silvery-colored metal that melts at 64°C. It reacts vigorously with water, with oxygen, and with chlorine. Identify all of the physical properties given in this description. Identify all of the chemical properties given.

See Problems  
1.47, 1.48, 1.49,  
and 1.50.

**Elements** Millions of substances have been characterized by chemists. Of these, a very small number are known as elements, from which all other substances are made. Lavoisier was the first to establish an experimentally useful definition of an element. He defined an **element** as a substance that cannot be decomposed by any chemical reaction into simpler substances. In 1789 Lavoisier listed 33 substances as elements, of which more than 20 are still so regarded. Today 118 elements are known. Some elements are shown in Figure 1.14. ◀

**Compounds** Most substances are compounds. A **compound** is a substance composed of two or more elements chemically combined. By the end of the eighteenth century, Lavoisier and others had examined many compounds and showed that all of them were composed of the elements in definite proportions by mass. Joseph Louis Proust (1754–1826), by his painstaking work, convinced the majority of chemists of the general validity of the **law of definite proportions** (also known as the **law of constant composition**): a pure compound, whatever its source, always contains definite or constant proportions of the elements by mass. For example, 1.0000 gram of sodium chloride always contains 0.3934 gram of sodium and 0.6066 gram of chlorine, chemically

In Chapter 2, we will redefine an element in terms of atoms.

Melissa Kelly Photography except  
Magnesium, which is © Cengage  
Learning

**Figure 1.14** ▲

Some elements

combined. Sodium chloride has definite proportions of sodium and chlorine; that is, it has constant or definite composition. ►

**Mixtures** Most of the materials around us are mixtures. A **mixture** is a material that can be separated by physical means into two or more substances. Unlike a pure compound, a mixture has variable composition. When you dissolve sodium chloride in water, you obtain a mixture; its composition depends on the relative amount of sodium chloride dissolved. You can separate the mixture by the physical process of distillation. ►

Mixtures are classified into two types. A **heterogeneous mixture** is a mixture that consists of physically distinct parts, each with different properties. Figure 1.15 shows a heterogeneous mixture of potassium dichromate and iron filings. Another example is salt and sugar that have been stirred together. If you were to look closely, you would see the separate crystals of sugar and salt. A **homogeneous mixture** (also known as a **solution**) is a mixture that is uniform in its properties throughout given samples. When sodium chloride is dissolved in water, you obtain a homogeneous mixture, or solution. Air is a gaseous solution, principally of two elementary substances, nitrogen and oxygen, which are physically mixed but not chemically combined.

A **phase** is one of several different homogeneous materials present in the portion of matter under study. A heterogeneous mixture of salt and sugar is said to be composed of two different phases: one of the phases is salt; the other is sugar.

It is now known that some compounds do not follow the law of definite proportions. These nonstoichiometric compounds, as they are called, are described briefly in Chapter 11.

Chromatography, another example of a physical method used to separate mixtures, is described in the essay at the end of this section.

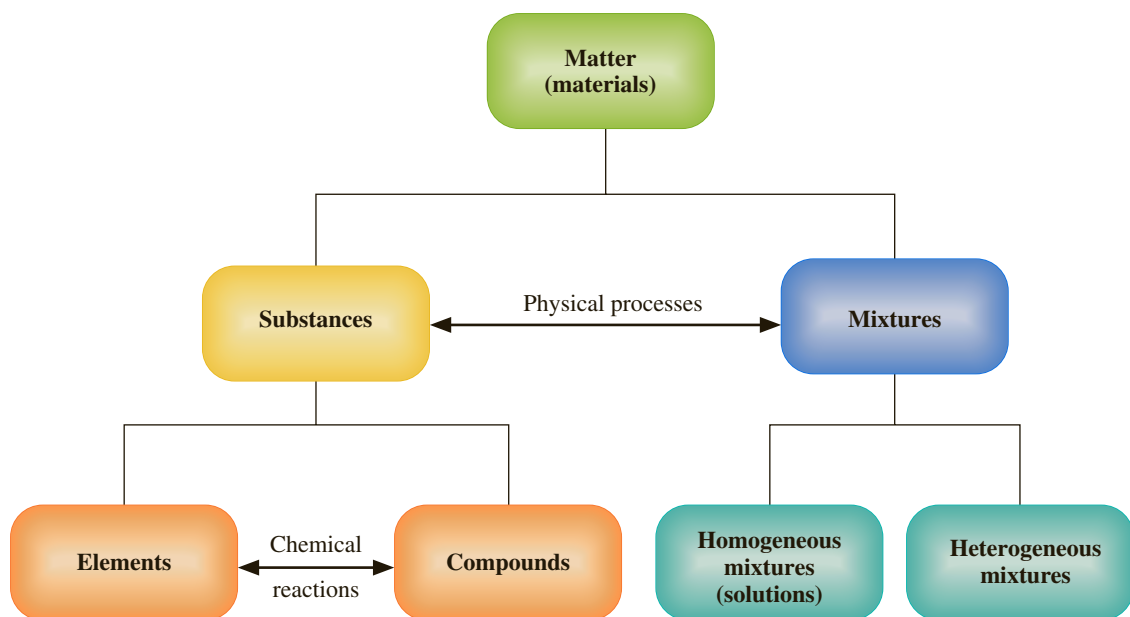

The mixture on the watch glass consists of potassium dichromate (orange crystals) and iron filings.

A magnet separates the iron filings from the mixture.

**Figure 1.15** ▲

A heterogeneous mixture

**Figure 1.16** ▲

**Relationships among elements, compounds, and mixtures** Mixtures can be separated by physical processes into substances, and substances can be combined physically into mixtures. Compounds can be separated by chemical reactions into their elements, and elements can be combined chemically to form compounds.

Similarly, ice cubes in water are said to be composed of two phases: one phase is ice; the other is liquid water. Ice floating in a solution of sodium chloride in water also consists of two phases, ice and the liquid solution. Note that a phase may be either a pure substance in a particular state or a solution in a particular state (solid, liquid, or gaseous). Also, the portion of matter under consideration may consist of several phases of the same substance or several phases of different substances.

Figure 1.16 summarizes the relationships among elements, compounds, and mixtures. Materials are either substances or mixtures. Substances can be mixed by physical processes, and other physical processes can be used to separate the mixtures into substances. Substances are either elements or compounds. Elements may react chemically to yield compounds, and compounds may be decomposed by chemical reactions into elements.

**✓ CONCEPT CHECK 1.1**

Matter can be represented as being composed of individual units. For example, the smallest individual unit of matter can be represented as a single circle, •, and chemical combinations of these units of matter as connected circles, ••, with each element represented by a different color. Using this model, place the appropriate label—element, compound, or mixture—below each representation.

## Instrumental Methods

# Separation of Mixtures by Chromatography

*Chromatography* is a group of similar separation techniques. Each depends on how fast a substance moves, in a stream of gas or liquid, past a stationary phase to which the substance may be slightly attracted. An example is provided by a simple experiment in *paper chromatography* (see Figure 1.17). In this experiment, a line of ink is drawn near one edge of a sheet of paper, and the paper is placed upright with this edge in a solution of methanol and water. As the solution creeps up the paper, the ink moves upward, separating into a series of different-colored bands that correspond to the different dyes in the ink. All the dyes are attracted to the wet paper fibers, but with different strengths of attraction. As the solution moves upward, the dyes less strongly attracted to the paper fibers move more rapidly.

The Russian botanist Mikhail Tswett was the first to understand the basis of chromatography and to apply it systematically as a method of separation. In 1906 Tswett separated pigments in plant leaves by *column chromatography*. He first dissolved the pigments from the leaves in petroleum ether, a liquid similar to gasoline. After packing a glass tube or column with powdered chalk, he poured the solution of pigments into the top of the column (see Figure 1.18). When he washed the column by pouring in more petroleum ether, it began to show distinct yellow and green bands. These bands, each containing a pure pigment, became well separated as they moved down the

column, so that the pure pigments could be obtained. The name *chromatography* originates from this early separation of colored substances (the stem *chromato-* means “color”), although the technique is not limited to colored substances.

*Gas chromatography* (GC) is a more recent separation method. Here the moving stream is a gaseous mixture of vaporized substances plus a gas such as helium, which is called the *carrier*. The stationary material is either a solid or a liquid adhering to a solid, packed in a column. As the gas passes through the column, substances in the mixture are attracted differently to the stationary column packing and thus are separated. Gas chromatography is a rapid, small-scale method of separating mixtures. It is also important in the analysis of mixtures because the time it takes for a substance at a given temperature to travel through the column to a detector (called the *retention time*) is fixed. You can therefore use retention times to help identify substances. Figure 1.19 shows a gas chromatograph and a portion of a computer plot (*chromatogram*). Each peak on the chromatogram corresponds to a specific substance. The peaks were automatically recorded by the instrument as the different substances in the mixture passed the detector. Chemists have analyzed complicated mixtures by gas chromatography. Analysis of chocolate, for example, shows that it contains over 800 flavor compounds.

**Figure 1.17** ▶

**An illustration of paper chromatography** A line of ink has been drawn along the lower edge of a sheet of paper. The dyes in the ink separate as a solution of methanol and water creeps up the paper.

## ► Physical Measurements

Chemists characterize and identify substances by their particular properties. To determine many of these properties requires physical measurements. Cisplatin, the substance featured in the chapter opening, is a yellow substance whose solubility in water (the amount that dissolves in a given quantity of water) is 0.252 gram in 100 grams of water. You can use the solubility, as well as other physical properties, to identify cisplatin. In a modern chemical laboratory, measurements often are complex, but many experiments begin with simple measurements of mass, volume, time, and so forth. In the next few sections, we will look at the measurement process. We first consider the concept of *precision* of a measurement.

### 1.5 Measurement and Significant Figures

Measurement is the comparison of a physical quantity to be measured with a **unit** of measurement—that is, with a *fixed standard of measurement*. On a centimeter scale, the centimeter unit is the standard of comparison. ► A steel rod that measures 9.12 times the centimeter unit has a length of 9.12 centimeters. To record the measurement, you must be careful to give both the *measured number* (9.12) and the *unit* (centimeters).

2.54 centimeters = 1 inch

If you repeat a particular measurement, you usually do not obtain precisely the same result, because each measurement is subject to experimental error. The measured values vary slightly from one another. Suppose you perform a series of identical measurements of a quantity. The term **precision** refers to *the closeness of the set of values obtained from similar measurements of an identical quantity*. **Accuracy** is a related term; it refers to *the closeness of a single measurement to its true value*. To illustrate the idea of precision, consider a simple measuring device, the centimeter ruler. In Figure 1.20, a steel rod has been placed near a ruler subdivided into tenths of a centimeter. You can see that the rod measures just over 9.1 cm (cm = centimeter). With care, it is possible to estimate by eye to hundredths of a centimeter. Here you might give the measurement as 9.12 cm. Suppose you measure the length of this rod twice more. You find the values to be 9.11 cm and 9.13 cm. Thus, you record the length of the rod as being somewhere between 9.11 cm and 9.13 cm. The spread of values indicates the precision with which a measurement can be made by this centimeter ruler. ►

To indicate the precision of a measured number (or result of calculations on measured numbers), we often use the concept of significant figures. **Significant figures** are *those digits in a measured number (or in the result of a calculation with measured numbers) that include all certain digits plus a final digit having some uncertainty*. When you measured the rod, you obtained the values 9.12 cm, 9.11 cm, and 9.13 cm. You could report the result as the average, 9.12 cm. The first two digits (9.1) are certain; the next digit (2) is estimated, so it has some uncertainty. It would be incorrect to write 9.120 cm for the length of the rod. This would say that the last digit (0) has some uncertainty but that the other digits (9.12) are certain, which is not true.

Measurements that are of high precision are usually accurate. It is possible, however, to have a systematic error in a measurement. Suppose that, in calibrating a ruler, the first centimeter is made too small by 0.1 cm. Then, although the measurements of length on this ruler are still precise to 0.01 cm, they are accurate to only 0.1 cm.

**Figure 1.20** ◀

**Precision of measurement with a centimeter ruler** The length of the rod is just over 9.1 cm. On successive measurements, we estimate the length by eye at 9.12, 9.11, and 9.13 cm. We record the length as between 9.11 cm and 9.13 cm.

## Number of Significant Figures

The term **number of significant figures** refers to *the number of digits reported for the value of a measured or calculated quantity, indicating the precision of the value*. Thus, there are three significant figures in 9.12 cm, whereas 9.123 cm has four. To count the number of significant figures in a given measured quantity, you observe the following rules:

1. All digits are significant except zeros at the beginning of the number and possibly terminal zeros (one or more zeros at the end of a number). Thus, 9.12 cm, 0.912 cm, and 0.00912 cm all contain three significant figures.
2. Terminal zeros ending at the right of the decimal point are significant. Each of the following has three significant figures: 9.00 cm, 9.10 cm, 90.0 cm.
3. Terminal zeros in a number without an explicit decimal point may or may not be significant. If someone gives a measurement as 900 cm, you do not know whether one, two, or three significant figures are intended. If the person writes 900. cm (note the decimal point), the zeros are significant. More generally, you can remove any uncertainty in such cases by expressing the measurement in scientific notation.

**Scientific notation** is the representation of a number in the form  $A \times 10^n$ , where  $A$  is a number with a single nonzero digit to the left of the decimal point and  $n$  is an integer, or whole number. In scientific notation, the measurement 900 cm precise to two significant figures is written  $9.0 \times 10^2$  cm. If precise to three significant figures, it is written  $9.00 \times 10^2$  cm. Scientific notation is also convenient for expressing very large or very small quantities. It is much easier (and simplifies calculations) to write the speed of light as  $3.00 \times 10^8$  (rather than as 300,000,000) meters per second. ◀

See Appendix A for a review of scientific notation.

## Significant Figures in Calculations

Measurements are often used in calculations. How do you determine the correct number of significant figures to report for the answer to a calculation? The following are two rules that we use:

1. **Multiplication and division.** When multiplying or dividing measured quantities, give as many significant figures in the answer as there are in the measurement with *the least number of significant figures*.
2. **Addition and subtraction.** When adding or subtracting measured quantities, give the same number of decimal places in the answer as there are in the measurement with *the least number of decimal places*.

Let us see how you apply these rules. Suppose you have a substance believed to be cisplatin, and, in an effort to establish its identity, you measure its solubility (the amount that dissolves in a given quantity of water). You find that 0.0634 gram of the substance dissolves in 25.31 grams of water. The amount dissolving in 100.0 grams is

$$100.0 \text{ grams of water} \times \frac{0.0634 \text{ gram cisplatin}}{25.31 \text{ grams of water}}$$

Performing the arithmetic on a pocket calculator (Figure 1.21), you get 0.250493875 for the numerical part of the answer ( $100.0 \times 0.0634 \div 25.31$ ). It would be incorrect to give this number as the final answer. The measurement 0.0634 gram has the least number of significant figures (three). Therefore, you report the answer to three significant figures—that is, 0.250 gram.

Now consider the addition of 184.2 grams and 2.324 grams. On a calculator, you find that  $184.2 + 2.324 = 186.524$ . But because the quantity 184.2 grams has the least number of decimal places—one, whereas 2.324 grams has three—the answer is 186.5 grams.

## Exact Numbers

So far we have discussed only numbers that involve uncertainties. However, you will also encounter exact numbers. An **exact number** is *a number that arises when you count*

Figure 1.21 ▲

### Significant figures and calculators

Not all of the figures that appear on a calculator display are significant. In performing the calculation  $100.0 \times 0.0634 \div 25.31$ , the calculator display shows 0.250493875. We would report the answer as 0.250, however, because the factor 0.0634 has the least number of significant figures (three).

items or sometimes when you define a unit. For example, when you say there are 9 coins in a bottle, you mean exactly 9, not 8.9 or 9.1. Also, when you say there are 12 inches to a foot, you mean exactly 12. Similarly, the inch is defined to be exactly 2.54 centimeters. The conventions of significant figures do not apply to exact numbers. Thus, the 2.54 in the expression “1 inch equals 2.54 centimeters” should not be interpreted as a measured number with three significant figures. In effect, the 2.54 has an infinite number of significant figures, but of course it would be impossible to write out an infinite number of digits. You should make a mental note of any numbers in a calculation that are exact, because they have no effect on the number of significant figures in a calculation. The number of significant figures in a calculation result depends only on the numbers of significant figures in quantities having uncertainties. For example, suppose you want the total mass of 9 coins when each coin has a mass of 3.0 grams. The calculation is

$$3.0 \text{ grams} \times 9 = 27 \text{ grams}$$

You report the answer to two significant figures because 3.0 grams has two significant figures. The number 9 is exact and does not determine the number of significant figures.

## Rounding

In reporting the solubility of your substance in 100.0 grams of water as 0.250 gram, you *rounded* the number you read off the calculator (0.2504938). **Rounding** is the procedure of dropping nonsignificant digits in a calculation result and adjusting the last digit reported. The general procedure is as follows: Look at the leftmost digit to be dropped. Then . . .

1. If this digit is 5 or greater, add 1 to the last digit to be retained and drop all digits farther to the right. Thus, rounding 1.2151 to three significant figures gives 1.22.
2. If this digit is less than 5, simply drop it and all digits farther to the right. Rounding 1.2143 to three significant figures gives 1.21.

In doing a calculation of two or more steps, it is desirable to retain nonsignificant digits for intermediate answers. This ensures that accumulated small errors from rounding do not appear in the final result. If you use a calculator, you can simply enter numbers one after the other, performing each arithmetic operation and rounding only the final answer. ► To keep track of the correct number of significant figures, you may want to record intermediate answers with a line under the last significant figure, as shown in the solution to part d of the following example.

The answers for Exercises and Problems will follow this practice. For most Example Problems where intermediate answers are reported, all answers, intermediate and final, will be rounded.

### Example 1.2 Using Significant Figures in Calculations

#### Gaining Mastery Toolbox

##### Critical Concept 1.2

The final result of any calculation must be reported to the correct number of significant figures. When performing numerical operations (addition, subtraction, multiplication, and division), rules must be applied to determine the correct reporting of the final answer. Rounding should *only* be applied to the final result.

Perform the following calculations and round the answers to the correct number of significant figures (units of measurement have been omitted).

a.  $\frac{2.568 \times 5.8}{4.186}$

b.  $5.41 - 0.398$

c.  $3.38 - 3.01$

d.  $4.18 - 58.16 \times (3.38 - 3.01)$

**Problem Strategy** Parts a, b, and c are relatively straightforward; use the rule for significant figures that applies in each case. In a multistep calculation as in d, proceed step by step, applying the relevant rule to each step. First, do the operations within parentheses. By convention, you perform multiplications and divisions before additions and subtractions. Do not round intermediate answers, but do keep track of the least significant digit—say, by underlining it.

#### Solution

a. The factor 5.8 has the fewest significant figures; therefore, the answer should be reported to two significant figures. Round the answer to **3.6**. b. The number with the least number of decimal places is 5.41. Therefore, round the answer to two decimal places, to **5.01**. c. The answer is **0.37**. Note how you have lost one

(continued)

**Example 1.2** (continued)**Solution Essentials:**

- Determination of the number of significant figures in a measured value
- Tracking the number of significant figures of each measured and calculated value throughout the calculation process
- Reporting a calculated value (often the "answer") to the correct number of significant figures by applying the appropriate rules for the operations (multiplication/division and addition/subtraction) and the rule for rounding

significant figure in the subtraction. d. You first do the subtraction within parentheses, underlining the least significant digits.

$$4.\underline{18} - 58.\underline{16} \times (3.\underline{38} - 3.0\underline{1}) = 4.\underline{18} - 58.\underline{16} \times 0.\underline{37}$$

Following convention, you do the multiplication before the subtraction.

$$4.\underline{18} - 58.\underline{16} \times 0.\underline{37} = 4.\underline{18} - 21.5192 = -17.3392$$

The final answer is  $-17$ .

**Answer Check** When performing any calculation, you should always report answers to the correct number of significant figures. If a set of calculations involves *only* multiplication and division, it is not necessary to track the significant figures through intermediate calculations; you just need to use the measurement with the least number of significant figures as the guide. However, when addition or subtraction is involved, make sure that you have noted the correct number of significant figures in each calculated step in order to ensure that your answer is correctly reported.

**Exercise 1.3** Give answers to the following arithmetic setups. Round to the correct number of significant figures.

a.  $\frac{5.61 \times 7.891}{9.1}$

b.  $8.91 - 6.435$

c.  $6.81 - 6.730$

d.  $38.91 \times (6.81 - 6.730)$

See Problems 1.61 and 1.62.

**CONCEPT CHECK 1.2**

- When you report your weight to someone, how many significant figures do you typically use?
- What is your weight with two significant figures?
- Indicate your weight and the number of significant figures you would obtain if you weighed yourself on a truck scale that can measure in 50 kg or 100 lb increments.

**1.6 SI Units**

The first measurements were probably based on the human body (the length of the foot, for example). In time, fixed standards developed, but these varied from place to place. Each country or government (and often each trade) adopted its own units. As science became more quantitative in the seventeenth and eighteenth centuries, scientists found that the lack of standard units was a problem. ◀ They began to seek a simple, international system of measurement. In 1791 a study committee of the French Academy of Sciences devised such a system. Called the *metric system*, it became the official system of measurement for France and was soon used by scientists throughout the world. Most nations have since adopted the metric system or, at least, have set a schedule for changing to it.

**SI Base Units and SI Prefixes**

In 1960 the General Conference of Weights and Measures adopted the **International System of units** (or **SI**, after the French *le Système International d'Unités*), which is a particular choice of metric units. This system has seven **SI base units**, the *SI units from which all others can be derived*. Table 1.1 lists these base units and the symbols used to represent them. In this chapter, we will discuss four base quantities: length, mass, time, and temperature. ◀

One advantage of any metric system is that it is a decimal system. In SI, a larger or smaller unit for a physical quantity is indicated by an **SI prefix**, which is a prefix used in the International System to indicate a power of 10. For example,

In the system of units that Lavoisier used in the eighteenth century, there were 9216 grains to the pound (the *livre*). English chemists of the same period used a system in which there were 7000 grains to the pound—unless they were trained as apothecaries, in which case there were 5760 grains to the pound!

The amount of substance is discussed in Chapter 3, and the electric current (ampere) is introduced in Chapter 19. Luminous intensity will not be used in this book.

Quantity	Unit	Symbol
Length	meter	m
Mass	kilogram	kg
Time	second	s
Temperature	kelvin	K
Amount of substance	mole	mol
Electric current	ampere	A
Luminous intensity	candela	cd

Prefix	Multiple	Symbol
mega	$10^6$	M
kilo	$10^3$	k
deci	$10^{-1}$	d
centi	$10^{-2}$	c
milli	$10^{-3}$	m
micro	$10^{-6}$	$\mu^*$
nano	$10^{-9}$	n
pico	$10^{-12}$	p

\*Greek letter mu, pronounced “mew.”

the base unit of length in SI is the meter (somewhat longer than a yard), and  $10^{-2}$  meter is called a *centimeter*. Thus 2.54 centimeters equals  $2.54 \times 10^{-2}$  meters. The SI prefixes used in this book are presented in Table 1.2.

### Length, Mass, and Time

The **meter (m)** is *the SI base unit of length*. ► By combining it with one of the SI prefixes, you can get a unit of appropriate size for any length measurement. For the very small lengths used in chemistry, the nanometer (nm; 1 nanometer =  $10^{-9}$  m) or the picometer (pm; 1 picometer =  $10^{-12}$  m) is an acceptable SI unit. A *non-SI unit of length* traditionally used by chemists is the **angstrom (Å)**, which equals  $10^{-10}$  m. (An oxygen atom, one of the minute particles of which the substance oxygen is composed, has a diameter of about 1.3 Å. If you could place oxygen atoms adjacent to one another, you could line up over 75 million of them in 1 cm.)

The **kilogram (kg)** is *the SI base unit of mass*, equal to about 2.2 pounds. This is an unusual base unit in that it contains a prefix. In forming other SI mass units, prefixes are added to the word *gram (g)* to give units such as the *milligram* (mg; 1 mg =  $10^{-3}$  g).

The **second (s)** is *the SI base unit of time* (Figure 1.22). Combining this unit with prefixes such as *milli-*, *micro-*, *nano-*, and *pico-*, you create units appropriate for measuring very rapid events. The time required for the fastest chemical processes is about a picosecond, which is the current limit of timekeeping technology. When you measure times much longer than a few hundred seconds, you revert to *minutes* and *hours*, an obvious exception to the prefix–base format of the International System.

The meter was originally defined in terms of a standard platinum–iridium bar kept at Sèvres, France. In 1983, the meter was defined as the distance traveled by light in a vacuum in  $1/299,792,458$  seconds.

	<p><b>Exercise 1.4</b> Express the following quantities using an SI prefix and a base unit. For instance, <math>1.6 \times 10^{-6}</math> m = 1.6 <math>\mu</math>m. --	---	-----------------------------

### Temperature

Temperature is difficult to define precisely, but we all have an intuitive idea of what we mean by it. It is a measure of “hotness.” A hot object placed next to a cold one becomes cooler, while the cold object becomes hotter. Heat energy passes from a hot object to a cold one, and the quantity of heat passed between the objects depends on the difference in temperature between the two. Therefore, temperature and heat are different, but related, concepts.

A thermometer is a device for measuring temperature. The common type consists of a glass capillary containing a column of liquid whose length varies with

Courtesy of National Institute of Standards and Technology (NIST)

temperature. A scale alongside the capillary gives a measure of the temperature. The **Celsius scale** (formerly the centigrade scale) is *the temperature scale in general scientific use*. On this scale, the freezing point of water is  $0^{\circ}\text{C}$  and the boiling point of water at normal barometric pressure is  $100^{\circ}\text{C}$ . However, *the SI base unit of temperature is the kelvin (K)*, a unit on an *absolute temperature scale*. (See the first margin note on the next page.) On any absolute scale, the lowest temperature that can be attained theoretically is zero. The Celsius and the Kelvin scales have equal-size units (that is, a change of  $1^{\circ}\text{C}$  is equivalent to a change of 1 K), where  $0^{\circ}\text{C}$  is a temperature equivalent to 273.15 K. Thus, it is easy to convert from one scale to the other, using the formula

$$T_{\text{K}} = \left( t_{\text{C}} \times \frac{1 \text{ K}}{1^{\circ}\text{C}} \right) + 273.15 \text{ K}$$

**Figure 1.22** ▲

**NIST F-2 cesium fountain clock** Put into service in 2014 at the National Institute of Standards and Technology (NIST) in Boulder, Colorado, this atomic clock is so precise that it will change by less than one second in 300 million years.

where  $T_{\text{K}}$  is the temperature in kelvins and  $t_{\text{C}}$  is the temperature in degrees Celsius. A temperature of  $20^{\circ}\text{C}$  (about room temperature) equals 293 K.

The Fahrenheit scale is at present the common temperature scale in the United States. Figure 1.23 compares Kelvin, Celsius, and Fahrenheit scales. As the figure shows,  $0^{\circ}\text{C}$  is the same as  $32^{\circ}\text{F}$  (both exact), and  $100^{\circ}\text{C}$  corresponds to  $212^{\circ}\text{F}$  (both exact). Therefore, there are  $212 - 32 = 180$  Fahrenheit degrees in the range of

**Figure 1.23** ►

**Comparison of temperature scales** Room temperature is about  $68^{\circ}\text{F}$ ,  $20^{\circ}\text{C}$ , and 293 K. Water freezes at  $32^{\circ}\text{F}$ ,  $0^{\circ}\text{C}$ , and 273.15 K. Water boils under normal pressure at  $212^{\circ}\text{F}$ ,  $100^{\circ}\text{C}$ , and 373.15 K.

100 Celsius degrees. That is, there are exactly 9 Fahrenheit degrees for every 5 Celsius degrees. Knowing this, and knowing that  $0^{\circ}\text{C}$  equals  $32^{\circ}\text{F}$ , we can derive a formula to convert degrees Celsius to degrees Fahrenheit. ▶

$$t_{\text{F}} = \left( t_{\text{C}} \times \frac{9^{\circ}\text{F}}{5^{\circ}\text{C}} \right) + 32^{\circ}\text{F}$$

where  $t_{\text{F}}$  is the temperature in Fahrenheit and  $t_{\text{C}}$  is the temperature in Celsius. By rearranging this, we can obtain a formula for converting degrees Fahrenheit to degrees Celsius:

$$t_{\text{C}} = \frac{5^{\circ}\text{C}}{9^{\circ}\text{F}} \times (t_{\text{F}} - 32^{\circ}\text{F})$$

Note that the degree sign ( $^{\circ}$ ) is not used with the Kelvin scale, and the unit of temperature is simply the kelvin (not capitalized).

These two temperature conversion formulas are often written  $\text{K} = ^{\circ}\text{C} + 273.15$  and  $^{\circ}\text{F} = (1.8 \times ^{\circ}\text{C}) + 32$ . Although these yield the correct number, they do not take into account the units.

### Example 1.3 Converting from One Temperature Scale to Another

#### Gaining Mastery Toolbox

##### Critical Concept 1.3

There are several commonly used temperature scales: Celsius, Fahrenheit, and Kelvin. The Celsius temperature scale is used most frequently in the laboratory. Using mathematical relationships, temperature values can be converted between the Celsius, Kelvin, and Fahrenheit scales.

##### Solution Essentials:

- Relationship (conversion formula) between Kelvin and Celsius temperatures
- Relationship (conversion formula) between Celsius and Fahrenheit temperatures

The hottest place on record in North America is Death Valley in California. It reached a temperature of  $134^{\circ}\text{F}$  in 1913. What is this temperature reading in degrees Celsius? in kelvins?

**Problem Strategy** This calculation involves conversion of a temperature in degrees Fahrenheit ( $^{\circ}\text{F}$ ) to degrees Celsius ( $^{\circ}\text{C}$ ) and kelvins (K). This is a case where using formulas is the most reliable method for arriving at the answer.

**Solution** Substituting, we find that

$$t_{\text{C}} = \frac{5^{\circ}\text{C}}{9^{\circ}\text{F}} \times (t_{\text{F}} - 32^{\circ}\text{F}) = \frac{5^{\circ}\text{C}}{9^{\circ}\text{F}} \times (134^{\circ}\text{F} - 32^{\circ}\text{F}) = 56.7^{\circ}\text{C}$$

In kelvins,

$$T_{\text{K}} = \left( t_{\text{C}} \times \frac{1\text{K}}{1^{\circ}\text{C}} \right) + 273.15\text{K} = \left( 56.7^{\circ}\text{C} \times \frac{1\text{K}}{1^{\circ}\text{C}} \right) + 273.15\text{K} = 329.9\text{K}$$

**Answer Check** An easy way to check temperature conversions is to use the appropriate equation and convert your answer back to the original temperature to see whether it matches.

#### Exercise 1.5

a. A person with a fever has a temperature of  $102.5^{\circ}\text{F}$ . What is this temperature in degrees Celsius? b. A cooling mixture of dry ice and isopropyl alcohol has a temperature of  $-78^{\circ}\text{C}$ . What is this temperature in kelvins?

See Problems 1.69, 1.70, 1.71, and 1.72.

### CONCEPT CHECK 1.3

- Estimate and express the length of your leg in an appropriate metric unit.
- What would be a reasonable height, in meters, of a three-story building?
- How would you be feeling if your body temperature was  $39^{\circ}\text{C}$ ?
- Would you be comfortable sitting in a room at  $23^{\circ}\text{C}$  in a short-sleeved shirt?

## 1.7 Derived Units

Once base units have been defined for a system of measurement, you can derive other units from them. You do this by using the base units in equations that define other physical quantities. For example, *area* is defined as length times length. Therefore,

$$\text{SI unit of area} = (\text{SI unit of length}) \times (\text{SI unit of length})$$

**Table 1.3** Derived Units

Quantity	Definition of Quantity	SI Unit
Area	Length squared	m <sup>2</sup>
Volume	Length cubed	m <sup>3</sup>
Density	Mass per unit volume	kg/m <sup>3</sup>
Speed	Distance traveled per unit time	m/s
Acceleration	Speed changed per unit time	m/s <sup>2</sup>
Force	Mass times acceleration of object	kg · m/s <sup>2</sup> (=newton, N)
Pressure	Force per unit area	kg/(m · s <sup>2</sup> ) (=pascal, Pa)
Energy	Force times distance traveled	kg · m <sup>2</sup> /s <sup>2</sup> (=joule, J)

From this, you see that the SI unit of area is meter  $\times$  meter, or m<sup>2</sup>. Similarly, *speed* is defined as the rate of change of distance with time; that is, speed = distance/time. Consequently,

$$\text{SI unit of speed} = \frac{\text{SI unit of distance}}{\text{SI unit of time}}$$

The SI unit of speed is meters per second (that is, meters divided by seconds). The unit is symbolized m/s or m · s<sup>-1</sup>. The unit of speed is an example of an **SI derived unit**, which is *a unit derived by combining SI base units*. Table 1.3 defines a number of derived units. Volume and density are discussed in this section; pressure and energy are discussed later (in Sections 5.1 and 6.1, respectively).

### Volume

*Volume* is defined as length cubed and has the SI unit of cubic meter (m<sup>3</sup>). This is too large a unit for normal laboratory work, so we use either cubic decimeters (dm<sup>3</sup>) or cubic centimeters (cm<sup>3</sup>, also written cc). Traditionally, chemists have used the **liter (L)**, which is *a unit of volume equal to a cubic decimeter* (approximately one quart). In fact, most laboratory glassware (Figure 1.24) is calibrated in liters or milliliters (1000 mL = 1 L). Because 1 dm equals 10 cm, a cubic decimeter, or one liter, equals (10 cm)<sup>3</sup> = 1000 cm<sup>3</sup>. Therefore, a milliliter equals a cubic centimeter. In summary

$$1 \text{ L} = 1 \text{ dm}^3 \quad \text{and} \quad 1 \text{ mL} = 1 \text{ cm}^3$$

### Density

The **density** of an object is its *mass per unit volume*. You can express this as

$$d = \frac{m}{V}$$

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. WCH 02-200-203

**Figure 1.24** ▲  
Some laboratory glassware

Figure 1.25 ►

**The relative densities of copper and mercury** Copper floats on mercury because the density of copper ( $8.95 \text{ g/cm}^3$ ) is less than the density of mercury ( $13.5 \text{ g/cm}^3$ ). (This is a copper penny; recently minted pennies are copper-clad zinc.)

where  $d$  is the density,  $m$  is the mass, and  $V$  is the volume. Suppose an object has a mass of  $15.0 \text{ g}$  and a volume of  $10.0 \text{ cm}^3$ . Substituting, you find that

$$d = \frac{15.0 \text{ g}}{10.0 \text{ cm}^3} = 1.50 \text{ g/cm}^3$$

The density of the object is  $1.50 \text{ g/cm}^3$  (or  $1.50 \text{ g} \cdot \text{cm}^{-3}$ ).

Density is an important physical property of a material. Water, for example, has a density of  $1.000 \text{ g/cm}^3$  at  $4^\circ\text{C}$  and a density of  $0.998 \text{ g/cm}^3$  at  $20^\circ\text{C}$ . Lead has a density of  $11.3 \text{ g/cm}^3$  at  $20^\circ\text{C}$ . (Figures 1.25 and 1.26 dramatically show some relative densities.) ► Oxygen gas has a density of  $1.33 \times 10^{-3} \text{ g/cm}^3$  at normal pressure and  $20^\circ\text{C}$ . (Like other gases under normal conditions, oxygen has a density that is about 1000 times smaller than those of liquids and solids.) Because the density is characteristic of a substance, it can be helpful in identifying it. Example 1.4 illustrates this point. Density can also be useful in determining whether a substance is pure. Consider a gold bar whose purity is questioned. The metals likely to be mixed with gold, such as silver or copper, have lower densities than gold. Therefore, an adulterated (impure) gold bar can be expected to be far less dense than pure gold.

Figure 1.26 ▲

**Relative densities of some liquids**

Shown are three liquids (dye so that they will show up clearly): *ortho*-xylene, water, and 1,1,1-trichloroethane. Water (blue layer) is less dense than 1,1,1-trichloroethane (colorless) and floats on it. *Ortho*-xylene (top, golden layer) is less dense than water and floats on it.

The density of solid materials on earth ranges from about  $1 \text{ g/cm}^3$  to  $22.5 \text{ g/cm}^3$  (osmium metal). In the interior of certain stars, the density of matter is truly staggering. Black neutron stars—stars composed of neutrons, or atomic cores compressed by gravity to a superdense state—have densities of about  $10^{15} \text{ g/cm}^3$ .

### Example 1.4 Calculating the Density of a Substance

#### Gaining Mastery Toolbox

##### Critical Concept 1.4

Density is the relationship of the mass to volume ( $m/V$ ) of a substance. Unlike mass, density is a characteristic (physical property) that can be used to identify and distinguish pure substances from each other.

##### Solution Essentials:

- Density of a substance is calculated by dividing the mass of substance ( $m$ ) by the volume ( $V$ ) that the mass of substance occupies
- Rules for significant figures and rounding
- The metric system

A colorless liquid, used as a solvent (a liquid that dissolves other substances), is believed to be one of the following:

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. WCH 02-200-203

Substance	Density (in g/mL)
<i>n</i> -butyl alcohol	0.810
ethylene glycol	1.114
isopropyl alcohol	0.785
toluene	0.866

To identify the substance, a chemist determined its density. By pouring a sample of the liquid into a graduated cylinder, she found that the volume was  $35.1 \text{ mL}$ . She also found that the sample weighed  $30.5 \text{ g}$ . What was the density of the liquid? What was the substance?

**Problem Strategy** The solution to this problem lies in finding the density of the unknown substance. Once the density of the unknown substance is known, you can compare it to the list of known substances presented in the problem and look for

(continued)

**Example 1.4** (continued)

a match. Density is the relationship of the mass of a substance per volume of that substance. Expressed as an equation, density is the mass divided by the volume:  $d = m/V$ .

**Solution** You substitute 30.5 g for the mass and 35.1 mL for the volume into the equation.

$$d = \frac{m}{V} = \frac{30.5 \text{ g}}{35.1 \text{ mL}} = \mathbf{0.869 \text{ g/mL}}$$

The density of the liquid equals that of **toluene** (within experimental error).

**Answer Check** Always be sure to report the density in the units used when performing the calculation. Density is not always reported in units of g/mL or g/cm<sup>3</sup>, for example; gases are often reported with the units of g/L.

**Exercise 1.6** A piece of metal wire has a volume of 20.2 cm<sup>3</sup> and a mass of 159 g. What is the density of the metal? We know that the metal is manganese, iron, or nickel, and these have densities of 7.21 g/cm<sup>3</sup>, 7.87 g/cm<sup>3</sup>, and 8.90 g/cm<sup>3</sup>, respectively. From which metal is the wire made?

See Problems 1.73, 1.74, 1.75, and 1.76.

In addition to characterizing a substance, the density provides a useful relationship between mass and volume. For example, suppose an experiment calls for a certain mass of liquid. Rather than weigh the liquid on a balance, you might instead measure out the corresponding volume. Example 1.5 illustrates this idea.

**Interactive Example 1.5 Using the Density to Relate Mass and Volume****Gaining Mastery Toolbox****Critical Concept 1.5**

Density is a mathematical equation expressed as  $d = m/V$ . Because this relationship is an equation with three variables, it can be manipulated to solve for one variable when two of the variables are known.

**Solution Essentials:**

- Identify the unknown quantity in the  $d = m/V$  equation
- Rearrange the equation to solve for the unknown quantity
- Substitute known values into the rearranged equation to solve for unknown quantity
- The metric system
- Rules for significant figures and rounding

An experiment requires 43.7 g of isopropyl alcohol. Instead of measuring out the sample on a balance, a chemist dispenses the liquid into a graduated cylinder. The density of isopropyl alcohol is 0.785 g/mL. What volume of isopropyl alcohol should he use?

**Problem Strategy** The formula that defines density provides a relationship between the density of a substance and the mass and volume of the substance:  $d = m/V$ . Because this relationship is an equation, it can be used to solve for one variable when the other two are known. Examining this problem reveals that the mass ( $m$ ) and density ( $d$ ) of the substance are known, so the equation can be used to solve for the volume ( $V$ ) of the liquid.

**Solution** You rearrange the formula defining the density to obtain the volume.

$$V = \frac{m}{d}$$

Then you substitute into this formula:

$$V = \frac{43.7 \text{ g}}{0.785 \text{ g/mL}} = \mathbf{55.7 \text{ mL}}$$

**Answer Check** Note that the density of the alcohol is close to 1 g/mL, which is common for many substances. In cases like this, you can perform a very quick check of your answer, because the numerical value for the volume of the liquid should not be much different from the numerical value of the mass of the liquid.

**Exercise 1.7** Ethanol (grain alcohol) has a density of 0.789 g/cm<sup>3</sup>. What volume of ethanol must be poured into a graduated cylinder to equal 30.3 g?

See Problems 1.77, 1.78, 1.79, and 1.80.

**CONCEPT CHECK 1.4**

You are working in the office of a precious metals buyer. A miner brings you a nugget of metal that he claims is gold. You suspect that the metal is a form of “fool’s gold,” called marcasite, that is composed of iron and sulfur. In the back of your office, you have a chunk of pure gold. What simple experiments could you perform to determine whether the miner’s nugget is gold?

**1.8 Units and Dimensional Analysis (Factor-Label Method)**

In performing numerical calculations with physical quantities, it is good practice to enter each quantity as a number with its associated unit. Both the numbers and the units are then carried through the indicated algebraic operations. The advantages of this are twofold:

1. The units for the answer will come out of the calculations.
2. If you make an error in arranging factors in the calculation (for example, if you use the wrong formula), this will become apparent because the final units will be nonsense.

**Dimensional analysis** (or the **factor-label method**) is *the method of calculation in which one carries along the units for quantities*. As an illustration, suppose you want to find the volume  $V$  of a cube, given  $s$ , the length of a side of the cube. Because  $V = s^3$ , if  $s = 5.00$  cm, you find that  $V = (5.00 \text{ cm})^3 = 5.00^3 \text{ cm}^3$ . There is no guesswork about the unit of volume here; it is cubic centimeters ( $\text{cm}^3$ ).

Suppose, however, that you wish to express the volume in liters (L), a metric unit that equals  $10^3$  cubic centimeters (approximately one quart). You can write this equality as

$$1 \text{ L} = 10^3 \text{ cm}^3$$

If you divide both sides of the equality by the right-hand quantity, you get

$$\frac{1 \text{ L}}{10^3 \text{ cm}^3} = \frac{10^3 \cancel{\text{cm}^3}}{10^3 \cancel{\text{cm}^3}} = 1$$

Observe that you treat units in the same way as algebraic quantities. Note too that the right-hand side now equals 1 and no units are associated with it. Because it is always possible to multiply any quantity by 1 without changing that quantity, you can multiply the previous expression for the volume by the factor  $1 \text{ L}/10^3 \text{ cm}^3$  without changing the actual volume. You are changing only the way you express this volume:

$$V = 5.00^3 \text{ cm}^3 \times \underbrace{\frac{1 \text{ L}}{10^3 \text{ cm}^3}}_{\substack{\text{converts} \\ \text{cm}^3 \text{ to L}}} = 125 \times 10^{-3} \text{ L} = 0.125 \text{ L}$$

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. WCH 02-200-203

In order to solve problems using dimensional analysis, you may find it helpful to diagram a solution pathway using units as a guide. For example, in the problem above:

In this diagram the  $\rightarrow$  represents the ratio  $1 \text{ L}/10^3 \text{ cm}^3$ , which we use to convert from units of  $\text{cm}^3$  to L.

The ratio  $1 \text{ L}/10^3 \text{ cm}^3$  is called a **conversion factor** because it is *a factor equal to 1 that converts a quantity expressed in one unit to a quantity expressed in another unit*.  $\blacktriangleright$  Note that the numbers in this conversion factor are *exact*, because 1 L equals exactly  $1000 \text{ cm}^3$ . Such exact conversion factors do not affect the number of significant figures in an arithmetic result. In the previous calculation, the quantity

It takes more room to explain conversion factors than it does to use them. With practice, you will be able to write the final conversion step without the intermediate algebraic manipulations outlined here.

5.00 cm (the measured length of the side) does determine or limit the number of significant figures.

The next two examples illustrate how the conversion-factor method may be used to convert one metric unit to another.

### Example 1.6 Converting Units: Metric Unit to Metric Unit

#### Gaining Mastery Toolbox

##### Critical Concept 1.6

Dimensional analysis can be used to convert metric units. Unit conversion factors are the key to applying dimensional analysis to solve problems.

##### Solution Essentials:

- Metric conversion factors
- The metric system
- Rules for significant figures and rounding

Nitrogen gas is the major component of air. A sample of nitrogen gas in a glass bulb weighs 243 mg. What is this mass in SI base units of mass (kilograms)?

**Problem Strategy** This problem requires converting a mass in milligrams to kilograms. Finding the correct relationship for performing such a conversion directly in one step might be more difficult than doing the conversion in multiple steps. In this case, conversion factors for converting milligrams to grams and from grams to kilograms are relatively easy to derive, so it makes sense to do this conversion in two steps. First convert milligrams to grams; then convert grams to kilograms. To convert from milligrams to grams, note that the prefix *milli-* means  $10^{-3}$ . To convert from grams to kilograms, note that the prefix *kilo-* means  $10^3$ .

Diagramming the solution clearly shows how two conversion factors (2  $\rightarrow$ ) are used to solve the problem.

**Solution** Since  $1 \text{ mg} = 10^{-3} \text{ g}$ , you can write

$$243 \text{ mg} \times \frac{10^{-3} \text{ g}}{1 \text{ mg}} = 2.43 \times 10^{-1} \text{ g}$$

Then, because the prefix *kilo-* means  $10^3$ , you write

$$1 \text{ kg} = 10^3 \text{ g}$$

and

$$2.43 \times 10^{-1} \text{ g} \times \frac{1 \text{ kg}}{10^3 \text{ g}} = 2.43 \times 10^{-4} \text{ kg}$$

Note, however, that you can combine the two conversion steps as follows:

$$243 \text{ mg} \times \underbrace{\frac{10^{-3} \text{ g}}{1 \text{ mg}}}_{\text{converts mg to g}} \times \underbrace{\frac{1 \text{ kg}}{10^3 \text{ g}}}_{\text{converts g to kg}} = 2.43 \times 10^{-4} \text{ kg}$$

Nitrogen molecular model

**Answer Check** Often, mistakes lead to answers that are easily detected by giving them a *reasonableness check*. For example, if while solving this problem you mistakenly write the conversion factors in inverted order (although this should not happen if you use units in your calculation), the final answer will be very large. Or perhaps you inadvertently copy the exponent from your calculator with the wrong sign, giving the answer as  $2.43 \times 10^4 \text{ kg}$ . A large answer is not reasonable, given that you are converting from small mass units (mg) to relatively large mass units (kg). Both of these errors can be caught simply by taking the time to make sure that your answer is reasonable. After completing any calculations, be sure to check for reasonableness in your answers.

Oxygen molecular model

**Exercise 1.8** The oxygen molecule (the smallest particle of oxygen gas) consists of two oxygen atoms a distance of 121 pm apart. How many millimeters is this distance?

See Problems 1.81, 1.82, 1.83, and 1.84.

**Example 1.7 Converting Units: Metric Volume to Metric Volume****Gaining Mastery Toolbox****Critical Concept 1.7**

Dimensional analysis can be used to convert between volumes. Volume measurements typically involve cubed conversion factors.

**Solution Essentials:**

- Derive cubic (volume) conversion factors from metric conversion factors
- Metric conversion factors
- The metric system
- Rules for significant figures and rounding

The world's oceans contain approximately  $1.35 \times 10^9 \text{ km}^3$  of water. What is this volume in liters?

**Problem Strategy** This problem requires several conversions. A relationship that will prove helpful here is the definition of the liter:  $1 \text{ dm}^3 = 1 \text{ L}$ . This provides a clue that if we can convert cubic kilometers ( $\text{km}^3$ ) to cubic decimeters ( $\text{dm}^3$ ), we can use this relationship to convert to liters. When solving problems that involve cubic units such as this one, it is often helpful to think of the conversion factors that you would use if the units were not cubed. In this case, convert from kilometers to meters and then from meters to decimeters. Next, think about how these conversion factors would look if they were cubed. For example,  $10^3 \text{ m} = 1 \text{ km}$ , so  $(10^3 \text{ m})^3 = (1 \text{ km})^3$  is the cubic relationship. Likewise,  $10^{-1} \text{ m} = 1 \text{ dm}$ , so  $(10^{-1} \text{ m})^3 = (1 \text{ dm})^3$  is the cubic relationship. Now these two cubic conversion factors can be combined into three steps to solve the problem.

**Solution**

$$1.35 \times 10^9 \text{ km}^3 \times \underbrace{\left(\frac{10^3 \text{ m}}{1 \text{ km}}\right)^3}_{\text{converts } \text{km}^3 \text{ to } \text{m}^3} \times \underbrace{\left(\frac{1 \text{ dm}}{10^{-1} \text{ m}}\right)^3}_{\text{converts } \text{m}^3 \text{ to } \text{dm}^3} = 1.35 \times 10^{21} \text{ dm}^3$$

Because a cubic decimeter is equal to a liter, the volume of the oceans is  
 **$1.35 \times 10^{21} \text{ L}$**

**Answer Check** One of the most common errors made with this type of problem is a failure to cube both the numerator and the denominator in the conversion factors. For example,  $(10^3 \text{ m}/1 \text{ km})^3 = 109 \text{ m}^3/1 \text{ km}^3$ .

**Exercise 1.9** A large crystal is constructed by stacking small, identical pieces of crystal, much as you construct a brick wall by stacking bricks. A unit cell is the smallest such piece from which a crystal can be made. The unit cell of a crystal of gold metal has a volume of  $67.6 \text{ \AA}^3$ . What is this volume in cubic decimeters?

See Problems 1.85 and 1.86.

The conversion-factor method can be used to convert any unit to another unit, provided a conversion equation exists between the two units. Relationships between certain U.S. units and metric units are given in Table 1.4. You can use these to convert between U.S. and metric units. Suppose you wish to convert 0.547 lb to grams. From Table 1.4, note that  $1 \text{ lb} = 0.4536 \text{ kg}$ , or  $1 \text{ lb} = 453.6 \text{ g}$ , so the conversion factor from pounds to grams is  $453.6 \text{ g}/1 \text{ lb}$ . Therefore,

$$0.547 \text{ lb} \times \frac{453.6 \text{ g}}{1 \text{ lb}} = 248 \text{ g}$$

The next example illustrates a conversion requiring several steps.

**Table 1.4** Relationships of Some U.S. and Metric Units

Length	Mass	Volume
1 in. = 2.54 cm (exact)	1 lb = 0.4536 kg	1 qt = 0.9464 L
1 yd = 0.9144 m (exact)	1 lb = 16 oz (exact)	4 qt = 1 gal (exact)
1 mi = 1.609 km	1 oz = 28.35 g	
1 mi = 5280 ft (exact)		

**Example 1.8 Converting Units: Any Unit to Another Unit****Gaining Mastery Toolbox****Critical Concept 1.8**

Dimensional analysis can be used to perform any type of unit conversion. As long as conversion factors between units exist, dimensional analysis can be applied to solve the problem.

**Solution Essentials:**

- U.S. to metric conversion factors
- Metric conversion factors
- The metric system
- Rules for significant figures and rounding

How many centimeters are there in 6.51 miles?

**Problem Strategy** This problem involves converting from U.S. to metric units: specifically, from miles to centimeters. One path to a solution is using three conversions: miles to feet, feet to inches, and inches to centimeters. Table 1.4 has the information you need to develop the conversion factors for U.S. to metric units.

**Solution** From the definitions, you obtain the following conversion factors:

$$1 = \frac{5280 \text{ ft}}{1 \text{ mi}} \quad 1 = \frac{12 \text{ in.}}{1 \text{ ft}} \quad 1 = \frac{2.54 \text{ cm}}{1 \text{ in.}}$$

Then,

$$6.51 \text{ mi} \times \underbrace{\frac{5280 \text{ ft}}{1 \text{ mi}}}_{\text{converts mi to ft}} \times \underbrace{\frac{12 \text{ in.}}{1 \text{ ft}}}_{\text{converts ft to in.}} \times \underbrace{\frac{2.54 \text{ cm}}{1 \text{ in.}}}_{\text{converts in. to cm}} = 1.05 \times 10^6 \text{ cm}$$

All of the conversion factors used in this example are exact, so the number of significant figures in the result is determined by the number of significant figures in 6.51 mi.

Thomas Jablonski/Fotolia LLC

**Answer Check** Because miles are a relatively large unit of length and centimeters are a relatively small unit of length, one would expect that converting from miles to centimeters would yield a very large number. This is the case here, so the answer is reasonable.

**Exercise 1.10** Using the definitions  $1 \text{ in.} = 2.54 \text{ cm}$  and  $1 \text{ yd} = 36 \text{ in.}$  (both exact), obtain the conversion factor for yards to meters. How many meters are there in 3.54 yd?

See Problems 1.87, 1.88, 1.89, and 1.90.

## A Checklist for Review

**Summary of Facts and Concepts**

Chemistry is an experimental science in that the facts of chemistry are obtained by *experiment*. These facts are systematized and explained by *theory*, and theory suggests more experiments. The *scientific method* involves this interplay, in which the body of accepted knowledge grows as it is tested by experiment.

Chemistry emerged as a *quantitative science* with the work of the eighteenth-century French chemist Antoine Lavoisier. He made use of the idea that the mass, or quantity of matter, remains constant during a chemical reaction (*law of conservation of mass*).

Matter may be classified by its physical state as a *gas*, *liquid*, or *solid*. Matter may also be classified by its chemical composition as an *element*, *compound*, or *mixture*. Materials are either substances or mixtures of substances. Substances are either elements or compounds, which are composed of two or more elements. Mixtures can be separated into substances by physical processes, but compounds can be separated into elements only by chemical reactions.

A quantitative science requires the making of measurements. Any measurement has limited *precision*, which you convey by writing the measured number to a certain

number of *significant figures*. There are many different systems of measurement, but scientists generally use the metric system. The International System (SI) uses a particular selection of metric units. It employs seven *base units* combined with *prefixes* to obtain units of various size. Units for other quantities are derived from these. To obtain a *derived unit* in SI for a quantity such as the volume

or density, you merely substitute base units into a defining equation for the quantity.

*Dimensional analysis* is a technique of calculating with physical quantities in which units are included and treated in the same way as numbers. You can thus obtain the *conversion factor* needed to express a quantity in new units.

## Learning Objectives

## Important Terms

### 1.1 Modern Chemistry: A Brief Glimpse

- Provide examples of the contributions of chemistry to humanity.

### 1.2 Experiment and Explanation

- Describe how chemistry is an experimental science.
- Understand how the scientific method is an approach to performing science.

**experiment**  
**law**  
**hypothesis**  
**theory**

### 1.3 Law of Conservation of Mass

- Explain the law of conservation of mass.
- Apply the law of the conservation of mass. **Example 1.1**

**mass**  
**matter**  
**law of conservation of mass**

### 1.4 Matter: Physical State and Chemical Composition

- Compare and contrast the three common states of matter: solid, liquid, and gas.
- Describe the classifications of matter: elements, compounds, and mixtures (heterogeneous and homogeneous).
- Understand the difference between chemical changes (chemical reactions) and physical changes.
- Distinguish between chemical properties and physical properties.

**solid**  
**liquid**  
**gas**  
**states of matter**  
**physical change**  
**chemical change (chemical reaction)**  
**physical property**  
**chemical property**  
**substance**  
**element**  
**compound**  
**law of definite proportions (law of constant composition)**  
**mixture**  
**heterogeneous mixture**  
**homogeneous mixture (solution)**  
**phase**

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. WCH 02-200-203

### 1.5 Measurement and Significant Figures

- Define and use the terms *precision* and *accuracy* when describing measured quantities.
- Learn the rules for determining significant figures in reported measurements.
- Know how to represent numbers using scientific notation.
- Apply the rules of significant figures to reporting calculated values.
- Be able to recognize exact numbers.
- Know when and how to apply the rules for rounding.
- Use significant figures in calculations. **Example 1.2**

**unit**  
**precision**  
**accuracy**  
**significant figures**  
**number of significant figures**  
**scientific notation**  
**exact number**  
**rounding**

**1.6 SI Units**

- Become familiar with the SI (metric) system of units, including the SI prefixes.
- Convert from one temperature scale to another.

**Example 1.3**

**International System of units (SI)****SI base units****SI prefix**

meter (m)

angstrom (Å)

kilogram (kg)

second (s)

Celsius scale

kelvin (K)

**1.7 Derived Units**

- Define and provide examples of derived units.
- Calculate the density of a substance. **Example 1.4**
- Use density to relate mass and volume. **Example 1.5**

**SI derived unit**

liter (L)

density

**1.8 Units and Dimensional Analysis (Factor-Label Method)**

- Apply dimensional analysis to solving numerical problems.
- Convert from one metric unit to another metric unit. **Example 1.6**
- Convert from one metric volume to another metric volume. **Example 1.7**
- Convert from any unit to another unit. **Example 1.8**

**dimensional analysis (factor-label method)**

conversion factor

**Key Equations**

$$T_K = \left( t_C \times \frac{1 \text{ K}}{1^\circ\text{C}} \right) + 273.15 \text{ K}$$

$$t_C = \frac{5^\circ\text{C}}{9^\circ\text{F}} \times (t_F - 32^\circ\text{F})$$

$$d = m/V$$

**Questions and Problems****Self-Assessment and Review Questions**

**Key:** These questions test your understanding of the ideas you worked with in the chapter. These problems vary in difficulty and often can be used for the basis of discussion.

**1.1** Discuss some ways in which chemistry has changed technology. Give one or more examples of how chemistry has affected another science.

**1.2** Define the terms *experiment* and *theory*. How are theory and experiment related? What is a hypothesis?

**1.3** Illustrate the steps in the scientific method using Rosenberg's discovery of the anticancer activity of cisplatin.

**1.4** Define the terms *matter* and *mass*. What is the difference between mass and weight?

**1.5** State the law of conservation of mass. Describe how you might demonstrate this law.

**1.6** A chemical reaction is often accompanied by definite changes in appearance. For example, heat and light may be emitted, and there may be a change of color of the substances. Figure 1.9 shows the reactions of the metal mercury with oxygen in air. Describe the changes that occur.

**1.7** Characterize gases, liquids, and solids in terms of compressibility and fluidity.

**1.8** Choose a substance and give several of its physical properties and several of its chemical properties.

**1.9** Give examples of an element, a compound, a heterogeneous mixture, and a homogeneous mixture.

**1.10** What phases or states of matter are present in a glass of bubbling carbonated beverage that contains ice cubes?

**1.11** What distinguishes an element from a compound? Can a compound also be an element?

**1.12** What is meant by the precision of a measurement? How is it indicated?

**1.13** Two rules are used to decide how to round the result of a calculation to the correct number of significant figures. Use a calculation to illustrate each rule. Explain how you obtained the number of significant figures in the answers.

**1.14** Distinguish between a measured number and an exact number. Give examples of each.

1.15 How does the International System (SI) obtain units of different size from a given unit? How does the International System obtain units for all possible physical quantities from only seven base units?

1.16 What is an absolute temperature scale? How are degrees Celsius related to kelvins?

1.17 Define *density*. Describe some uses of density.

1.18 Why should units be carried along with numbers in a calculation?

1.19 When the quantity 12.9 g is added to  $2 \times 10^{-02}$  g, how many significant figures should be reported in the answer?

- a one    b two    c three    d four    e five

1.20 You perform an experiment in the lab and determine that there are 36.3 inches in a meter. Using this experimental value, how many millimeters are there in 1.34 feet?

- a  $4.43 \times 10^2$  mm    b  $4.05 \times 10^2$  mm  
 c 44.3 mm    d  $4.43 \times 10^5$  mm  
 e  $4.05 \times 10^8$  mm

1.21 A 75.0-g sample of a pure liquid, liquid A, with a density of 3.00 g/mL is mixed with a 50.0-mL sample of a pure liquid, liquid B, with a density of 2.00 g/mL. What is the total volume of the mixture? (Assume there is no reaction upon the mixing of A and B and volumes are additive.)

- a 275 mL    b 175 mL  
 c 125 mL    d 100 mL  
 e 75 mL

1.22 Which of the following represents the *smallest* mass?

- a 23 cg  
 b  $2.3 \times 10^3$   $\mu$ g  
 c 0.23 mg  
 d 0.23 g  
 e  $2.3 \times 10^{-2}$  kg

## Concept Explorations

**Key:** Concept explorations are comprehensive problems that provide a framework that will enable you to explore and learn many of the critical concepts and ideas in each chapter. If you master the concepts associated with these explorations, you will have a better understanding of many important chemistry ideas and will be more successful in solving all types of chemistry problems. These problems are well suited for group work and for use as in-class activities.

### 1.23 Physical and Chemical Changes

Say you are presented with two beakers, beaker A and beaker B, each containing a white, powdery compound.

- a From your initial observations, you suspect that the two beakers contain the same compound. Describe, in general terms, some experiments in a laboratory that you could do to help prove or disprove that the beakers contain the same compound.
- b Would it be easier to prove that the compounds are the same or to prove that they are different? Explain your reasoning.
- c Which of the experiments that you listed above are the most convincing in determining whether the compounds are the same? Justify your answer.
- d A friend states that the best experiment for determining whether the compounds are the same is to see if they both dissolve in water. He proceeds to take 10.0 g of each compound and places them in separate beakers, each containing 100 mL of water. Both compounds completely dissolve. He then states, "Since the same amount of both substances dissolved in the same volume of water, they must both have the same chemical composition." Is he justified in making this claim? Why or why not?

### 1.24 Significant Figures

#### Part 1:

- a Consider three masses that you wish to add together: 3 g, 1.4 g, and 3.3 g. These numbers represent measured values. Add the numbers together and report your answer to the correct number of significant figures.

- b Now perform the addition in a stepwise fashion in the following manner. Add 3 g and 1.4 g, reporting this sum to the correct number of significant figures. Next, take the number from the first step and add it to 3.3 g, reporting this sum to the correct number of significant figures.
- c Compare your answers from performing the addition in the two distinct ways presented in parts a and b. Does one of the answers represent a "better" way of reporting the results of the addition? If your answer is yes, explain why your choice is better.
- d A student performs the calculation  $(5.0 \times 5.143 \text{ g}) + 2.80 \text{ g}$  and, being mindful of significant figures, reports an answer of 29 g. Is this the correct answer? If not, what might this student have done incorrectly?
- e Another student performs the calculation  $(5 \times 5.143 \text{ g}) + 2.80$  and reports an answer of 29 g. Is this the correct answer? If not, what might this student have done incorrectly?
- f Yet another student performs the calculation  $(5.00 \times 5.143 \text{ g}) + 2.80$  and reports an answer of 28.5 g. Is this the correct answer? If not, what did this student probably do incorrectly?
- g Referring to the calculations above, outline a procedure or rule(s) that will always enable you to report answers using the correct number of significant figures.

#### Part 2:

- a A student wants to determine the volume of 27.2 g of a substance. He looks up the density of the material in a reference book, where it is reported to be 2.4451 g/cm<sup>3</sup>. He performs the calculation in the following manner:

$$27.2 \text{ g} \times 1.0 \text{ cm}^3/2.4 \text{ g} = 11.3 \text{ cm}^3$$

Is the calculated answer correct? If not, explain why it is not correct.

- b Another student performs the calculation in the following manner:

$$27.2 \text{ g} \times 1.00 \text{ cm}^3/2.45 \text{ g} = 11.1 \text{ cm}^3$$

Is this a “better” answer than that of the first student? Is this the “best” answer, or could it be “improved”? Explain.

- c** Say that you have ten ball bearings, each having a mass of 1.234 g and a density of 3.1569 g/cm<sup>3</sup>. Calculate the volume of these ten ball bearings. In performing

the calculation, present your work as unit conversions, and report your answer to the correct number of significant figures.

- d** Explain how the answer that you calculated in part c is the “best” answer to the problem?

## Conceptual Problems

**Key:** These problems are designed to check your understanding of the concepts associated with some of the main topics presented in each chapter. A strong conceptual understanding of chemistry is the foundation for both applying chemical knowledge and solving chemical problems. These problems vary in level of difficulty and often can be used as a basis for group discussion.

### 1.25

- a** Sodium metal is partially melted. What are the two phases present?
- b** A sample of sand is composed of granules of quartz (silicon dioxide) and seashells (calcium carbonate). The sand is mixed with water. What phases are present?

**1.26** A material is believed to be a compound. Suppose you have several samples of this material obtained from various places around the world. Comment on what you would expect to find upon observing the melting point and color for each sample. What would you expect to find upon determining the elemental composition for each sample?

**1.27** You need a thermometer that is accurate to  $\pm 5^\circ\text{C}$  to conduct some experiments in the temperature range of  $0^\circ\text{C}$  to  $100^\circ\text{C}$ . You find one in your lab drawer that has lost its markings.

- a** What experiments could you do to make sure your thermometer is suitable for your experiments?
- b** Assuming that the thermometer works, what procedure could you follow to put a scale on your thermometer that has the desired accuracy?

**1.28** Imagine that you get the chance to shoot five arrows at each of the targets depicted below. On each of the targets, indicate the pattern that the five arrows make when

- a** You have poor accuracy and good precision.
- b** You have poor accuracy and poor precision.
- c** You have good accuracy and good precision.

**1.29** Say you live in a climate where the temperature ranges from  $-100^\circ\text{F}$  to  $20^\circ\text{F}$  and you want to define a new temperature scale, YS (YS is the “Your Scale” temperature scale), which defines this range as  $0.0^\circ\text{YS}$  to  $100.0^\circ\text{YS}$ .

- a** Come up with an equation that would allow you to convert between  $^\circ\text{F}$  and  $^\circ\text{YS}$ .
- b** Using your equation, what would be the temperature in  $^\circ\text{F}$  if it were  $66^\circ\text{YS}$ ?

**1.30** You are presented with a piece of metal in a jar. It is your job to determine what the metal is. What are

some physical properties that you could measure in order to determine the type of metal? You suspect that the metal might be sodium; what are some chemical properties that you could investigate? (See Section 1.4 for some ideas.)

**1.31** You have two identical boxes with interior dimensions of  $8.0\text{ cm} \times 8.0\text{ cm} \times 8.0\text{ cm}$ . You completely fill one of the boxes with wooden spheres that are 1.6 cm in diameter. The other box gets filled with wooden cubes that are 1.6 cm on each edge. After putting the lid on the filled boxes, you then measure the density of each. Which one is more dense?

**1.32** Consider the following compounds and their densities.

Substance	Density (g/mL)	Substance	Density (g/mL)
Isopropyl alcohol	0.785	Toluene	0.866
<i>n</i> -Butyl alcohol	0.810	Ethylene glycol	1.114

You create a column of the liquids in a glass cylinder with the most dense material on the bottom layer and the least dense on the top. You do not allow the liquids to mix.

- a** First you drop a plastic bead that has a density of  $0.24\text{ g/cm}^3$  into the column. What do you expect to observe?
- b** Next you drop a different plastic bead that has a volume of 0.043 mL and a mass of  $3.92 \times 10^{-2}\text{ g}$  into the column. What would you expect to observe in this case?
- c** You drop another bead into the column and observe that it makes it all the way to the bottom of the column. What can you conclude about the density of this bead?

### 1.33

- a** Which of the following items have a mass of about 1 g?  
 a grain of sand  
 a paper clip  
 a nickel  
 a 5.0-gallon bucket of water  
 a brick  
 a car
- b** What is the approximate mass (using SI mass units) of each of the items in part a?

**1.34** What is the length of the nail reported to the correct number of significant figures?

1.35 For these questions, be sure to apply the rules for significant figures.

- a You are conducting an experiment where you need the volume of a box; you take the length, height, and width measurements and then multiply the values together to find the volume. You report the volume of the box as  $0.310 \text{ m}^3$ . If two of your measurements were  $0.7120 \text{ m}$  and  $0.52145 \text{ m}$ , what was the other measurement?
- b If you were to add the two measurements from the first part of the problem to a third length measurement

with the reported result of  $1.509 \text{ m}$ , what was the value of the third measurement?

- 1.36 You are teaching a class of second graders some chemistry, and they are confused about an object's mass versus its density. Keeping in mind that most second graders don't understand fractions, how would you explain these two ideas and illustrate how they differ? What examples would you use as a part of your explanation?

## Practice Problems

**Key:** These problems are for practice in applying problem-solving skills. They are divided by topic, and some are keyed to exercises (see the ends of the exercises). The problems are arranged in matching pairs; the odd-numbered problem of each pair is listed first, and its answer is given in the back of the book.

### Conservation of Mass

1.37 A  $15.5 \text{ g}$  sample of sodium carbonate is added to a solution of acetic acid weighing  $19.7 \text{ g}$ . The two substances react, releasing carbon dioxide gas to the atmosphere. After reaction, the contents of the reaction vessel weigh  $28.7 \text{ g}$ . What is the mass of carbon dioxide given off during the reaction?

1.38 Some iron wire weighing  $5.6 \text{ g}$  is placed in a beaker and covered with  $15.0 \text{ g}$  of dilute hydrochloric acid. The acid reacts with the metal and gives off hydrogen gas, which escapes into the surrounding air. After reaction, the contents of the beaker weigh  $20.4 \text{ g}$ . What is the mass of hydrogen gas produced by the reaction?

1.39 Zinc metal reacts with yellow crystals of sulfur in a fiery reaction to produce a white powder of zinc sulfide. A chemist determines that  $65.4 \text{ g}$  of zinc reacts with  $32.1 \text{ g}$  of sulfur. How many grams of zinc sulfide could be produced from  $36.9 \text{ g}$  of zinc metal?

1.40 Aluminum metal reacts with bromine, a red-brown liquid with a noxious odor. The reaction is vigorous and produces aluminum bromide, a white crystalline substance. A sample of  $27.0 \text{ g}$  of aluminum yields  $266.7 \text{ g}$  of aluminum bromide. How many grams of bromine react with  $18.1 \text{ g}$  of aluminum?

### Solids, Liquids, and Gases

1.41 Give the normal state (solid, liquid, or gas) of each of the following.

- a sodium hydrogen carbonate (baking soda)  
 b isopropyl alcohol (rubbing alcohol)  
 c carbon monoxide  
 d lead

1.42 Give the normal state (solid, liquid, or gas) of each of the following.

- a potassium hydrogen tartrate (cream of tartar)  
 b tungsten

- c carbon (graphite)  
 d mercury

### Chemical and Physical Changes; Properties of Substances

1.43 Which of the following are physical changes and which are chemical changes?

- a melting of sodium chloride  
 b pulverizing of rock salt  
 c burning of sulfur  
 d dissolving of salt in water

1.44 For each of the following, decide whether a physical or a chemical change is involved.

- a dissolving of sugar in water  
 b rusting of iron  
 c burning of wood  
 d evaporation of alcohol

1.45 A sample of mercury(II) oxide was heated to produce mercury metal and oxygen gas. Then the liquid mercury was cooled to  $-40^\circ\text{C}$ , where it solidified. A glowing wood splint was thrust into the oxygen, and the splint burst into flame. Identify each physical change and each chemical change.

1.46 Solid iodine, contaminated with salt, was heated until the iodine vaporized. The violet vapor of iodine was then cooled to yield the pure solid. Solid iodine and zinc metal powder were mixed and ignited to give a white powder. Identify each physical change and each chemical change.

1.47 The following are properties of substances. Decide whether each is a physical property or a chemical property.

- a Chlorine gas liquefies at  $-35^\circ\text{C}$  under normal pressure.  
 b Hydrogen burns in chlorine gas.  
 c Bromine melts at  $-7.2^\circ\text{C}$ .  
 d Lithium is a soft, silvery-colored metal.  
 e Iron rusts in an atmosphere of moist air.

1.48 Decide whether each of the following is a physical property or a chemical property of the substance.

- a Salt substitute, potassium chloride, dissolves in water.  
 b Seashells, calcium carbonate, fizz when immersed in vinegar.  
 c The gas hydrogen sulfide smells like rotten eggs.  
 d Fine steel wool (Fe) can be burned in air.  
 e Pure water freezes at  $0^\circ\text{C}$ .

**1.49** Iodine is a solid having somewhat lustrous, blue-black crystals. The crystals vaporize readily to a violet-colored gas. Iodine combines with many metals. For example, aluminum combines with iodine to give aluminum iodide. Identify the physical and the chemical properties of iodine that are cited.

**1.50** Mercury(II) oxide is an orange-red solid with a density of  $11.1 \text{ g/cm}^3$ . It decomposes when heated to give mercury and oxygen. The compound is insoluble in water (does not dissolve in water). Identify the physical and the chemical properties of mercury(II) oxide that are cited.

### Elements, Compounds, and Mixtures

**1.51** Consider the following separations of materials. State whether a physical process or a chemical reaction is involved in each separation.

- a** Sodium chloride is obtained from seawater by evaporation of the water.
- b** Mercury is obtained by heating the substance mercury(II) oxide; oxygen is also obtained.
- c** Pure water is obtained from ocean water by evaporating the water, then condensing it.
- d** Iron is produced from an iron ore that contains the substance iron(III) oxide.
- e** Gold is obtained from river sand by panning (allowing the heavy metal to settle in flowing water).

**1.52** All of the following processes involve a separation of either a mixture into substances or a compound into elements. For each, decide whether a physical process or a chemical reaction is required.

- a** Sodium metal is obtained from the substance sodium chloride.
- b** Iron filings are separated from sand by using a magnet.
- c** Sugar crystals are separated from a sugar syrup by evaporation of water.
- d** Fine crystals of silver chloride are separated from a suspension of the crystals in water.
- e** Copper is produced when zinc metal is placed in a solution of copper(II) sulfate, a compound.

**1.53** Label each of the following as a substance, a heterogeneous mixture, or a solution.

- |                   |                     |
|-------------------|---------------------|
| <b>a</b> seawater | <b>b</b> sulfur     |
| <b>c</b> fluorine | <b>d</b> beach sand |

**1.54** Indicate whether each of the following materials is a substance, a heterogeneous mixture, or a solution.

- |                   |                   |
|-------------------|-------------------|
| <b>a</b> milk     | <b>b</b> bromine  |
| <b>c</b> gasoline | <b>d</b> aluminum |

**1.55** Which of the following are pure substances and which are mixtures? For each, list all of the different phases present.

- a** bromine liquid and its vapor
- b** paint, containing a liquid solution and a dispersed solid pigment
- c** partially molten iron
- d** baking powder containing sodium hydrogen carbonate and potassium hydrogen tartrate

**1.56** Which of the following are pure substances and which are mixtures? For each, list all of the different phases present.

- a** a sugar solution with sugar crystals at the bottom
- b** ink containing a liquid solution with fine particles of carbon
- c** a sand containing quartz (silicon dioxide) and calcite (calcium carbonate)
- d** liquid water and steam at  $100^\circ\text{C}$

### Significant Figures

**1.57** How many significant figures are there in each of the following measurements?

- |   |                    |
|---|--------------------|
| <b>a</b> 57.00 g                          | <b>b</b> 0.0503 kg |
| <b>c</b> 6.310 J                          | <b>d</b> 0.80090 m |
| <b>e</b> $5.06 \times 10^{-7} \text{ cm}$ | <b>f</b> 2.010 s   |

**1.58** How many significant figures are there in each of the following measurements?

- |                                       |   |
|---------------------------------------|---|
| <b>a</b> 4.0100 mg                    | <b>b</b> 0.05930 g                      |
| <b>c</b> 0.035 mm                     | <b>d</b> 3.100 s                        |
| <b>e</b> $8.91 \times 10^1 \text{ L}$ | <b>f</b> $9.100 \times 10^4 \text{ cm}$ |

**1.59** The circumference of the earth at the equator is 40,000 km. This value is precise to two significant figures. Write this in scientific notation to express correctly the number of significant figures.

**1.60** The astronomical unit equals the mean distance between the earth and the sun. This distance is 150,000,000 km, which is precise to three significant figures. Express this in scientific notation to the correct number of significant figures.

**1.61** Assuming all numbers are measured quantities, do the indicated arithmetic and give the answer to the correct number of significant figures.

- a**  $\frac{8.71 \times 0.0301}{0.031}$
- b**  $0.71 + 89.3$
- c**  $934 \times 0.00435 + 107$
- d**  $(847.89 - 847.73) \times 14673$

**1.62** Assuming all numbers are measured quantities, do the indicated arithmetic and give the answer to the correct number of significant figures.

- a**  $\frac{08.71 \times 0.57}{5.871}$
- b**  $8.937 - 8.930$
- c**  $8.937 + 8.930$
- d**  $0.00015 \times 54.6 + 1.002$

**1.63** One sphere has a radius of 4.52 cm; another has a radius of 4.72 cm. What is the difference in volume (in cubic centimeters) between the two spheres? Give the answer to the correct number of significant figures. The volume of a sphere is  $(4/3) \pi r^3$ , where  $\pi = 3.1416$  and  $r$  is the radius.

**1.64** A solid circular cylinder of iron with a radius of 1.500 cm has a ruler etched along its length. What is the volume of iron contained between the marks labeled 3.20 cm and 3.50 cm? The volume of a circular cylinder is  $\pi r^2 l$ , where  $\pi = 3.1416$ ,  $r$  is the radius, and  $l$  is the length.

**SI Units**

**1.65** Write the following measurements, without scientific notation, using the appropriate SI prefix.

- |                                   |                               |
|-----------------------------------|-------------------------------|
| <b>a</b> $5.89 \times 10^{-12}$ s | <b>b</b> 0.2010 m             |
| <b>c</b> $2.560 \times 10^{-9}$ g | <b>d</b> $6.05 \times 10^3$ m |

**1.66** Write the following measurements, without scientific notation, using the appropriate SI prefix.

- |                                   |                                   |
|-----------------------------------|-----------------------------------|
| <b>a</b> $4.851 \times 10^{-6}$ g | <b>b</b> $3.16 \times 10^{-2}$ m  |
| <b>c</b> $2.591 \times 10^{-9}$ s | <b>d</b> $8.93 \times 10^{-12}$ g |

**1.67** Using scientific notation, convert:

- |                                  |                                   |
|----------------------------------|-----------------------------------|
| <b>a</b> 6.15 ps to s            | <b>b</b> 3.781 $\mu\text{m}$ to m |
| <b>c</b> 1.546 $\text{\AA}$ to m | <b>d</b> 9.7 mg to g              |

**1.68** Using scientific notation, convert:

- |                       |                                  |
|-----------------------|----------------------------------|
| <b>a</b> 6.20 km to m | <b>b</b> 1.98 ns to s            |
| <b>c</b> 2.54 cm to m | <b>d</b> 5.23 $\mu\text{g}$ to g |

**Temperature Conversion**

**1.69** Convert:

- |                                      |
|--------------------------------------|
| <b>a</b> 68°F to degrees Celsius     |
| <b>b</b> -23°F to degrees Celsius    |
| <b>c</b> 26°C to degrees Fahrenheit  |
| <b>d</b> -81°C to degrees Fahrenheit |

**1.70** Convert:

- |                                      |
|--------------------------------------|
| <b>a</b> 51°F to degrees Celsius     |
| <b>b</b> -11°F to degrees Celsius    |
| <b>c</b> -41°C to degrees Fahrenheit |
| <b>d</b> 22°C to degrees Fahrenheit  |

**1.71** Salt and ice are stirred together to give a mixture to freeze ice cream. The temperature of the mixture is  $-20.0^\circ\text{C}$ . What is this temperature in degrees Fahrenheit?

**1.72** The reaction of oxygen and hydrogen is used to propel rockets. Liquid oxygen has a boiling point of  $-222.7^\circ\text{C}$ . What is this temperature in degrees Fahrenheit?

**Density**

**1.73** A certain sample of the mineral galena (lead sulfide) weighs 12.4 g and has a volume of  $1.64\text{ cm}^3$ . What is the density of galena?

**1.74** A flask contains a 30.0 mL sample of acetone (nail polish remover) that weighs 23.6 grams. What is the density of the acetone?

**1.75** A liquid with a volume of 8.5 mL has a mass of 6.71 g. The liquid is either octane, ethanol, or benzene, the densities of which are  $0.702\text{ g/cm}^3$ ,  $0.789\text{ g/cm}^3$ , and  $0.879\text{ g/cm}^3$ , respectively. What is the identity of the liquid?

**1.76** A mineral sample has a mass of 5.94 g and a volume of  $0.73\text{ cm}^3$ . The mineral is either sphalerite (density =  $4.0\text{ g/cm}^3$ ), cassiterite (density =  $6.99\text{ g/cm}^3$ ), or cinnabar (density =  $8.10\text{ g/cm}^3$ ). Which is it?

**1.77** Platinum has a density of  $21.4\text{ g/cm}^3$ . What is the mass of  $5.9\text{ cm}^3$  of this metal?

**1.78** What is the mass of a 43.8-mL sample of gasoline, which has a density of  $0.70\text{ g/cm}^3$ ?

**1.79** Ethanol has a density of  $0.789\text{ g/cm}^3$ . What volume must be poured into a graduated cylinder to give 19.8 g of alcohol?

**1.80** Bromine is a red-brown liquid with a density of  $3.10\text{ g/mL}$ . A sample of bromine weighing 88.5 g occupies what volume?

**Unit Conversions**

**1.81** Sodium hydrogen carbonate, known commercially as baking soda, reacts with acidic materials such as vinegar to release carbon dioxide gas. An experiment calls for 0.450 kg of sodium hydrogen carbonate. Express this mass in milligrams.

**1.82** The acidic constituent in vinegar is acetic acid. A 10.0-mL sample of a certain vinegar contains 611 mg of acetic acid. What is this mass of acetic acid expressed in micrograms?

**1.83** The different colors of light have different wavelengths. The human eye is most sensitive to light whose wavelength is 555 nm (greenish-yellow). What is this wavelength in centimeters?

**1.84** Water consists of molecules (groups of atoms). A water molecule has two hydrogen atoms, each connected to an oxygen atom. The distance between any one hydrogen atom and the oxygen atom is  $0.96\text{ \AA}$ . What is this distance in millimeters?

**1.85** The total amount of fresh water on earth is estimated to be  $3.73 \times 10^8\text{ km}^3$ . What is this volume in cubic meters? in liters?

**1.86** A submicroscopic particle suspended in a solution has a volume of  $1.3\text{ }\mu\text{m}^3$ . What is this volume in liters?

**1.87** How many grams are there in 3.58 short tons? Note that  $1\text{ g} = 0.03527\text{ oz}$  (ounces avoirdupois),  $1\text{ lb}$  (pound) = 16 oz, and  $1\text{ short ton} = 2000\text{ lb}$ . (These relations are exact.)

**1.88** The calorie, the Btu (British thermal unit), and the joule are units of energy;  $1\text{ calorie} = 4.184\text{ joules}$  (exact), and  $1\text{ Btu} = 252.0\text{ calories}$ . Convert 3.15 Btu to joules.

**1.89** The first measurement of sea depth was made in 1840 in the central South Atlantic, where a plummet was lowered 2425 fathoms. What is this depth in meters? Note that  $1\text{ fathom} = 6\text{ ft}$ ,  $1\text{ ft} = 12\text{ in.}$ , and  $1\text{ in.} = 2.54 \times 10^{-2}\text{ m}$ . (These relations are exact.)

**1.90** The estimated amount of recoverable oil from the field at Prudhoe Bay in Alaska is  $1.3 \times 10^{10}$  barrels. What is this amount of oil in cubic meters? One barrel = 42 gal (exact),  $1\text{ gal} = 4\text{ qt}$  (exact), and  $1\text{ qt} = 9.46 \times 10^{-4}\text{ m}^3$ .

**1.91** A fish tank is 24.2 in. long, 15.9 in. deep, and 14.8 in. high. What is the maximum volume of water, in liters, that the fish tank can hold?

1.92 The population density of worms in a particular field is 33 worms per cubic meter of soil. How many worms

would there be in the top meter of soil in a field that has dimensions of 1.00 km by 2.0 km?

## General Problems

**Key:** These problems provide more practice but are not divided by topic or keyed to exercises. Each section ends with essay questions, each of which is color coded to refer to the *A Chemist Looks at Daily Life* (orange) or *Instrumental Methods* (light blue) chapter essay on which it is based. Odd-numbered problems and the even-numbered problems that follow are similar; answers to all odd-numbered problems except the essay questions are given in the back of the book.

1.93 Sodium metal reacts vigorously with water. A piece of sodium weighing 19.70 g was added to a beaker containing 126.22 g of water. During reaction, hydrogen gas was produced and bubbled from the solution. The solution, containing sodium hydroxide, weighed 145.06 g. How many grams of hydrogen gas were produced?

1.94 An antacid tablet weighing 0.853 g contained calcium carbonate as the active ingredient, in addition to an inert binder. When an acid solution weighing 56.519 g was added to the tablet, carbon dioxide gas was released, producing a fizz. The resulting solution weighed 57.152 g. How many grams of carbon dioxide were produced?

1.95 When a mixture of aluminum powder and iron(III) oxide is ignited, it produces molten iron and aluminum oxide. In an experiment, 5.40 g of aluminum was mixed with 18.50 g of iron(III) oxide. At the end of the reaction, the mixture contained 11.17 g of iron, 10.20 g of aluminum oxide, and an undetermined amount of unreacted iron(III) oxide. No aluminum was left. What is the mass of the iron(III) oxide?

1.96 When chlorine gas is bubbled into a solution of sodium bromide, the sodium bromide reacts to give bromine, a red-brown liquid, and sodium chloride (ordinary table salt). A solution was made by dissolving 20.6 g of sodium bromide in 100.0 g of water. After passing chlorine through the solution, investigators analyzed the mixture. It contained 16.0 g of bromine and 11.7 g of sodium chloride. How many grams of chlorine reacted?

1.97 A beaker weighed 50.90 g. To the beaker was added 5.680 g of iron pellets and 53.3 g of hydrochloric acid. What was the total mass of the beaker and the mixture (before reaction)? Express the answer to the correct number of significant figures.

1.98 A graduated cylinder weighed 66.5 g. To the cylinder was added 58.2 g of water and 5.279 g of sodium chloride. What was the total mass of the cylinder and the solution? Express the answer to the correct number of significant figures.

1.99 Describe each of the following as a physical or chemical property of each listed chemical substance.

- a baking soda reacts with vinegar
- b ice melts at 0°C
- c graphite is a soft, black solid
- d hydrogen burns in air

1.100 Describe each of the following as a physical or chemical property of each listed chemical substance.

- a chlorine is a green gas
- b zinc reacts with acids
- c magnesium has a density of 1.74 g/cm<sup>3</sup>
- d iron can rust

1.101 Analyses of several samples of a material containing only iron and oxygen gave the following results. Could this material be a compound?

	<i>Mass of Sample</i>	<i>Mass of Iron</i>	<i>Mass of Oxygen</i>
Sample A	1.518 g	1.094 g	0.424 g
Sample B	2.056 g	1.449 g	0.607 g
Sample C	1.873 g	1.335 g	0.538 g

1.102 A red-orange solid contains only mercury and oxygen. Analyses of three different samples gave the following results. Are the data consistent with the hypothesis that the material is a compound?

	<i>Mass of Sample</i>	<i>Mass of Mercury</i>	<i>Mass of Oxygen</i>
Sample A	1.0410 g	0.9641g	0.0769 g
Sample B	1.5434 g	1.4293 g	0.1141 g
Sample C	1.2183 g	1.1283 g	0.0900 g

1.103 A cubic box measures 39.3 cm on an edge. What is the volume of the box in cubic centimeters? Express the answer to the correct number of significant figures.

1.104 A cylinder with circular cross section has a radius of 2.56 cm and a height of 56.32 cm. What is the volume of the cylinder? Express the answer to the correct number of significant figures.

1.105 An aquarium has a rectangular cross section that is 47.8 in. by 12.5 in.; it is 19.5 in. high. How many U.S. gallons does the aquarium contain? One U.S. gallon equals exactly 231 in<sup>3</sup>.

1.106 A spherical tank has a radius of 175.0 in. Calculate the volume of the tank in cubic inches; then convert this to Imperial gallons. The volume of a sphere is  $(4/3)\pi r^3$ , where  $r$  is the radius. One Imperial gallon equals 277.4 in<sup>3</sup>.

1.107 Obtain the difference in volume between two spheres, one of radius 5.61 cm, the other of radius 5.85 cm. The volume  $V$  of a sphere is  $(4/3)\pi r^3$ , where  $r$  is the radius. Give the result to the correct number of significant figures.

1.108 What is the difference in surface area between two circles, one of radius 7.98 cm, the other of radius 8.50 cm? The surface area of a circle of radius  $r$  is  $\pi r^2$ . Obtain the result to the correct number of significant figures.

**1.109** Perform the following arithmetic setups and express the answers to the correct number of significant figures.

$$\text{a } \frac{56.1 - 51.1}{6.58}$$

$$\text{b } \frac{56.1 + 51.1}{6.58}$$

$$\text{c } (9.1 + 8.6) \times 26.91$$

$$\text{d } 0.0065 \times 3.21 + 0.0911$$

**1.110** Assuming all of the numbers are measured quantities, perform the following arithmetic setups and report the answers to the correct number of significant figures.

$$\text{a } \frac{9.345 - 9.005}{9.811}$$

$$\text{b } \frac{9.345 + 9.005}{9.811}$$

$$\text{c } (7.50 + 7.53) \times 3.71$$

$$\text{d } 0.71 \times 0.36 + 17.36$$

**1.111** For each of the following, write the measurement in terms of an appropriate prefix and base unit.

**a** The mass of calcium per milliliter in a sample of blood serum is 0.0912 g.

**b** The radius of an oxygen atom is about 0.000000000066 m.

**c** A particular red blood cell measures 0.0000071 m.

**d** The wavelength of a certain ultraviolet radiation is 0.000000056 m.

**1.112** For each of the following, write the measurement in terms of an appropriate prefix and base unit.

**a** The mass of magnesium per milliliter in a sample of blood serum is 0.0186 g.

**b** The radius of a carbon atom is about 0.000000000077 m.

**c** The hemoglobin molecule, a component of red blood cells, is 0.000000065 m in diameter.

**d** The wavelength of a certain infrared radiation is 0.00000085 m.

**1.113** Write each of the following in terms of the SI base unit (that is, express the prefix as the power of 10).

$$\text{a } 1.07 \text{ ps}$$

$$\text{b } 5.8 \mu\text{m}$$

$$\text{c } 319 \text{ nm}$$

$$\text{d } 15.3 \text{ ms}$$

**1.114** Write each of the following in terms of the SI base unit (that is, express the prefix as the power of 10).

$$\text{a } 6.6 \text{ mK}$$

$$\text{b } 275 \text{ pm}$$

$$\text{c } 22.1 \text{ ms}$$

$$\text{d } 45 \mu\text{m}$$

**1.115** Tungsten metal, which is used in lightbulb filaments, has the highest melting point of any metal (3410°C). What is this melting point in degrees Fahrenheit?

**1.116** Titanium metal is used in aerospace alloys to add strength and corrosion resistance. Titanium melts at 1677°C. What is this temperature in degrees Fahrenheit?

**1.117** Calcium carbonate, a white powder used in toothpastes, antacids, and other preparations, decomposes when heated to about 825°C. What is this temperature in degrees Fahrenheit?

**1.118** Sodium hydrogen carbonate (baking soda) starts to decompose to sodium carbonate (soda ash) at about 50°C. What is this temperature in degrees Fahrenheit?

**1.119** Gallium metal can be melted by the heat of one's hand. Its melting point is 29.8°C. What is this temperature in kelvins? in degrees Fahrenheit?

**1.120** Mercury metal is liquid at normal temperatures but freezes at -38.9°C. What is this temperature in kelvins? in degrees Fahrenheit?

**1.121** Zinc metal can be purified by distillation (transforming the liquid metal to vapor, then condensing the vapor back to liquid). The metal boils at normal atmospheric pressure at 1666°F. What is this temperature in degrees Celsius? in kelvins?

**1.122** Iodine is a bluish-black solid. It forms a violet-colored vapor when heated. The solid melts at 236°F. What is this temperature in degrees Celsius? in kelvins?

**1.123** An aluminum alloy used in the construction of aircraft wings has a density of 2.70 g/cm<sup>3</sup>. Express this density in SI units (kg/m<sup>3</sup>).

**1.124** Vanadium metal is added to steel to impart strength. The density of vanadium is 5.96 g/cm<sup>3</sup>. Express this in SI units (kg/m<sup>3</sup>).

**1.125** The density of quartz mineral was determined by adding a weighed piece to a graduated cylinder containing 52.2 mL water. After the quartz was submerged, the water level was 67.1 mL. The quartz piece weighed 39.8 g. What was the density of the quartz?

**1.126** Hematite (iron ore) weighing 70.7 g was placed in a flask whose volume was 53.2 mL. The flask with hematite was then carefully filled with water and weighed. The hematite and water weighed 109.3 g. The density of the water was 0.997 g/cm<sup>3</sup>. What was the density of the hematite?

**1.127** Some bottles of colorless liquids were being labeled when the technicians accidentally mixed them up and lost track of their contents. A 15.0-mL sample withdrawn from one bottle weighed 22.3 g. The technicians knew that the liquid was either acetone, benzene, chloroform, or carbon tetrachloride (which have densities of 0.792 g/cm<sup>3</sup>, 0.899 g/cm<sup>3</sup>, 1.489 g/cm<sup>3</sup>, and 1.595 g/cm<sup>3</sup>, respectively). What was the identity of the liquid?

**1.128** Providing no reaction occurs, a solid will float on any liquid that is more dense than it is. The volume of a piece of calcite weighing 35.6 g is 12.9 cm<sup>3</sup>. On which of the following liquids will the calcite float: carbon tetrachloride (density = 1.60 g/cm<sup>3</sup>), methylene bromide (density = 2.50 g/cm<sup>3</sup>), tetrabromoethane (density = 2.96 g/cm<sup>3</sup>), or methylene iodide (density = 3.33 g/cm<sup>3</sup>)?

**1.129** Platinum metal is used in jewelry; it is also used in automobile catalytic converters. What is the mass of a cube of platinum 4.40 cm on an edge? The density of platinum is 21.4 g/cm<sup>3</sup>.

**1.130** Ultrapure silicon is used to make solid-state devices, such as computer chips. What is the mass of a circular cylinder of silicon that is 12.40 cm long and has a radius of 4.00 cm? The density of silicon is 2.33 g/cm<sup>3</sup>.

**1.131** Vinegar contains acetic acid (about 5% by mass). Pure acetic acid has a strong vinegar smell but is corrosive to the skin. What volume of pure acetic acid has a mass of 35.00 g? The density of acetic acid is 1.053 g/mL.

**1.132** Ethyl acetate has a characteristic fruity odor and is used as a solvent in paint lacquers and perfumes. An experiment requires 0.070 kg of ethyl acetate. What volume is this (in liters)? The density of ethyl acetate is 0.902 g/mL.

**1.133** Convert:

- a 8.45 kg to micrograms
- b 318  $\mu\text{s}$  to milliseconds
- c 93 km to nanometers
- d 37.1 mm to centimeters

**1.134** Convert:

- a 127 Å to micrometers
- b 21.0 kg to milligrams
- c 1.09 cm to millimeters
- d 4.6 ns to microseconds

**1.135** Convert:

- a 5.91 kg of chrome yellow to milligrams
- b 753 mg of vitamin A to micrograms
- c 90.1 MHz (megahertz), the wavelength of an FM signal, to kilohertz
- d 498 mJ (the joule, J, is a unit of energy) to kilojoules

**1.136** Convert:

- a 7.19  $\mu\text{g}$  of cyanocobalamin (vitamin B<sub>12</sub>) to milligrams
- b 104 pm, the radius of a sulfur atom, to angstroms
- c 0.010 mm, the diameter of a typical blood capillary, to centimeters
- d 0.0605 kPa (the pascal, Pa, is a unit of pressure) to centipascals

**1.137** The largest of the Great Lakes is Lake Superior, which has a volume of 12,230 km<sup>3</sup>. What is this volume in liters?

**1.138** The average flow of the Niagara River is 3.50 km<sup>3</sup> per week. What is this volume in liters?

**1.139** A room measures 10.0 ft  $\times$  11.0 ft and is 9.0 ft high. What is its volume in liters?

**1.140** A cylindrical settling tank is 5.0 ft deep and has a radius of 15.0 ft. What is the volume of the tank in liters?

**1.141** The masses of diamonds and gems are measured in carats. A carat is defined as 200 mg. If a jeweler has 384 carats of diamonds, how many grams does she have?

**1.142** One year of world production of gold was  $49.6 \times 10^6$  troy ounces. One troy ounce equals 31.10 g. What was the world production of gold in metric tons ( $10^6$  g) for that year?

■ **1.143** What are some characteristics of the adhesive used for Post-it Notes?

■ **1.144** All good experiments start with a scientific question. What was the scientific question that Art Fry was trying to answer when he embarked on finding the adhesive for the Post-it Note?

■ **1.145** What do the various chromatographic separation techniques have in common?

■ **1.146** Describe how gas chromatography works.

## Strategy Problems

**Key:** As noted earlier, all of the practice and general problems are matched pairs. This section is a selection of problems that are not in matched-pair format. These challenging problems require that you employ many of the concepts and strategies that were developed in the chapter. In some cases, you will have to integrate several concepts and operational skills in order to solve the problem successfully.

**1.147** When the quantity  $5 \times 10^{-2}$  mg is subtracted from 4.7 mg, how many significant figures should be reported in the answer?

**1.148** A 33.0-g sample of an unknown liquid at 20.0°C is heated to 120°C. During this heating, the density of the liquid changes from 0.854 g/cm<sup>3</sup> to 0.797 g/cm<sup>3</sup>. What volume would this sample occupy at 120°C?

**1.149** A 124-g sample of a pure liquid, liquid A, with a density of 3.00 g/mL is mixed with a 40.8-mL sample of a pure liquid, liquid B, with a density of 2.00 g/mL. What is the total volume of the mixture? (Assume there is no reaction upon the mixing of A and B, and volumes are additive.)

**1.150** On a long trip you travel 832 miles in 21 hours. During this trip, you use 31 gallons of gasoline.

- a Calculate your average speed in miles per hour.
- b Calculate your average speed in kilometers per hour.
- c Calculate your gas mileage in kilometers per liter.

**1.151** The density of lead at 20°C is 11.3 g/cm<sup>3</sup>. Rank the volumes of the following quantities of lead from least to greatest: 50.0 mL, 0.100 qt, 50.0 g, and 0.0250 lb.

**1.152** A 2010 oil spill in the Gulf of Mexico was estimated to dump as much as  $7.6 \times 10^8$  L of crude oil into the water. Calculate the volume of this spill in cubic feet.

**1.153** Catalytic converters are used in automobiles to convert harmful gaseous substances in the exhaust to more benign substances, for example, carbon monoxide to carbon dioxide. Beads used in these converters have extremely large surface areas. For instance, a single 3.0-mm porous bead can have a surface area of  $1.0 \times 10^6$  cm<sup>2</sup>. If a car has two catalytic converters, each with  $5.0 \times 10^3$  beads, calculate the surface area of the two catalytic converters in km<sup>2</sup>.

**1.154** The density of liquid water at 80°C is 972 kg/m<sup>3</sup> and at 20°C is 998 kg/m<sup>3</sup>. If you have 200.0 mL of water at 20°C, what volume (mL) will the water occupy at 80°C? Which will contain more water molecules, 1.0 L of water at 80°C or 1.0 L of water at 20°C?

**1.155** A 47.0-cm<sup>3</sup> sample of ocean water has a density of 1025 kg/m<sup>3</sup>. Assuming all of the solids stay in solution, what will be the density of this water sample in units of g/cm<sup>3</sup> after 4.1 mL of water has evaporated?

**1.156** At 20°C liquid gasoline gas has a density of 0.75 g/cm<sup>3</sup>. If a 5.5-mL sample of gasoline is placed into a

sealed 3.00-L container at 50°C and allowed to completely evaporate, what will be the density of the gasoline vapor in the container?

**1.157** The figures below represent a gas trapped in containers. The orange balls represent individual gas atoms. Container A on the left has a volume that is one-half the volume of container B on the right.

- How does the mass of gas in one container compare with the mass of gas in the other?
- Which container has the greater density of gas?
- If the volume of container A were increased to the same volume as container B, how would the density of the gas in container A change?

**1.158** An ice cube measures 3.50 cm on each edge and weighs 39.45 g.

- Calculate the density of ice.
- Calculate the mass of 400.4 mL of water in an ice cube.

**1.159** The total length of all the DNA molecules contained in a human body is  $1 \times 10^{10}$  miles. The population of the United States is about 300 million. What is the total length of all the DNA of the U.S. population in lightyears? (A lightyear is the distance that light travels in a year and is  $9.46 \times 10^{15}$  m.)

**1.160** Prospectors are considering searching for gold on a plot of land that contains 1.31 g of gold per bucket of soil. If the volume of the bucket is 4.67 L, how many grams of gold are there likely to be in  $2.38 \times 10^3$  cubic feet of soil?

**1.161** A solution is prepared by dissolving table salt, sodium chloride, in water at room temperature.

- Assuming there is no significant change in the volume of water during the preparation of the solution, how would the density of the solution compare to that of pure water?
- If you were to boil the solution for several minutes and then allow it to cool to room temperature, how would the density of the solution compare to the density in part a?
- If you took the solution prepared in part a and added more water, how would this affect the density of the solution?

**1.162** Water and saline (salt) solution have in common that they are both homogeneous. How do these materials differ? Be specific and use chemical terms to describe the two systems.

## Capstone Problems

**Key:** The problems under this heading combine skills, strategies, and concepts learned in previous chapters with those introduced in the current one.

**1.163** When 11.1 g of marble chips (calcium carbonate) is treated with 54.3 mL of hydrochloric acid (density 1.096 g/mL), the marble dissolves, giving a solution and releasing carbon dioxide gas. The solution weighs 65.7 g. How many liters of carbon dioxide gas are released? The density of the gas is 1.798 g/L.

**1.164** Zinc ore (zinc sulfide) is treated with sulfuric acid, leaving a solution with some undissolved bits of material and releasing hydrogen sulfide gas. If 10.8 g of zinc ore is treated with 50.0 mL of sulfuric acid (density 1.153 g/mL), 65.1 g of solution and undissolved material remains. In addition, hydrogen sulfide (density 1.393 g/L) is evolved. What is the volume (in liters) of this gas?

**1.165** A steel sphere has a radius of 1.58 in. If this steel has a density of 7.88 g/cm<sup>3</sup>, what is the mass of the sphere in grams?

**1.166** A weather balloon filled with helium has a diameter of 3.50 ft. What is the mass in grams of the helium in the balloon at 21°C and normal pressure? The density of helium under these conditions is 0.166 g/L.

**1.167** The land area of Greenland is 840,000 mi<sup>2</sup>, with only 132,000 mi<sup>2</sup> free of perpetual ice. The average thickness of this ice is 5000 ft. Estimate the mass of the ice (assume two significant figures). The density of ice is 0.917 g/cm<sup>3</sup>.

**1.168** Antarctica, almost completely covered in ice, has an area of 5,500,000 mi<sup>2</sup> with an average height of 7500 ft.

Without the ice, the height would be only 1500 ft. Estimate the mass of this ice (two significant figures). The density of ice is 0.917 g/cm<sup>3</sup>.

**1.169** A sample of an ethanol–water solution has a volume of 54.2 cm<sup>3</sup> and a mass of 49.6 g. What is the percentage of ethanol (by mass) in the solution? (Assume that there is no change in volume when the pure compounds are mixed.) The density of ethanol is 0.789 g/cm<sup>3</sup> and that of water is 0.998 g/cm<sup>3</sup>. Alcoholic beverages are rated in *proof*, which is a measure of the relative amount of ethanol in the beverage. Pure ethanol is exactly 200 proof; a solution that is 50% ethanol by volume is exactly 100 proof. What is the proof of the given ethanol–water solution?

**1.170** You have a piece of gold jewelry weighing 9.35 g. Its volume is 0.654 cm<sup>3</sup>. Assume that the metal is an alloy (mixture) of gold and silver, which have densities of 19.3 g/cm<sup>3</sup> and 10.5 g/cm<sup>3</sup>, respectively. Also assume that there is no change in volume when the pure metals are mixed. Calculate the percentage of gold (by mass) in the alloy. The relative amount of gold in an alloy is measured in *karats*. Pure gold is 24 karats; an alloy of 50% gold is 12 karats. State the proportion of gold in the jewelry in karats.

**1.171** A sample of vermilion-colored mineral was weighed in air, then weighed again while suspended in water. An object is buoyed up by the mass of the fluid displaced by the object. In air, the mineral weighed 18.49 g; in water, it weighed 16.21 g. The densities of air and water are 1.205 g/L and 0.9982 g/cm<sup>3</sup>, respectively. What is the density of the mineral?

**1.172** A sample of a bright blue mineral was weighed in air, then weighed again while suspended in water. An object is buoyed up by the mass of the fluid displaced by the object. In air, the mineral weighed 7.35 g; in water, it weighed 5.40 g. The densities of air and water are 1.205 g/L and 0.9982 g/cm<sup>3</sup>, respectively. What is the density of the mineral?

**1.173** A student gently drops an object weighing 15.8 g into an open vessel that is full of ethanol, so that a volume of ethanol spills out equal to the volume of the object. The experimenter now finds that the vessel and its contents weigh 10.5 g more than the vessel full of ethanol only. The density of ethanol is 0.789 g/cm<sup>3</sup>. What is the density of the object?

**1.174** An experimenter places a piece of a solid metal weighing 255 g into a graduated cylinder, which she then fills with liquid mercury. After weighing the cylinder and its contents, she removes the solid metal and fills the cylinder with mercury. She now finds that the cylinder and its contents weigh 101 g less than before. The density of mercury is 13.6 g/cm<sup>3</sup>. What is the density of the solid metal?

**1.175** An expected experimental outcome is 37.45 grams. Describe the following data sets as accurate and/or precise by selecting “Yes” or “No” in each case.

<i>Data</i>	<i>Accurate?</i>	<i>Precise?</i>
38.74, 38.75, 38.76		
37.15, 37.44, 37.75		
37.44, 37.46, 37.48		
39.43, 37.45, 38.64		

**1.176** The expected outcome for the amount of sugar in a beverage is 32.00 g sugar. Describe the following data sets as accurate and/or precise by selecting “Yes” or “No” in each case.

<i>Data</i>	<i>Precise?</i>	<i>Accurate?</i>
32.00, 32.01, 31.99		
29.50, 32.00, 34.50		
29.00, 29.01, 29.02		
25.00, 27.00, 29.00		

**1.177** *Specific gravity* is a physical property used in many industrial applications. Broadly speaking, for liquids or solids, it is a unit-less ratio of the substance’s density to the density of water at a specified temperature, oftentimes chosen to be 4°C. If a substance’s specific gravity is greater than one, it is more dense than water; if less than one, it is less dense than water. For instance, over the temperature range of 4°C to 20°C, the specific gravity of seawater is 1.03; on the other hand, the specific gravity of typical fresh or brackish water lakes and/or rivers can range down to near 1.00.

- a** If 1 gallon of pure water at 4°C has a mass of 8.35 lbs, what is the mass (in kg) of a sea-going barge’s cargo carrying 24,500 gallons of a liquid chemical (specific gravity = 1.01) known to not mix well with water?
- b** If the barge ruptures its hull on a submerged obstacle, the liquid that leaks out of the barge may sink or float, thereby creating different environmental scenarios. If such an incident occurred where the river empties into the ocean, would surface cleanup be feasible? In other words, could surface booms potentially be used to collect the leaked liquid?

**1.178** The solubility of a salt in water depends on a broad range of intermolecular bonding forces. These occur between the particles or ions making up the salt, between the salt’s particles and solvating water molecules, and between water molecules themselves. Although the solubility of many salts tends to increase with temperature, this is not always the case. Take sodium chloride as an example. It’s solubility in water at 25°C is 35.89 g per 100 g H<sub>2</sub>O, and over the temperature range of 0°C to 100°C the solubility modestly ranges upwards from 35.65 g to 38.99 g per 100 g H<sub>2</sub>O. Still, the solubility of some salts decreases with temperature. Below is a table giving the solubility (in g salt/100 g H<sub>2</sub>O) for a few selected salts over the 0°C to 80°C temperature range. Follow the steps below to prepare the graphs (you can use Excel or other graphing tool) and answer the questions.

Salt	0°C	10°C	20°C	30°C	40°C	50°C	60°C	70°C	80°C
NaCl	35.65	35.72	35.89	36.09	36.37	36.69	37.04	37.46	37.93
KCl	28	31.2	34.2	37.2	40.1	42.6	45.8		51.3
K <sub>2</sub> Cr <sub>2</sub> O <sub>7</sub>	4.7	7	12.3	18.1	26.3	34	45.6		73
Ce <sub>2</sub> (SO <sub>4</sub> ) <sub>3</sub> ·2H <sub>2</sub> O	21.4		9.84	7.24	5.63		3.87		
KNO <sub>3</sub>	13	22	33	48	65	84	106	132	167
KNO <sub>2</sub>	279	292	306	320	329		348		376
Nd <sub>2</sub> (SO <sub>4</sub> ) <sub>3</sub>	13	9.7	7.1	5.3	4.1		2.8		2.2
MnSO <sub>4</sub>	52.9	59.7	62.9	62.9	60		53.6		45.6
PbI <sub>2</sub>	0.044	0.056	0.0756	0.09	0.124		0.193		0.294

Step 1: Prepare a plot of solubility (y-axis) vs. temperature (°C) using the tabulated data above.

Step 2: Rescale the vertical axis to a maximum of 100 g/100 g H<sub>2</sub>O.

Step 3: Rescale the vertical axis to a maximum of 25 g/100 g H<sub>2</sub>O.

Step 4: Answer the following questions by reading the prepared graphs.

- a** Many substances dissolve in water and absorb heat when doing so. This is referred to as an endothermic process and will be discussed in more detail in later chapters. For now, simply recognize that these processes

are further favored as the temperature is increased. For the chosen substances, which ones show an upward trend in solubility over the selected temperature range?

NaCl, KCl,  $K_2Cr_2O_7$ ,  $Ce_2(SO_4)_3 \cdot 2H_2O$ ,  $KNO_3$ ,  $KNO_2$ ,  $Nd_2(SO_4)_3$ ,  $MnSO_4$ ,  $PbI_2$

- b** Other substances dissolve in water and release heat when doing so. This is referred to as an exothermic process and will be discussed in more detail in later chapters. For now, simply recognize that these processes are less favored as the temperature is increased. For the chosen substances, which show a downward trend in solubility over the selected temperature range?

NaCl, KCl,  $K_2Cr_2O_7$ ,  $Ce_2(SO_4)_3 \cdot 2H_2O$ ,  $KNO_3$ ,  $KNO_2$ ,  $Nd_2(SO_4)_3$ ,  $MnSO_4$ ,  $PbI_2$ ,

- c** Still other substances show more unusual solubility behaviors as the temperature is changed. For the chosen substances, which show neither a significantly

upward or significantly downward trend in solubility over the selected temperature range?

NaCl, KCl,  $K_2Cr_2O_7$ ,  $Ce_2(SO_4)_3 \cdot 2H_2O$ ,  $KNO_3$ ,  $KNO_2$ ,  $Nd_2(SO_4)_3$ ,  $MnSO_4$ ,  $PbI_2$

Step 5: Prepare a scatter plot of the tabulated data. Note that some solubility data is missing in the original data set.

- a** Use an appropriately scaled scatter plot to estimate the following solubilities:
- solubility of  $Ce_2(SO_4)_3 \cdot 2H_2O$  at 10°C
  - solubility of  $Ce_2(SO_4)_3 \cdot 2H_2O$  at 50°C
  - solubility of  $KNO_2$  at 50°C

- b** Many substances have such low solubility they are considered insoluble for all intents and purposes in the earlier discussions of aqueous phase chemistry reactions. Which of the chosen substances would you consider to be insoluble in this context?

NaCl, KCl,  $K_2Cr_2O_7$ ,  $Ce_2(SO_4)_3 \cdot 2H_2O$ ,  $KNO_3$ ,  $KNO_2$ ,  $Nd_2(SO_4)_3$ ,  $MnSO_4$ ,  $PbI_2$ ,

**2.8** Naming Simple Compounds

**Chemical Reactions: Equations**

**2.9** Writing Chemical Equations

**2.10** Balancing Chemical Equations

**S**odium is a soft, silvery metal. This metal cannot be handled with bare fingers, because it reacts with any moisture on the skin, causing a burn. Chlorine is a poisonous, greenish yellow gas with a choking odor. When molten sodium is placed into an atmosphere of chlorine, a dramatic reaction occurs: the sodium bursts into flame and a white, crystalline powder forms (see Figure 2.1). What is particularly interesting about this reaction is that this chemical combination of two toxic substances produces sodium chloride, the substance that we commonly call table salt.

Sodium metal and chlorine gas are particular forms of matter. In burning, they undergo a chemical change—a chemical reaction—in which these forms of matter change to a form of matter with different chemical and physical properties. How do we explain the differences in properties of different forms of matter? And how do we explain chemical reactions such as the burning of sodium metal in chlorine gas? This chapter and the next take an introductory look at these basic questions in chemistry. In later chapters we will develop the concepts introduced here.

## ► Atomic Theory and Atomic Structure

As noted in Chapter 1, all matter is composed of atoms. In this first part of Chapter 2, we explore the atomic theory of matter and the structure of atoms. We also examine the *periodic table*, which is an organizational chart designed to highlight similarities among the elements.

**Figure 2.1** ▲

**Reaction of sodium and chlorine** *Left to Right:* Sodium metal, chlorine gas, a small piece of sodium metal reacting with chlorine, the sodium chloride product of the reaction. The sparks in the flask of the reaction indicate that energy is produced.

Figure 2.2 ◀

**Image of iodine atoms on a platinum metal surface** This computer-screen image was obtained by a scanning tunneling microscope (discussed in Chapter 7); the color was added to the image by computer. Iodine atoms are the large peaks with pink tops. Note the “vacancy” in the array of iodine atoms. A scale shows the size of the atoms in nanometers.

## 2.1 Atomic Theory of Matter

As we noted in Chapter 1, Lavoisier laid the experimental foundation of modern chemistry. But the British chemist John Dalton (1766–1844) provided the basic theory: all matter—whether element, compound, or mixture—is composed of small particles called atoms. The postulates, or basic statements, of Dalton’s theory are presented in this section. Note that the terms *element*, *compound*, and *chemical reaction*, which were defined in Chapter 1 in terms of matter as we normally see it, are redefined here by the postulates of Dalton’s theory in terms of atoms.

### Postulates of Dalton’s Atomic Theory

The main points of Dalton’s **atomic theory**, *an explanation of the structure of matter in terms of different combinations of very small particles*, are given by the following postulates:

1. All matter is composed of indivisible atoms. An **atom** is *an extremely small particle of matter that retains its identity during chemical reactions*. (See Figure 2.2.)
2. An **element** is *a type of matter composed of only one kind of atom*, each atom of a given kind having the same properties. Mass is one such property. Thus, the atoms of a given element have a characteristic mass. (We will need to revise this definition of element in Section 2.3 so that it is stated in modern terms.) ▶
3. A **compound** is *a type of matter composed of atoms of two or more elements chemically combined in fixed proportions*. The relative numbers of any two kinds of atoms in a compound occur in simple ratios. Water, for example, a compound of the elements hydrogen and oxygen, consists of hydrogen and oxygen atoms in the ratio of 2 to 1.
4. A **chemical reaction** consists of *the rearrangement of the atoms present in the reacting substances to give new chemical combinations present in the substances formed by the reaction*. Atoms are not created, destroyed, or broken into smaller particles by any chemical reaction.

Today we know that atoms are not truly indivisible; they are themselves made up of particles. Nevertheless, Dalton’s postulates are essentially correct.

### Atomic Symbols and Models

It is convenient to use symbols for the atoms of the different elements. An **atomic symbol** is *a one- or two-letter notation used to represent an atom corresponding to a particular element*. ▶ Typically, the atomic symbol consists of the first letter, capitalized, from the name of the element, sometimes with an additional letter from the name in lowercase. For example, chlorine has the symbol Cl. Other symbols are derived from a name in another language (usually Latin). Sodium is given the symbol Na from its Latin name, *natrium*. Symbols of selected elements are listed in Table 2.1.

Early in the development of his atomic theory, Dalton built spheres to represent atoms and used combinations of these spheres to represent compounds. Chemists continue to use this idea of representing atoms by three-dimensional

As you will see in Section 2.4, it is the average mass of an atom that is characteristic of each element on earth.

The atomic names (temporary) given to newly discovered elements are derived from the atomic number (discussed in Section 2.3) using the numerical roots: nil (0), un (1), bi (2), tri (3), quad (4), pent (5), hex (6), sept (7), oct (8), and enn (9) with the ending *-ium*. For example, the element with atomic number 116 is ununhexium; its atomic symbol is Uuh.

**Table 2.1** Some Common Elements

Name of Element	Atomic Symbol	Physical Appearance of Element*
Aluminum	Al	Silvery-white metal
Barium	Ba	Silvery-white metal
Bromine	Br	Reddish-brown liquid
Calcium	Ca	Silvery-white metal
Carbon	C	
Graphite		Soft, black solid
Diamond		Hard, colorless crystal
Chlorine	Cl	Greenish-yellow gas
Chromium	Cr	Silvery-white metal
Cobalt	Co	Silvery-white metal
Copper	Cu (from <i>cuprum</i> )	Reddish metal
Fluorine	F	Pale yellow gas
Gold	Au (from <i>aurum</i> )	Pale yellow metal
Helium	He	Colorless gas
Hydrogen	H	Colorless gas
Iodine	I	Bluish-black solid
Iron	Fe (from <i>ferrum</i> )	Silvery-white metal
Lead	Pb (from <i>plumbum</i> )	Bluish-white metal
Magnesium	Mg	Silvery-white metal
Manganese	Mn	Gray-white metal
Mercury	Hg (from <i>hydrargyrum</i> )	Silvery-white liquid metal
Neon	Ne	Colorless gas
Nickel	Ni	Silvery-white metal
Nitrogen	N	Colorless gas
Oxygen	O	Colorless gas
Phosphorus (white)	P	Yellowish-white, waxy solid
Potassium	K (from <i>kalium</i> )	Soft, silvery-white metal
Silicon	Si	Gray, lustrous solid
Silver	Ag (from <i>argentum</i> )	Silvery-white metal
Sodium	Na (from <i>natrium</i> )	Soft, silvery-white metal
Sulfur	S	Yellow solid
Tin	Sn (from <i>stannum</i> )	Silvery-white metal
Zinc	Zn	Bluish-white metal

\*Common form of the element under normal conditions.

models, but because we now know so much more about atoms and molecules than Dalton did, these models have become more refined. Section 2.6 describes these models in more detail.

### Deductions from Dalton's Atomic Theory

Note how atomic theory explains the difference between an element and a compound. Atomic theory also explains two laws we considered earlier. One of these is the law of conservation of mass, which states that the total mass remains constant during a chemical reaction. By postulate 2, every atom has a definite mass. Because a chemical reaction only rearranges the chemical combinations of atoms (postulate 4),

the mass must remain constant. The other law explained by atomic theory is the law of definite proportions (constant composition). Postulate 3 defines a compound as a type of matter containing the atoms of two or more elements in definite proportions. Because the atoms have definite mass, compounds must have the elements in definite proportions by mass.

A good theory should not only explain known facts and laws but also predict new ones. The **law of multiple proportions**, deduced by Dalton from his atomic theory, states that *when two elements form more than one compound, the masses of one element in these compounds for a fixed mass of the other element are in ratios of small whole numbers*. To illustrate this law, consider the following. If we take a fixed mass of carbon, 1.000 gram, and react it with oxygen, we end up with two compounds: one that contains 1.3321 grams of oxygen for each 1.000 gram of carbon, and one that contains 2.6642 grams of oxygen per 1.000 gram of carbon. Note that the ratio of the amounts of oxygen in the two compounds is 2 to 1 ( $2.6642 \div 1.3321$ ), which indicates that there must be twice as much oxygen in the second compound. Applying atomic theory, if we assume that the compound that has 1.3321 grams of oxygen to 1.000 gram of carbon is CO (the combination of one carbon atom and one oxygen atom), then the compound that contains twice as much oxygen per 1.000 gram of carbon must be CO<sub>2</sub> (the combination of one carbon atom and two oxygen atoms). The deduction of the law of multiple proportions from atomic theory was important in convincing chemists of the validity of the theory.

### CONCEPT CHECK 2.1

Like Dalton, chemists continue to model atoms using spheres. Modern models are usually drawn with a computer and use different colors to represent atoms of different elements. Which of the models below represents CO<sub>2</sub>?

## 2.2 The Structure of the Atom

Although Dalton had postulated that atoms were indivisible particles, experiments conducted around the beginning of the last century showed that atoms themselves consist of particles. These experiments showed that an atom consists of two kinds of particles: a **nucleus**, *the atom's central core, which is positively charged and contains most of the atom's mass*, and one or more electrons. An **electron** is *a very light, negatively charged particle that exists in the region around the atom's positively charged nucleus*.

### Discovery of the Electron

In 1897 the British physicist J. J. Thomson (Figure 2.3) conducted a series of experiments that showed that atoms were not indivisible particles. Figure 2.4 shows an experimental apparatus similar to the one used by Thomson. In this apparatus, two electrodes from a high-voltage source are sealed into a glass tube from which the air has been evacuated. The negative electrode is called the *cathode*; the positive one, the *anode*. When the high-voltage current is turned on, the glass tube emits a greenish light. Experiments showed that this greenish light is caused by the interaction of the glass with *cathode rays*, which are rays that originate from the cathode. ►

The Cavendish Laboratory

Figure 2.3 ▲

**Joseph John Thomson (1856–1940)**  
J. J. Thomson's scientific ability was recognized early with his appointment as professor of physics in the Cavendish Laboratory at Cambridge University when he was not quite 28 years old. Soon after this appointment, Thomson began research on the discharge of electricity through gases. This work culminated in 1897 with the discovery of the electron. Thomson was awarded the Nobel Prize in physics in 1906.

A television tube uses the deflection of cathode rays by magnetic fields. A beam of cathode rays is directed toward a coated screen on the front of the tube, where by varying the magnetism generated by electromagnetic coils, the beam traces a luminescent image. Television tubes are becoming much less common with the advent of flat screen displays. Flat screen displays use a much different technology.

Figure 2.4 ►

**Formation of cathode rays** Cathode rays leave the cathode, or negative electrode, and are accelerated toward the anode, or positive electrode. Some of the rays pass through the hole in the anode to form a beam, which then is bent by the electric plates in the tube.

Figure 2.5 ▲

### Bending of cathode rays by a magnet

After the cathode rays leave the negative electrode, they move toward the anode, where some rays pass through a hole to form a beam (Figure 2.4). This beam bends away from the negatively charged plate and toward the positively charged plate. (Cathode rays are not directly visible, but do cause certain materials such as zinc sulfide to glow so you can observe them.) Figure 2.5 shows a similar experiment, in which cathode rays are seen to bend when a magnet is brought toward them. Thomson showed that the characteristics of cathode rays are independent of the material making up the cathode. From such evidence, he concluded that a cathode ray consists of a beam of negatively charged particles (or electrons) and that electrons are constituents of all matter.

From his experiments, Thomson could also calculate the ratio of the electron's mass,  $m_e$ , to its electric charge,  $e$ . He could not obtain either the mass or the charge separately, however. In 1909 the U.S. physicist Robert Millikan performed a series of ingenious experiments in which he obtained the charge on the electron by observing how a charged drop of oil falls in the presence and in the absence of an electric field (Figure 2.6). From this type of experiment, the charge on the electron is found to be  $1.602 \times 10^{-19}$  coulombs (the *coulomb*, abbreviated C, is a unit of electric charge). If you use this charge with the most recent value of the mass-to-charge ratio of the electron, you obtain an electron mass of  $9.109 \times 10^{-31}$  kg, which is more than 1800 times smaller than the mass of the lightest atom (hydrogen). This shows quite clearly that the electron is indeed a subatomic particle.

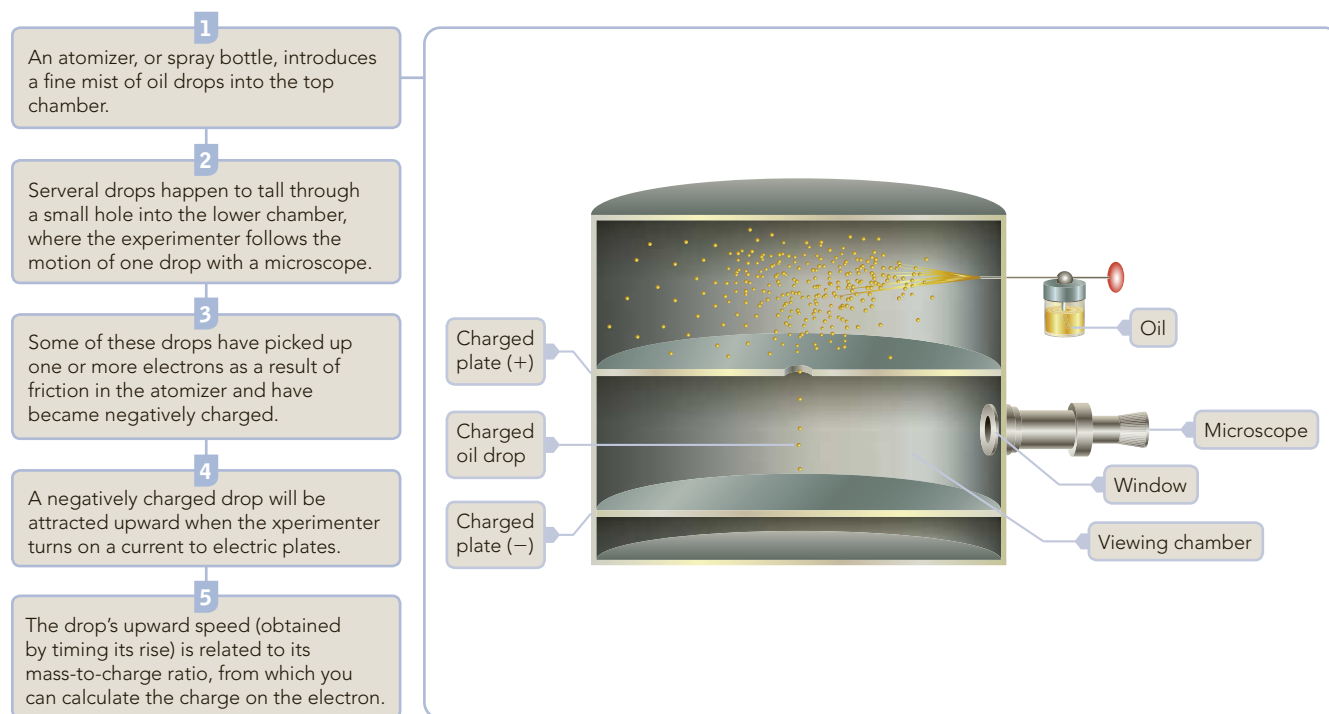

Figure 2.6 ▲

Millikan's oil-drop experiment

### The Nuclear Model of the Atom

Ernest Rutherford (1871–1937), a British physicist, put forth the idea of the *nuclear model* of the atom in 1911, based on experiments done in his laboratory by Hans Geiger and Ernest Marsden. These scientists observed the effect of bombarding thin gold foil (and other metal foils) with alpha radiation from radioactive substances such as uranium (Figure 2.7). Rutherford had already shown that alpha rays consist of positively charged particles. Geiger and Marsden found that most of the alpha particles passed through a metal foil as though nothing were there, but a few (about 1 in 8000) were scattered at large angles and sometimes almost backward.

According to Rutherford's model, most of the mass of the atom (99.95% or more) is concentrated in a positively charged center, or nucleus, around which the negatively charged electrons move. Although most of the mass of an atom is in its nucleus, the nucleus occupies only a very small portion of the space of the atom. Nuclei have diameters of about  $10^{-15}$  m ( $10^{-3}$  pm), whereas atomic diameters are about  $10^{-10}$  m (100 pm), a hundred thousand times larger. If you were to use a golf ball to represent the nucleus, the atom would be about 3 miles in diameter!

The nuclear model easily explains the results of bombarding gold and other metal foils with alpha particles. Alpha particles are much lighter than gold atoms. (Alpha particles are helium nuclei.) Most of the alpha particles pass through the metal atoms of the foil, undeflected by the lightweight electrons. When an

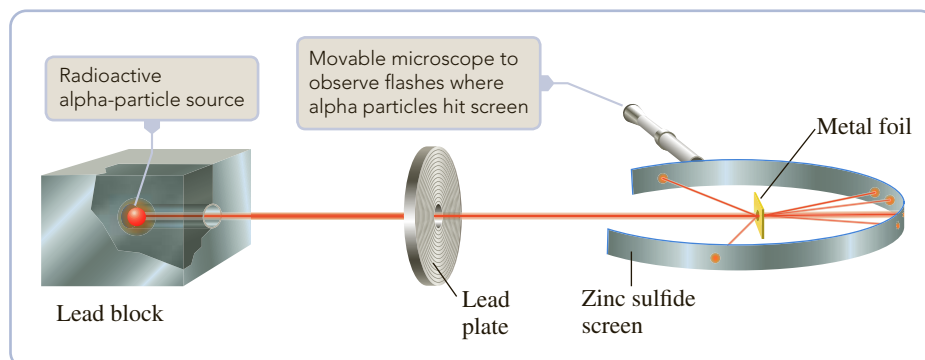

Figure 2.7 ◀

**Alpha-particle scattering from metal foils** Alpha radiation is produced by a radioactive source and formed into a beam by a lead plate with a hole in it. (Lead absorbs the radiation.) Scattered alpha particles are made visible by a zinc sulfide screen, which emits tiny flashes where particles strike it. A movable microscope is used for viewing the flashes.

**Figure 2.8** ▶**Representation of the scattering of alpha particles by a gold foil**

Most of the alpha particles pass through the foil barely deflected. A few, however, collide with gold nuclei and are deflected at large angles. (The relative sizes of nuclei are smaller than can be drawn here.)

alpha particle does happen to hit a metal-atom nucleus, however, it is scattered at a wide angle because it is deflected by the massive, positively charged nucleus (Figure 2.8).

**CONCEPT CHECK 2.2**

What would be a feasible model for the atom if Geiger and Marsden had found that 7999 out of 8000 alpha particles were deflected back at the alpha-particle source?

**2.3 Nuclear Structure; Isotopes**

The nucleus of an atom also has a structure; the nucleus is composed of two different kinds of particles, protons and neutrons. The type of alpha-particle scattering experiment that led to the nuclear model of the atom was also instrumental in clarifying this structure of the nucleus.

An important property of the nucleus is its electric charge. One way to determine the value of the positive charge of a nucleus is by analyzing the distribution of alpha particles scattered from a metal foil; other experiments also provide the nuclear charge. ◀ From such experiments, researchers discovered that each element has a unique nuclear charge that is an integer multiple of the magnitude of the electron charge. This integer, which is characteristic of an element, is called the *atomic number* ( $Z$ ). A hydrogen atom nucleus, whose magnitude of charge equals that of the electron, has the smallest atomic number, which is 1.

In 1919, Rutherford discovered that hydrogen nuclei, or what we now call protons, form when alpha particles strike some of the lighter elements, such as nitrogen. A **proton** is a nuclear particle having a positive charge equal in magnitude to that of the electron and a mass more than 1800 times that of the electron. When an alpha particle collides with a nitrogen atom, a proton may be knocked out of the nitrogen nucleus. The protons in a nucleus give the nucleus its positive charge.

The **atomic number** ( $Z$ ) is therefore *the number of protons in the nucleus of an atom*. Because you can determine the atomic number experimentally, you can determine unambiguously whether or not a sample is a pure element or if perhaps you have discovered a new element. We can now state the definition of an element with more precision than we could in Section 2.1. An **element** is a substance whose atoms all have the same atomic number. The inside back cover of the book lists the elements and their atomic numbers (see the Table of Atomic Numbers and Atomic Weights).

The simplest way to obtain the nuclear charge is by analyzing the x rays emitted by the element when irradiated with cathode rays. This is discussed in the essay at the end of Section 8.2.

Particle	Mass (kg)	Charge (C)	Mass (amu)*	Charge (e)
Electron	$9.10938 \times 10^{-31}$	$-1.60218 \times 10^{-19}$	0.00055	-1
Proton	$1.67262 \times 10^{-27}$	$+1.60218 \times 10^{-19}$	1.00728	+1
Neutron	$1.67493 \times 10^{-27}$	0	1.00866	0

\*The atomic mass unit (amu) equals  $1.66054 \times 10^{-27}$  kg; it is defined in Section 2.4.

The neutron was also discovered by alpha-particle scattering experiments. When beryllium metal is irradiated with alpha rays, a strongly penetrating radiation is obtained from the metal. In 1932 the British physicist James Chadwick (1891–1974) showed that this penetrating radiation consists of neutral particles, or neutrons. The **neutron** is a nuclear particle having a mass almost identical to that of the proton but no electric charge. When beryllium nuclei are struck by alpha particles, neutrons are knocked out. Table 2.2 compares the masses and charges of the electron and the two nuclear particles, the proton and the neutron.

Now consider the nucleus of some atom, say of the naturally occurring sodium atom. The nucleus contains 11 protons and 12 neutrons. Thus, the charge on the sodium nucleus is  $+11e$ , which we usually write as simply  $+11$ , meaning  $+11$  units of electron charge  $e$ . Similarly, the nucleus of a naturally occurring aluminum atom contains 13 protons and 14 neutrons; the charge on the nucleus is  $+13$ .

We characterize a nucleus by its atomic number ( $Z$ ) and its mass number ( $A$ ). The **mass number** ( $A$ ) is the total number of protons and neutrons in a nucleus. The nucleus of the naturally occurring sodium atom has an atomic number of 11 and a mass number of 23 ( $11 + 12$ ).

A **nuclide** is an atom characterized by an atomic number and mass number. The shorthand notation for any nuclide consists of the symbol of the element with the atomic number written as a subscript on the left and the mass number as a superscript on the left. You write the *nuclide symbol* for the naturally occurring sodium nuclide as follows:

An atom is normally electrically neutral, so it has as many electrons about its nucleus as the nucleus has protons; that is, the number of electrons in a neutral atom equals its atomic number. A sodium atom has a nucleus of charge  $+11$ , and around this nucleus are 11 electrons (with a charge of  $-11$ , giving the atom a charge of 0).

All nuclei of the atoms of a particular element have the same atomic number, but the nuclei may have different mass numbers. **Isotopes** are atoms whose nuclei have the same atomic number but different mass numbers; that is, the nuclei have the same number of protons but different numbers of neutrons. Sodium has only one naturally occurring isotope, which we denote by the same symbol we used for the nuclide ( ${}_{11}^{23}\text{Na}$ ); we also call the isotope sodium-23. Naturally occurring oxygen is a mixture of isotopes; it contains 99.759% oxygen-16, 0.037% oxygen-17, and 0.204% oxygen-18. ▶

Figure 2.9 may help you to visualize the relationship among the different subatomic particles in the isotopes of an element. The size of the nucleus as represented in the figure is very much exaggerated in order to show the numbers of protons and neutrons. In fact, the space taken up by the nucleus is minuscule compared with the region occupied by electrons. Electrons, although extremely light particles, move throughout relatively large diffuse regions, or “shells,” about the nucleus of an atom.

Figure 2.9 ▲

**A representation of two isotopes of carbon** The drawing shows the basic particles making up the carbon-12 and carbon-13 isotopes. (The relative sizes of the nuclei are much exaggerated here.)

Isotopes were first suspected in about 1912 when chemically identical elements with different atomic weights were found in radioactive materials. The most convincing evidence, however, came from the mass spectrometer, discussed in Section 2.4.

**Example 2.1 Writing Nuclide Symbols****Gaining Mastery Toolbox****Critical Concept 2.1**

The atomic number defines an element. The atomic number is the number of protons in the nucleus of an atom.

**Solution Essentials:**

- Nuclear particles: protons, neutrons, and electrons
- Atomic number
- Mass number

What is the nuclide symbol for a nucleus that contains 38 protons and 50 neutrons?

**Problem Strategy** To solve this problem, we need to keep in mind that the number of protons in the nucleus (the atomic number) is what uniquely identifies an element and that the mass number is the sum of the protons and neutrons.

**Solution** From the Table of Atomic Numbers and Atomic Weights on the inside back cover of this book, you will note that the element with atomic number 38 is strontium, symbol Sr. The mass number is  $38 + 50 = 88$ . The symbol is  ${}^{88}_{38}\text{Sr}$ .

**Answer Check** When writing elemental symbols, as you have done here, make sure that you always capitalize *only* the first letter of the symbol.

**Exercise 2.1** A nucleus consists of 17 protons and 18 neutrons. What is its nuclide symbol?

See Problems 2.47 and 2.48.

Some variation of isotopic composition occurs in a number of elements, and this limits the significant figures in their average atomic weights.

Dalton had assumed the formula for water to be HO. Using this formula and accurate data, he would have obtained 7.9367 for the relative atomic weight of oxygen.

Science Source

**Figure 2.10** ▲

**A mass spectrometer** This instrument measures the masses of atoms and molecules.

## 2.4 Atomic Weights

A central feature of Dalton's atomic theory was the idea that an atom of an element has a characteristic mass. Now we know that a naturally occurring element may be a mixture of isotopes, each isotope having its own characteristic mass. However, the percentages of the different isotopes in most naturally occurring elements have remained essentially constant over time and in most cases are independent of the origin of the element. Thus, what Dalton actually calculated were *average* atomic masses (actually average *relative* masses, as we will discuss). Since you normally work with naturally occurring mixtures of elements (whether in pure form or as compounds), it is indeed these average atomic masses that you need in ordinary chemical work. ◀

### Relative Atomic Weights

Dalton could not weigh individual atoms. What he could do was find the average mass of one atom relative to the average mass of another. We will refer to these relative atomic masses as *atomic weights*. To see how Dalton obtained his atomic weights, imagine that you burn hydrogen gas in oxygen. The product of this reaction is water, a compound of hydrogen and oxygen. By experiment, you find that 1.0000 gram of hydrogen reacts with 7.9367 g of oxygen to form water. To obtain the atomic weight of oxygen (relative to hydrogen), you need to know the relative numbers of hydrogen atoms and oxygen atoms in water. As you might imagine, Dalton had difficulty with this. Today we know that water contains two atoms of hydrogen for every atom of oxygen. So the atomic weight of oxygen is  $2 \times 7.9367 = 15.873$  times that of the mass of the average hydrogen atom. ◀

### Atomic Mass Units

Dalton's hydrogen-based atomic weight scale was eventually replaced by a scale based on oxygen and then, in 1961, by the present carbon-12 mass scale. This scale depends on measurements of atomic mass by an instrument called a *mass spectrometer* (Figure 2.10), which we will describe briefly later in this section. You make accurate measurements of mass on this instrument by comparing the mass of an atom to the mass of a particular atom chosen as a standard. On the present atomic weight scale, the carbon-12 isotope is chosen as the standard and is arbitrarily assigned a mass of exactly 12 atomic mass units. One **atomic mass unit (amu)** is, therefore, *a mass unit equal to exactly one-twelfth the mass of a carbon-12 atom*.

Figure 2.11 ▲

Diagram of a simple mass spectrometer, showing the separation of neon isotopes

On this modern scale, the **atomic weight** of an element is *the average atomic mass for the naturally occurring element, expressed in atomic mass units*. A complete table of atomic weights appears on the inside back cover of this book. (Atomic weight is sometimes referred to as atomic mass. Although the use of the term *weight* in *atomic weight* is not strictly correct, it is sanctioned by convention to mean “average atomic mass.”)

### Mass Spectrometry and Atomic Weights

Earlier we noted that you use a mass spectrometer to obtain accurate masses of atoms. The earliest mass spectrometers measured the mass-to-charge ratios of positively charged atoms using the same ideas that Thomson used to study electrons. Modern instruments may use other techniques, but all measure the mass-to-charge ratios of positively charged atoms (and molecules as well). Figure 2.11 shows a simplified sketch of a mass spectrometer running a neon sample (see the essay on page 83 for a discussion of modern mass spectrometry).

Mass spectrometers produce a *mass spectrum*, which shows the relative numbers of atoms for various masses. If a sample of neon, which has the three isotopes depicted in Figure 2.12, is introduced into a mass spectrometer, it produces the mass spectrum shown in Figure 2.13. This mass spectrum gives us the information

Figure 2.12 ▼

Representations of the three naturally occurring isotopes of Ne. Top to bottom: Ne-20, Ne-21, and Ne-22. Ne-20 is the most abundant isotope. Representations are not drawn to scale.

Figure 2.13 ►

**The mass spectrum of neon** Neon is separated into its isotopes Ne-20, Ne-21, and Ne-22. The height at each mass peak is proportional to the fraction of that isotope in the element.

we need to calculate the atomic weight of neon: all of the isotopic masses (neon-20, neon-21, and neon-22) and the relative number, or fractional abundance, of each isotope. The **fractional abundance** of an isotope is *the fraction of the total number of atoms that is composed of a particular isotope*. The fractional abundances of the neon isotopes in naturally occurring neon are neon-20, 0.9051; neon-21, 0.0027; and neon-22, 0.0922.

You calculate the atomic weight of an element by multiplying each isotopic mass by its fractional abundance and summing the values. If you do that for neon using the data given here, you will obtain 20.179 amu. The next example illustrates the calculation in full for chromium.

### Example 2.2 Determining Atomic Weight from Isotopic Masses and Fractional Abundances

#### Gaining Mastery Toolbox

##### Critical Concept 2.2

The atomic weights of the elements are calculated. Typically each element has more than one naturally occurring isotope. Therefore, the mass of each element must be calculated based on the mass and relative abundance of each isotope; it is the average atomic weight.

##### Solution Essentials:

- Isotope
- Atomic mass unit
- Fractional abundance
- Rules for significant figures and rounding

Chromium, Cr, has the following isotopic masses and fractional abundances:

<i>Mass Number</i>	<i>Isotopic Mass (amu)</i>	<i>Fractional Abundance</i>
50	49.9461	0.0435
52	51.9405	0.8379
53	52.9407	0.0950
54	53.9389	0.0236

What is the atomic weight of chromium?

**Problem Strategy** The type of average used to calculate the atomic weight of an element is similar to the “average” an instructor might use to obtain a student’s final grade in a class. Suppose the student has a total exam grade of 76 and a total laboratory grade of 84. The instructor decides to give a weight of 70% to the exams and 30% to the laboratory. How would the instructor calculate the final grade? He or she would multiply each type of grade by its weight factor and add the results:

$$(76 \times 0.70) + (84 \times 0.30) = 78$$

The final grade is closer to the exam grade, because the instructor chose to give the exam grade greater weight.

**Solution** Multiply each isotopic mass by its fractional abundance, then sum:

$$49.9461 \text{ amu} \times 0.0435 = 2.17 \text{ amu}$$

$$51.9405 \text{ amu} \times 0.8379 = 43.52 \text{ amu}$$

$$52.9407 \text{ amu} \times 0.0950 = 5.03 \text{ amu}$$

$$53.9389 \text{ amu} \times 0.0236 = \underline{1.27 \text{ amu}}$$

$$51.99 \text{ amu}$$

The atomic weight of chromium is **51.99 amu**.

**Answer Check** The average mass (atomic weight) should be near the mass of the isotope with greatest abundance: in this case, 51.9405 amu with fractional abundance of 0.8379. This provides a quick check on your answer to this type of problem; any “answer” that is far from this will be incorrect.

(continued)

**Example 2.2** (continued)**Exercise 2.2** Chlorine consists of the following isotopes:

See Problems 2.51, 2.52, 2.53, and 2.54.

<i>Isotope</i>	<i>Isotopic Mass (amu)</i>	<i>Fractional Abundance</i>
Chlorine-35	34.96885	0.75771
Chlorine-37	36.96590	0.24229

What is the atomic weight of chlorine?

## 2.5 Periodic Table of the Elements

In 1869 the Russian chemist Dmitri Mendeleev (1834–1907) (Figure 2.14) and the German chemist J. Lothar Meyer (1830–1895), working independently, made similar discoveries. They found that when they arranged the elements in order of atomic weight, they could place them in horizontal rows, one row under the other, so that the elements in each vertical column have similar properties. *A tabular arrangement of elements in rows and columns, highlighting the regular repetition of properties of the elements, is called a periodic table.*

Eventually, more accurate determinations of atomic weights revealed discrepancies in this ordering of the elements. However, in the early part of the last century, it was shown that the elements are characterized by their atomic numbers, rather than atomic weights. When the elements in the periodic table are ordered by atomic number, such discrepancies vanish.

A modern version of the periodic table, with the elements arranged by atomic number, is shown in Figure 2.15 (see also inside front cover). Each entry lists the atomic number, atomic symbol, and atomic weight of an element. This is a convenient way of tabulating such information, and you should become familiar with using the periodic table for that purpose. As we develop the subject matter of chemistry throughout the text, you will see how useful the periodic table is.

### Periods and Groups

The basic structure of the periodic table is its division into rows and columns, or periods and groups. A **period** consists of *the elements in any one horizontal row of the periodic table*. A **group** consists of *the elements in any one column of the periodic table*.

The first period of elements consists of only hydrogen (H) and helium (He). The second period has 8 elements, beginning with lithium (Li) and ending with neon (Ne). There is then another period of 8 elements, and this is followed by a period having 18 elements, beginning with potassium (K) and ending with krypton (Kr). The fifth period also has 18 elements. The sixth period actually consists of 32 elements, but in order for the row to fit on a page, part of it appears at the bottom of the table. Otherwise the table would have to be expanded, with the additional elements placed after barium (Ba, atomic number 56). The seventh period, though not complete, also has some of its elements placed as a row at the bottom of the table.

The groups are usually numbered. The numbering frequently seen in North America labels the groups with numerals and A's and B's. In Europe a similar convention has been used, but some columns have the A's and B's interchanged. To eliminate this confusion, the International Union of Pure and Applied Chemistry (IUPAC) suggested a convention in which the columns are numbered 1 to 18. Figure 2.15 shows the North American and the IUPAC conventions. When we

Figure 2.15 ▲

**A modern form of the periodic table** This table is also given on the inside front cover of the book.

refer to an element by its periodic group, we will use the North American convention. The A groups are called *main-group* (or *representative*) *elements*; the B groups are called *transition elements*. The two rows of elements at the bottom of the table are called *inner transition elements* (the first row is referred to as the *lanthanides*; the second row, as the *actinides*).

As noted earlier, the elements in any one group have similar properties. For example, the elements in Group 1A, often known as the *alkali metals*, are soft metals that react easily with water. (Hydrogen, a gas, is an exception and might better be put in a group by itself.) Sodium is an alkali metal. So is potassium. The Group 7A elements, known as *halogens*, are also reactive elements. Chlorine is a halogen. We have already noted its vigorous reaction with sodium. Bromine, which is a red-brown liquid, is another halogen. It too reacts vigorously with sodium.

### Metals, Nonmetals, and Metalloids

The elements of the periodic table in Figure 2.15 are divided by a heavy “staircase” line into metals on the left and nonmetals on the right. A **metal** is a substance that has a characteristic luster, or shine, and is generally a good conductor of heat and electricity. Except for mercury, the metallic elements are solids at room temperature (about 20°C). They are more or less *malleable* (can be hammered into sheets) and *ductile* (can be drawn into wire).

A **nonmetal** is an element that does not exhibit the characteristics of a metal. Most of the nonmetals are gases (for example, chlorine and oxygen) or solids (for example, phosphorus and sulfur). The solid nonmetals are usually hard, brittle substances. Bromine is the only liquid nonmetal. Chemists have been able to synthesize materials

A CHEMIST Looks at . . .

## The Discovery of New Elements

The discovery of new elements has always had a special allure for chemists and physicists. After all, everything around us is composed of the elements, and knowing about them would seem to give us important basic knowledge. At the moment, there are 118 known elements. The question is, are there more to be discovered?

One problem is that all elements beyond lead (atomic number 82) are radioactive and tend to become less stable with increasing atomic number. (The possibility that there is an “island of stability” in which yet-to-be discovered isotopes have special stability is one of the driving forces in the search for new elements.) The nucleus of a radioactive element is unstable and tends to break apart or decay, the usual products being elements of lower atomic number. This stability is seen in the half-life of a radioactive isotope, which is the time it takes for one-half of a sample of the isotope to decay into products. For example, the half-life of uranium-238 (atomic number 92), the most stable isotope of the element, is 4.5 billion years. (The half-life of bismuth-209, the commonly occurring isotope of bismuth, is a billion times that of the age of the Earth, which explains why its radioactivity had gone undetected until 2003.) However, the half-life of one of the more common isotopes of americium (atomic number 95)—used in some smoke detectors—is just over 432 years, and the half-life of the longest-lived isotope of fermium (atomic number 100) is just over 100 days. Element 118 with a mass number of 294, whose discovery was reported in 2002, has a half-life of less than a millisecond!

All of the elements beyond uranium, except perhaps for trace quantities of plutonium (atomic number 94), are synthetic; that is, they have been produced in nuclear reactors or by other means. The method used to produce the elements that are presently known beyond fermium (atomic number 100) is to accelerate a beam of ions of

**Figure 2.16** ▲

The cyclotron accelerator used in the experiments to produce element 117, located in the Flerov Laboratory of Nuclear Reactions at the Joint Institute for Nuclear Research in Dubna, Russia.

an element of low atomic number into a target of an element of high atomic number, where a target nucleus and ion may fuse to give a nucleus with greater atomic number.

In 2010, a team of Russian and U.S. scientists at the Joint Institute for Nuclear Research at Dubna, Russia, announced the discovery of element 117; they accelerated a beam of calcium-48 ions into a target of berkelium-249. (The cyclotron accelerator used in the experiment is shown in Figure 2.16.) Most of the collisions between beam and target nuclei do not fuse to give a nucleus with 117 protons. In fact, during the period of the five months the experiments were conducted, only six atoms of element 117 were produced. The half-life of element 117 with mass number of 294 is about 78 ms.

Element 117 is known provisionally, following rules provided by IUPAC (the International Union of Pure and Applied Chemistry), as ununseptium, Uus, where each of the digits of the atomic number 117 has been replaced by a root, *un* for 1 and *sept* for 7, with the suffix *-ium*. Once other laboratories can satisfactorily reproduce the element,

## A CHEMIST Looks at . . . The Discovery of New Elements *(continued)*

the IUPAC will rule on allowing the initial discoverers to give a permanent name to the element. In 2014, scientists at the GSI Helmholtz Center for Heavy Ion Research in Darmstadt, Germany, announced that they had confirmed the discovery of element 117. Ruling on the discovery by IUPAC is pending.

Our question at the beginning of this essay was “are there more elements to be discovered?” The next elements would be ununennium (atomic number 119) and unbinilium

(atomic number 120). The problems in trying to produce these elements by accelerating an ion beam into a target are the short half-lives of possible target elements and the extended times required for a successful observation of a new element. So far, elements 119 and 120 have eluded discovery. But you can expect that scientists will continue to search for new elements.

■ See Problems 2.131 and 2.132.

When these pure semiconductor elements have small amounts of certain other elements added to them (a process called doping), they become very good conductors of electricity. Semiconductors are the critical materials in solid-state electronic devices.

from nonmetal elements that exhibit properties like metals. For example, graphene, a form of elemental carbon, is a good conductor of heat and electricity. Despite exceptions like graphene, the general classification of a nonmetal element as defined here is very useful.

Most of the elements bordering the staircase line in the periodic table (Figure 2.15) are metalloids, or semimetals. A **metalloid**, or **semimetal**, is *an element having both metallic and nonmetallic properties*. These elements, such as silicon (Si) and germanium (Ge), are usually good *semiconductors*—elements that, when pure, are poor conductors of electricity at room temperature but become moderately good conductors at higher temperatures. ◀

**Exercise 2.3** By referring to the periodic table (Figure 2.15 or inside front cover), identify the group and period to which each of the following elements belongs. Then decide whether the element is a metal, nonmetal, or metalloid.

- a. Se    b. Cs    c. Fe    d. Cu    e. Br

See Problems 2.57 and 2.58.

### CONCEPT CHECK 2.3

Consider the elements He, Ne, and Ar. Can you come up with a reason why they are in the same group in the periodic table?

## ▶ Chemical Substances: Formulas and Names

Atomic theory has developed steadily since Dalton's time and has become the cornerstone of chemistry. It results in an enormous simplification: all of the millions of compounds we know today are composed of the atoms of just a few elements. Now we look more closely at how we describe the composition and structure of chemical substances in terms of atoms.

### 2.6 Chemical Formulas; Molecular and Ionic Substances

The **chemical formula** of a substance is *a notation that uses atomic symbols with numerical subscripts to convey the relative proportions of atoms of the different*

*elements in the substance.* Consider the formula of aluminum oxide,  $\text{Al}_2\text{O}_3$ . This means that the compound is composed of aluminum atoms and oxygen atoms in the ratio 2 : 3. Consider the formula for sodium chloride,  $\text{NaCl}$ . When no subscript is written for a symbol, it is assumed to be 1. Therefore, the formula  $\text{NaCl}$  means that the compound is composed of sodium atoms and chlorine atoms in the ratio 1 : 1 (Figure 2.17).

Additional information may be conveyed by different kinds of chemical formulas. To understand this, we need to look briefly at two main types of substances: molecular and ionic.

### Molecular Substances

A **molecule** is a definite group of atoms that are chemically bonded together—that is, tightly connected by attractive forces. The nature of these strong forces is discussed in Chapters 9 and 10. A *molecular substance* is a substance that is composed of molecules, all of which are alike. The molecules in such a substance are so small that even extremely minute samples contain tremendous numbers of them. One billionth ( $10^{-9}$ ) of a drop of water, for example, contains about 2 trillion ( $2 \times 10^{12}$ ) water molecules. ▶

A **molecular formula** gives the exact number of different atoms of an element in a molecule. The hydrogen peroxide molecule contains two hydrogen atoms and two oxygen atoms chemically bonded. Therefore, its molecular formula is  $\text{H}_2\text{O}_2$ . Other simple molecular substances are water,  $\text{H}_2\text{O}$ ; ammonia,  $\text{NH}_3$ ; carbon dioxide,  $\text{CO}_2$ ; and ethanol (ethyl alcohol),  $\text{C}_2\text{H}_6\text{O}$ . In Chapter 3, you will see how we determine such formulas.

The atoms in a molecule are not simply piled together randomly. Rather, the atoms are chemically bonded in a definite way. A *structural formula* is a chemical formula that shows how the atoms are bonded to one another in a molecule. For example, it is known that each of the hydrogen atoms in the water molecule is bonded to the oxygen atom. Thus, the structural formula of water is  $\text{H—O—H}$ . A line joining two atomic symbols in such a formula represents the chemical bond connecting the atoms. Figure 2.18 shows some structural formulas. Structural formulas are sometimes condensed in writing. For example, the structural formula of ethanol may be written  $\text{CH}_3\text{CH}_2\text{OH}$  or  $\text{C}_2\text{H}_5\text{OH}$ , depending on the detail you want to convey.

The atoms in a molecule are not only connected in definite ways but exhibit definite spatial arrangements as well. Chemists often construct molecular models as an aid in visualizing the shapes and sizes of molecules. Figure 2.18 shows molecular models for several compounds. While the ball-and-stick type of model shows the bonds and bond angles clearly, the space-filling type gives a more realistic feeling of the space occupied by the atoms. Chemists also use computer-generated models of molecules, which can be produced in a variety of forms in addition to those shown here.

Some elements are molecular substances and are represented by molecular formulas. Chlorine, for example, is a molecular substance and has the formula  $\text{Cl}_2$ , each molecule being composed of two chlorine atoms bonded together. Sulfur consists of molecules composed of eight atoms; its molecular formula is  $\text{S}_8$ . Helium and neon are composed of isolated atoms; their formulas are  $\text{He}$  and  $\text{Ne}$ , respectively. Other elements, such as carbon (in the form of graphite or diamond), do not have a simple molecular structure but consist of a very large, indefinite number of atoms bonded together. These elements are represented simply by their atomic symbols. (An important exception is a form of carbon called buckminsterfullerene, which was discovered in 1985 and has the molecular formula  $\text{C}_{60}$ .) Models of some elementary substances are shown in Figure 2.19.

An important class of molecular substances is the polymers. **Polymers** are very large molecules that are made up of a number of smaller molecules repeatedly linked

Figure 2.17 ▲

**Sodium chloride model** This model of a sodium chloride crystal illustrates the 1 : 1 packing of the  $\text{Na}^+$  and  $\text{Cl}^-$  ions.

Another way to understand the large numbers of molecules involved in relatively small quantities of matter is to consider 1 g of water (about one-fifth teaspoon). It contains  $3.3 \times 10^{22}$  water molecules. If you had a penny for every molecule in this quantity of water, the height of your stack of pennies would be about 300 million times the distance from the earth to the sun.

Figure 2.18 ▶

**Examples of molecular and structural formulas, molecular models, and electrostatic potential maps** Three common molecules—water, ammonia, and ethanol—are shown. The electrostatic potential map representation at the bottom of the figure illustrates the distribution of electrons in the molecule using a color spectrum. Colors range from red (relatively high electron density) all the way to blue (low electron density).

**Molecular models of some elementary substances**

together. **Monomers** are the small molecules that are linked together to form the polymer. A good analogy for the formation of polymers from monomers is that of making a chain of paper clips. Say you have boxes of red, blue, and yellow paper clips. Each paper clip represents a monomer. You can make a large chain of paper clips, representing the polymer, with a variety of patterns and repeating units. One chain might involve a repeating pattern of two red, three yellow, and one blue. Another chain might consist of only blue paper clips. Just like the paper clips, the creation of a particular polymer in a laboratory involves controlling both the monomers that are being linked together and the linkage pattern.

Polymers are both natural and synthetic. Hard plastic soda bottles are made from chemically linking two different monomers in an alternating pattern. Wool and silk are natural polymers of amino acids linked by peptide bonds. Nylon<sup>®</sup> for fabrics, Kevlar<sup>®</sup> for bulletproof vests, and Nomex<sup>®</sup> for flame-retardant clothing all contain a CONH linkage. Plastics and rubbers are also polymers that are made from carbon- and hydrogen-containing monomers. Even the Teflon<sup>®</sup> coating on cookware is a polymer that is the result of linking  $\text{CF}_2\text{CF}_2$  monomers (Figure 2.20). From these examples, it is obvious that polymers are very important molecular materials that we use every day in a wide variety of applications. For more on the chemistry of polymers, refer to Chapter 24.

### Ionic Substances

Although many substances are molecular, others are composed of ions (pronounced “eye’-ons”). An **ion** is an electrically charged particle obtained from an atom or chemically bonded group of atoms by adding or removing electrons. Sodium chloride is a substance made up of ions.

Although isolated atoms are normally electrically neutral and therefore contain equal numbers of positive and negative charges, during the formation of certain compounds atoms can become ions. Metal atoms tend to lose electrons, whereas nonmetals tend to gain electrons. When a metal atom such as sodium and a nonmetal atom such as chlorine approach one another, an electron can transfer from the metal atom to the nonmetal atom to produce ions.

An atom that picks up an extra electron becomes a *negatively charged ion*, called an **anion** (pronounced “an'-ion”). An atom that loses an electron becomes a *positively charged ion*, called a **cation** (“cat'-ion”). A sodium atom, for example, can lose an electron to form a sodium cation (denoted  $\text{Na}^+$ ). A chlorine atom can gain an electron to form a chloride anion (denoted  $\text{Cl}^-$ ). A calcium atom can lose two electrons to form a calcium cation, denoted  $\text{Ca}^{2+}$ . Note that the positive-two charge on the ion is indicated by a superscript 2+.

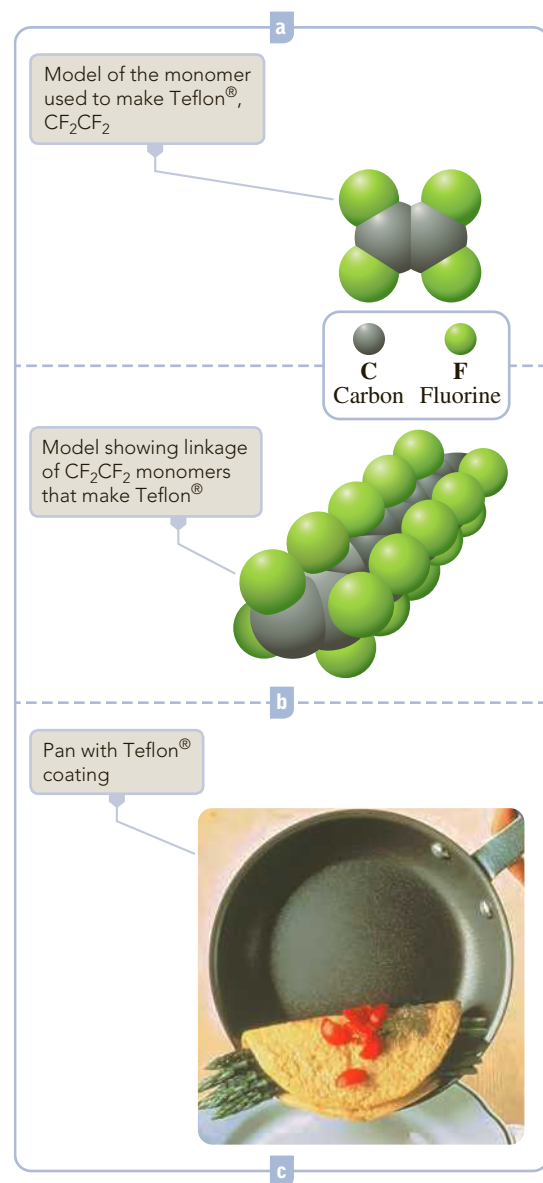

Some ions consist of two or more atoms chemically bonded but having an excess or deficiency of electrons so that the unit has an electric charge. An example is the sulfate ion,  $\text{SO}_4^{2-}$ . The superscript 2- indicates an excess of two electrons on the group of atoms.

An **ionic compound** is a compound composed of cations and anions. Sodium chloride consists of equal numbers of sodium ions,  $\text{Na}^+$ , and chloride ions,  $\text{Cl}^-$ . The strong attraction between positive and negative charges holds the ions together in a regular arrangement in space. For example, in sodium chloride, each  $\text{Na}^+$  ion is surrounded by six  $\text{Cl}^-$  ions, and each  $\text{Cl}^-$  ion is surrounded by six  $\text{Na}^+$  ions. The result is a *crystal*, which is a kind of solid having a regular three-dimensional arrangement of atoms, molecules, or (as in the case of sodium chloride) ions. Figure 2.21 shows sodium chloride crystals and two types of models used to depict the arrangement of the ions in the crystal.

The formula of an ionic compound is written by giving the smallest possible integer number of different ions in the substance, except that the charges on the ions are omitted so that the formulas merely indicate the atoms involved. For example, sodium chloride contains equal numbers of  $\text{Na}^+$  and  $\text{Cl}^-$  ions. The formula is written  $\text{NaCl}$  (not  $\text{Na}^+\text{Cl}^-$ ). Iron(III) sulfate is a compound consisting of iron(III) ions,  $\text{Fe}^{3+}$ , and sulfate ions,  $\text{SO}_4^{2-}$ , in the ratio 2 : 3. The formula is written  $\text{Fe}_2(\text{SO}_4)_3$ , in which parentheses enclose the formula of an ion composed of more than one atom (again, omitting ion charges); parentheses are used only when there are two or more such ions.

Although ionic substances do not contain molecules, we can speak of the smallest unit of such a substance. The **formula unit** of a substance is the *group of atoms or ions explicitly symbolized in the formula*. For example, the formula unit of water,  $\text{H}_2\text{O}$ , is the  $\text{H}_2\text{O}$  molecule. The formula unit of iron(III) sulfate,  $\text{Fe}_2(\text{SO}_4)_3$ , consists of two  $\text{Fe}^{3+}$  ions and three  $\text{SO}_4^{2-}$  ions. The formula unit is the smallest neutral unit of such substances.

All substances, including ionic compounds, are electrically neutral. You can use this fact to obtain the formula of an ionic compound, given the formulas of the ions. This is illustrated in the following example.

**Figure 2.20** ▲  
 **$\text{F}_2\text{C}=\text{CF}_2$  monomer and Teflon®**

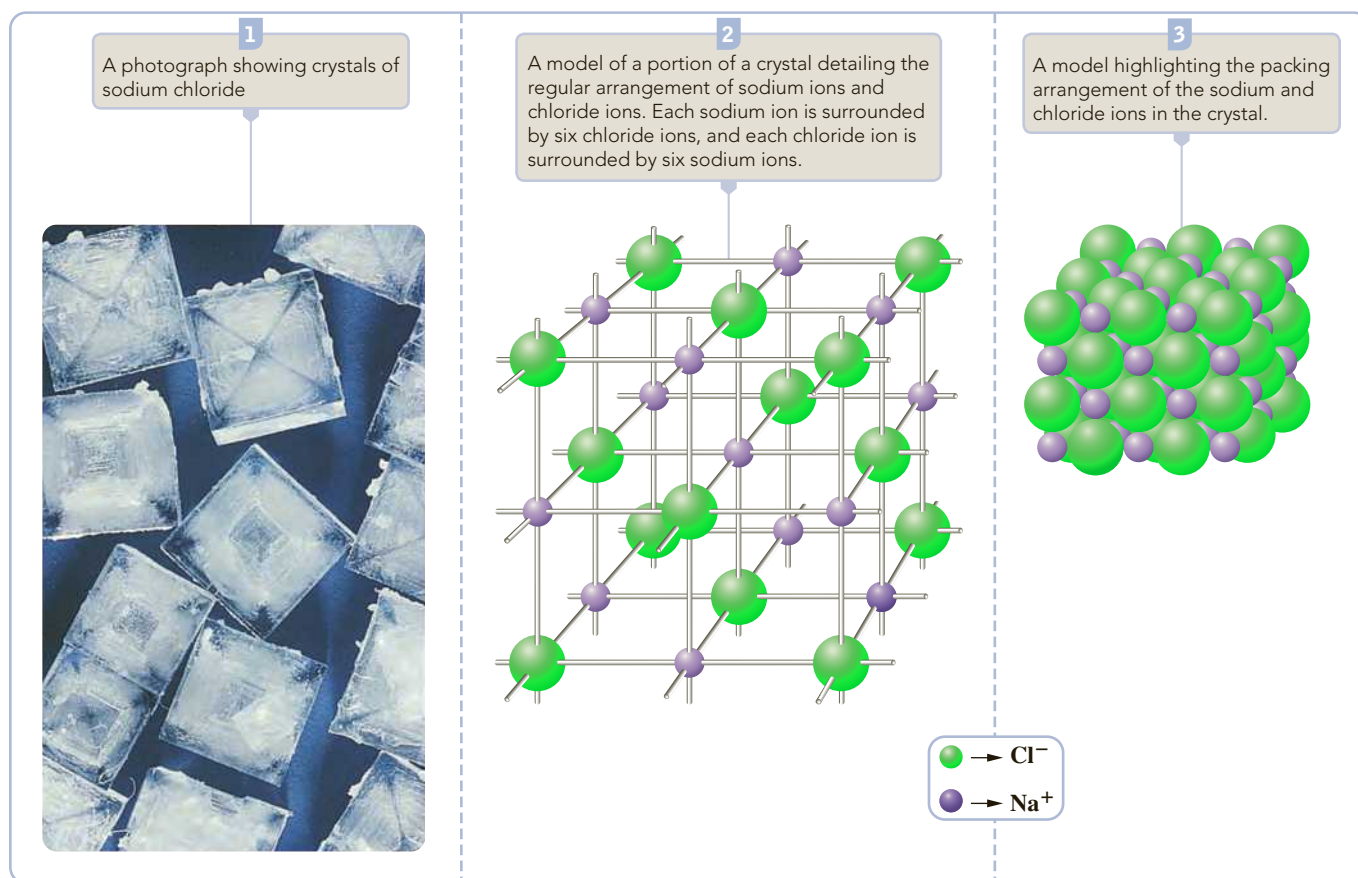

Figure 2.21 ▲

The sodium chloride crystal

### Example 2.3 Writing an Ionic Formula, Given the Ions

#### Gaining Mastery Toolbox

##### Critical Concept 2.3

Ionic compounds are formed by the combination of positively and negatively charged particles. When the charged particles (ions) combine, they combine in a ratio that yields a compound with an overall charge of zero. Ionic compounds are often combinations of metal and nonmetal atoms.

##### Solution Essentials:

- Compound
- Ion, anion, and cation
- Ionic compound
- Formula unit

- Chromium(III) oxide is used as a green paint pigment (Figure 2.22). It is a compound composed of Cr<sup>3+</sup> and O<sup>2-</sup> ions. What is the formula of chromium(III) oxide?
- Strontium oxide is a compound composed of Sr<sup>2+</sup> and O<sup>2-</sup> ions. Write the formula of this compound.

**Problem Strategy** Because a compound is neutral, the sum of positive and negative charges equals zero. Consider the ionic compound CaCl<sub>2</sub>, which consists of one Ca<sup>2+</sup> ion and two Cl<sup>-</sup> ions. The sum of the charges is

$$\underbrace{1 \times (+2)}_{\text{Positive charge}} + \underbrace{2 \times (-1)}_{\text{Negative charge}} = 0$$

Note that the number of calcium ions in CaCl<sub>2</sub> equals the magnitude of charge on the chloride ion (1), whereas the number of chloride ions in CaCl<sub>2</sub> equals the magnitude of charge on the calcium ion (2). In general, you use the magnitude of charge on one ion to obtain the subscript for the other ion. You may need to simplify the formula you obtain this way so that it expresses the simplest ratio of ions.

Figure 2.22 ▲

(continued)

**Example 2.3** (continued)**Solution**

a. You can achieve electrical neutrality by taking as many cations as there are units of charge on the anion and as many anions as there are units of charge on the cation. The unit of charge on the  $O^{2-}$  anion is 2, and the unit of charge on the  $Cr^{3+}$  cation is 3. Therefore, we predict that the ratio of  $Cr^{3+}$  to  $O^{2-}$  is 2 : 3. The correct formula of an ionic compound must have a net charge of zero when the charges of all the ions are combined; two  $Cr^{3+}$  ions have a total charge of  $6^+$ , and three  $O^{2-}$  ions have a total charge of  $6^-$ . The 2 : 3 ratio of  $Cr^{3+}$  to  $O^{2-}$  is the simplest ratio, and the formula is  $Cr_2O_3$ . The solution to this problem can be diagrammed in the following manner. However, keep in mind that one additional step of reducing the ratio might be required.

b. You see that equal numbers of  $Sr^{2+}$  and  $O^{2-}$  ions will give a neutral compound. Thus, the formula is  $SrO$ . If you use the units of charge to find the subscripts, you get

The final formula is  $SrO$ , because this gives the simplest ratio of ions.

**Figure 2.23** ▲**Potassium chromate**

Many compounds of chromium have bright colors, which is the origin of the name of the element. It comes from the Greek word *chroma*, meaning “color.”

**Answer Check** When writing ionic formulas, always make certain that the formula that you write reflects the smallest whole-number ratio of the ions. For example, using the technique presented in this example,  $Pb^{4+}$  and  $O^{2-}$  combine to give  $Pb_2O_4$ ; however, the correct formula is  $PbO_2$ , which reflects the simplest whole-number ratio of ions.

**Exercise 2.4** Potassium chromate is an important compound of chromium (Figure 2.23). It is composed of  $K^+$  and  $CrO_4^{2-}$  ions. Write the formula of the compound.

See Problems 2.75 and 2.76.

**CONCEPT CHECK 2.4**

Classify each of the following as either an ionic or molecular compound.

Which is the best statement regarding molecular compounds?

- a Molecular compounds always contain at least two elements. For example,  $H_2O$  is a molecular compound because it contains two elements: hydrogen and oxygen.
- b Molecular compounds usually contain carbon.
- c Molecular compounds consist of cations and anions.
- d A molecular compound is a combination of nonmetal atoms.
- e Molecular compounds are gases at room temperature.

**2.7 Organic Compounds**

An important class of *molecular substances that contain carbon combined with other elements, such as hydrogen, oxygen, and nitrogen*, is **organic compounds**. Organic chemistry is the area of chemistry that is concerned with these compounds (Chapter 23 is

**Figure 2.24** ▲

**Molecular model of urea**

**(CH<sub>4</sub>N<sub>2</sub>O)** Urea was the first organic molecule deliberately synthesized by a chemist from non-organic compounds.

devoted to this topic). Historically, organic compounds were restricted to those that could be produced only from living entities and were thought to contain a “vital force” based on their natural origin. The concept of the vital force was disproved in 1828 when a German chemist, Friedrich Wöhler, synthesized urea (a molecular compound in human urine, CH<sub>4</sub>N<sub>2</sub>O, Figure 2.24) from the molecular compounds ammonia (NH<sub>3</sub>) and cyanic acid (HNCO). His work clearly demonstrated that a given compound is exactly the same whether it comes from a living entity or is synthesized.

Organic compounds make up the majority of all known compounds. Since 1957, more than 13 million (60%) of the recorded substances in an international materials registry have been listed as organic. You encounter organic compounds in both living and nonliving materials every day. The proteins, amino acids, enzymes, and DNA that make up your body are all either individual organic molecules or contain organic molecules. Table sugar, peanut oil, antibiotic medicines, and methanol (windshield washer) are all examples of organic molecules as well. Organic chemistry and the compounds produced by the reactions of organic molecules are probably responsible for the majority of the materials that currently surround you as you read this page of text.

The simplest organic compounds are hydrocarbons. **Hydrocarbons** are *those compounds containing only hydrogen and carbon*. Common examples include methane (CH<sub>4</sub>), ethane (C<sub>2</sub>H<sub>6</sub>), propane (C<sub>3</sub>H<sub>8</sub>), acetylene (C<sub>2</sub>H<sub>2</sub>), and benzene (C<sub>6</sub>H<sub>6</sub>). Hydrocarbons are used extensively as sources of energy for heating our homes, for powering internal combustion engines, and for generating electricity. They also are the starting materials for most plastics. Much of the mobility and comfort of our current civilization is built on the low cost and availability of hydrocarbons.

The chemistry of organic molecules is often determined by groups of atoms in the molecule that have characteristic chemical properties. A **functional group** is *a reactive portion of a molecule that undergoes predictable reactions*. When you use the term *alcohol* when referring to a molecular compound, you actually are indicating a molecule that contains an —OH functional group. Methyl alcohol has the chemical formula CH<sub>3</sub>OH. The term *ether* indicates that an organic molecule contains an oxygen atom between two carbon atoms, as in diethyl ether (CH<sub>3</sub>CH<sub>2</sub>OCH<sub>2</sub>CH<sub>3</sub>). Table 2.3 contains a few examples of organic functional groups along with example compounds.

Chapter 23 contains a much more extensive treatment of organic chemistry. Due to its importance and its relation to living organisms, a substantial part of your future chemistry experience will likely be in the field of organic chemistry.

## 2.8 Naming Simple Compounds

Before the structural basis of chemical substances became established, compounds were named after people, places, or particular characteristics. Examples are Glauber’s salt (sodium sulfate, discovered by J. R. Glauber), sal ammoniac (ammonium chloride, named after the ancient Egyptian deity Ammon from the temple near which the substance was made), and washing soda (sodium carbonate, used for softening wash water). Today several million compounds are known and thousands of new ones are discovered every year. Without a system for naming compounds, coping with this

**Table 2.3** Examples of Organic Functional Groups

Functional Group	Name of Functional Group	Example Molecule	Common Use
—OH	Alcohol	Methyl alcohol (CH <sub>3</sub> OH)	Windshield washer
—O—	Ether	Dimethyl ether (CH <sub>3</sub> OCH <sub>3</sub> )	Solvent
—COOH	Carboxylic acid	Acetic acid (CH <sub>3</sub> COOH)	Acid in vinegar

multitude of substances would be a hopeless task. **Chemical nomenclature** is *the systematic naming of chemical compounds*.

### CONCEPT CHECK 2.5

Identify the following compounds as being a hydrocarbon, an alcohol, an ether, or a carboxylic acid.

If a compound is not classified as organic, as discussed in Section 2.7, it must be inorganic. **Inorganic compounds** are *composed of elements other than carbon*. A few notable exceptions to this classification scheme include carbon monoxide, carbon dioxide, carbonates, and the cyanides; all contain carbon and yet are generally considered to be inorganic.

In this section, we discuss the nomenclature of some simple inorganic compounds. We first look at the naming of ionic compounds. Then, we look at the naming of some simple molecular compounds, including binary molecular compounds (molecular compounds of two elements) and acids. Finally, we look at hydrates of ionic compounds. These substances contain water molecules in loose association with ionic compounds.

## Ionic Compounds

Ionic compounds, as we saw in the previous section, are substances composed of ions. Most ionic compounds contain metal and nonmetal atoms—for example, NaCl. (The ammonium salts, such as  $\text{NH}_4\text{Cl}$ , are a prominent exception.) You name an ionic compound by giving the name of the cation followed by the name of the anion. For example,

Before you can name ionic compounds, you need to be able to write and name ions.

The simplest ions are monatomic. **A monatomic ion is an ion formed from a single atom.** Table 2.4 lists common monatomic ions of the main-group elements.

	1A	2A	3A	4A	5A	6A	7A
Period 1							H <sup>+</sup>
Period 2	Li <sup>+</sup>	Be <sup>2+</sup>	B	C	N <sup>3-</sup>	O <sup>2-</sup>	F <sup>-</sup>
Period 3	Na <sup>+</sup>	Mg <sup>2+</sup>	Al <sup>3+</sup>	Si	P	S <sup>2-</sup>	Cl <sup>-</sup>
Period 4	K <sup>+</sup>	Ca <sup>2+</sup>	Ga <sup>3+</sup>	Ge	As	Se <sup>2-</sup>	Br <sup>-</sup>
Period 5	Rb <sup>+</sup>	Sr <sup>2+</sup>	In <sup>3+</sup>	Sn <sup>2+</sup>	Sb	Te <sup>2-</sup>	I <sup>-</sup>
Period 6	Cs <sup>+</sup>	Ba <sup>2+</sup>	Tl <sup>+</sup> , Tl <sup>3+</sup>	Pb <sup>2+</sup>	Bi <sup>3+</sup>		

\*Elements shown in color do not normally form compounds having monatomic ions.

You may want to look at the table while you read first the rules for predicting the charges on such ions and then the rules for naming the monatomic ions.

#### Rules for Predicting the Charges on Monatomic Ions

1. Most of the main-group metallic elements have one monatomic cation with a charge equal to the group number in the periodic table (the numeral paired with the letter A or B). Example: aluminum, in Group 3A, has a monatomic ion  $\text{Al}^{3+}$ .
2. Some metallic elements of high atomic number are exceptions to the previous rule; they have more than one cation. These elements have common cations with a charge equal to the group number minus 2, in addition to having a cation with a charge equal to the group number. Example: The common ion of lead is  $\text{Pb}^{2+}$ . (The group number is 4; the charge is  $4 - 2$ .) In addition to compounds containing  $\text{Pb}^{2+}$ , some lead compounds contain  $\text{Pb}^{4+}$ .
3. Most transition elements form more than one monatomic cation, each with a different charge. Most of these elements have one ion with a charge of  $+2$ . Example: Iron has common cations  $\text{Fe}^{2+}$  and  $\text{Fe}^{3+}$ . Copper has common cations  $\text{Cu}^+$  and  $\text{Cu}^{2+}$ .
4. The charge on a monatomic anion for a nonmetallic main-group element equals the group number minus 8. Example: Oxygen has the monatomic anion  $\text{O}^{2-}$ . (The group number is 6; the charge is  $6 - 8$ .)

#### Rules for Naming Monatomic Ions

1. Monatomic cations are named after the element if there is only one such ion. Example:  $\text{Al}^{3+}$  is called aluminum ion;  $\text{Na}^+$  is called sodium ion.
2. If there is more than one monatomic cation of an element, Rule 1 is not sufficient. The *Stock system* of nomenclature names the cations after the element, as in Rule 1, but follows this by a Roman numeral in parentheses denoting the charge on the ion. Example:  $\text{Fe}^{2+}$  is called iron(II) ion and  $\text{Fe}^{3+}$  is called iron(III) ion. ◀

In an older system of nomenclature, such ions are named by adding the suffixes *-ous* and *-ic* to a stem name of the element (which may be from the Latin) to indicate the ions of lower and higher charge, respectively. Example:  $\text{Fe}^{2+}$  is called ferrous ion;  $\text{Fe}^{3+}$ , ferric ion.  $\text{Cu}^+$  is called cuprous ion;  $\text{Cu}^{2+}$ , cupric ion.

Table 2.5 lists some common cations of the transition elements. Most of these elements have more than one ion, so require the Stock nomenclature system or the older suffix system. A few, such as zinc, have only a single ion that is normally encountered, and you usually name them by just the metal name. You would not be wrong, however, if, for example, you named  $\text{Zn}^{2+}$  as zinc(II) ion.

3. The names of the monatomic anions are obtained from a stem name of the element followed by the suffix *-ide*. Example:  $\text{Br}^-$  is called bromide ion, from the stem name *brom-* for bromine and the suffix *-ide*.

A **polyatomic ion** is an ion consisting of two or more atoms chemically bonded together and carrying a net electric charge. Table 2.6 lists some common polyatomic ions. The first two are cations ( $\text{Hg}_2^{2+}$  and  $\text{NH}_4^+$ ); the rest are anions. There are no simple rules for writing the formulas of such ions, although you will find it helpful to note a few points.

The Roman numeral actually denotes the oxidation state, or oxidation number, of the atom in the compound. For a monatomic ion, the oxidation state equals the charge. Otherwise, the oxidation state is a hypothetical charge assigned in accordance with certain rules; see Section 4.5.

**Table 2.5** Common Cations of the Transition Elements

Ion	Ion Name	Ion	Ion Name	Ion	Ion Name
$\text{Cr}^{3+}$	Chromium(III) or chromic	$\text{Co}^{2+}$	Cobalt(II) or cobaltous	$\text{Zn}^{2+}$	Zinc
$\text{Mn}^{2+}$	Manganese(II) or manganous	$\text{Ni}^{2+}$	Nickel(II) or nickel	$\text{Ag}^+$	Silver
$\text{Fe}^{2+}$	Iron(II) or ferrous	$\text{Cu}^+$	Copper(I) or cuprous	$\text{Cd}^{2+}$	Cadmium
$\text{Fe}^{3+}$	Iron(III) or ferric	$\text{Cu}^{2+}$	Copper(II) or cupric	$\text{Hg}^{2+}$	Mercury(II) or mercuric

Table 2.6 Some Common Polyatomic Ions			
Name	Formula	Name	Formula
Mercury(I) or mercurous	$\text{Hg}_2^{2+}$	Permanganate	$\text{MnO}_4^-$
Ammonium	$\text{NH}_4^+$	Nitrite	$\text{NO}_2^-$
Cyanide	$\text{CN}^-$	Nitrate	$\text{NO}_3^-$
Carbonate	$\text{CO}_3^{2-}$	Hydroxide	$\text{OH}^-$
Hydrogen carbonate (or bicarbonate)	$\text{HCO}_3^-$	Peroxide	$\text{O}_2^{2-}$
Acetate	$\text{C}_2\text{H}_3\text{O}_2^-$	Phosphate	$\text{PO}_4^{3-}$
Oxalate	$\text{C}_2\text{O}_4^{2-}$	Monohydrogen phosphate	$\text{HPO}_4^{2-}$
Hypochlorite	$\text{ClO}^-$	Dihydrogen phosphate	$\text{H}_2\text{PO}_4^-$
Chlorite	$\text{ClO}_2^-$	Sulfite	$\text{SO}_3^{2-}$
Chlorate	$\text{ClO}_3^-$	Sulfate	$\text{SO}_4^{2-}$
Perchlorate	$\text{ClO}_4^-$	Hydrogen sulfite (or bisulfite)	$\text{HSO}_3^-$
Chromate	$\text{CrO}_4^{2-}$	Hydrogen sulfate (or bisulfate)	$\text{HSO}_4^-$
Dichromate	$\text{Cr}_2\text{O}_7^{2-}$	Thiosulfate	$\text{S}_2\text{O}_3^{2-}$

Most of the ions in Table 2.6 are *oxoanions* (also called *oxyanions*), which consist of oxygen with another element (called the characteristic or central element). Sulfur, for example, forms the oxoanions sulfate ion,  $\text{SO}_4^{2-}$ , and sulfite ion,  $\text{SO}_3^{2-}$  (Figure 2.25). The oxoanions in the table are grouped by the characteristic element. For instance, the sulfur ions occur as a group at the end of the table.

Note that the names of the oxoanions have a stem name from the characteristic element, plus a suffix *-ate* or *-ite*. These suffixes denote the relative number of oxygen atoms in the oxoanions of a given characteristic element. The name of the oxoanion with the greater number of oxygen atoms has the suffix *-ate*; the name of the oxoanion with the lesser number of oxygen atoms has the suffix *-ite*. The sulfite ion,  $\text{SO}_3^{2-}$ , and sulfate ion,  $\text{SO}_4^{2-}$ , are examples. Another example are the two oxoanions of nitrogen listed in Table 2.6:

Unfortunately, the suffixes do not tell you the actual number of oxygen atoms in the oxoanion, only the relative number. However, if you were given the formulas of the two anions, you could name them.

The two suffixes *-ite* and *-ate* are not enough when there are more than two oxoanions of a given characteristic element. The oxoanions of chlorine are an example. Table 2.6 lists four oxoanions of chlorine:  $\text{ClO}^-$ ,  $\text{ClO}_2^-$ ,  $\text{ClO}_3^-$ , and  $\text{ClO}_4^-$ . In such cases, two prefixes, *hypo-* and *per-*, are used in addition to the two suffixes. The two oxoanions with the least number of oxygen atoms ( $\text{ClO}^-$  and  $\text{ClO}_2^-$ ) are named using the suffix *-ite*, and the prefix *hypo-* is added to the one of these two ions with the fewer oxygen atoms:

The two oxoanions with the greatest number of oxygen atoms ( $\text{ClO}_3^-$  and  $\text{ClO}_4^-$ ) are named using the suffix *-ate*, and the prefix *per-* is added to the one of these two ions with the greater number of oxygen atoms:

Some of the polyatomic ions in Table 2.6 are oxoanions bonded to one or more hydrogen ions ( $\text{H}^+$ ). They are sometimes referred to as *acid anions*, because acids

**Figure 2.25** ▲  
**Sulfate and sulfite oxoanions** Molecular models of the sulfate (top) and sulfite (bottom) oxoanions.

are substances that provide  $H^+$  ions. As an example, monohydrogen phosphate ion,  $HPO_4^{2-}$ , is essentially a phosphate ion ( $PO_4^{3-}$ ) to which a hydrogen ion ( $H^+$ ) has bonded. The prefix *mono-*, from the Greek, means “one.” Similarly, *di-* is a prefix from the Greek meaning “two,” so dihydrogen phosphate ion is a phosphate ion to which two hydrogen ions have bonded. In an older terminology, ions such as hydrogen carbonate and hydrogen sulfate were called bicarbonate and bisulfate, respectively.

The last anion in the table is thiosulfate ion,  $S_2O_3^{2-}$ . The prefix *thio-* means that an oxygen atom in the root ion name (sulfate,  $SO_4^{2-}$ ) has been replaced by a sulfur atom.

There are only a few common polyatomic cations. Those listed in Table 2.6 are the mercury(I) ion (also called mercurous ion) and the ammonium ion. Mercury(I) ion is one of the few common metal ions that is not monatomic; its formula is  $Hg_2^{2+}$ . The ion charge indicated in parentheses is the charge per metal atom. The ammonium ion,  $NH_4^+$ , is one of the few common cations composed of only non-metal atoms.

Now that we have discussed the naming of ions, let us look at the naming of ionic compounds. Example 2.4 illustrates how you name an ionic compound given its formula.

### Interactive Example 2.4 Naming an Ionic Compound from Its Formula

#### Gaining Mastery Toolbox

##### Critical Concept 2.4

There are rules that can be applied to naming ionic compounds. In order to be successful in naming ionic compounds, you have to know both the names and charges of the cation and anion that form the compound. Ionic compounds are often metal–nonmetal combinations of atoms.

##### Solution Essentials:

- Monatomic ions and charges
- Polyatomic ions and charges
- Cation names (monatomic and polyatomic)
- Anion names (monatomic and polyatomic)
- The naming rules of three possible combinations of ions: monatomic ions, monatomic and polyatomic ions, and polyatomic ions
- Metal and nonmetal
- Main group and transition metal

Name the following: a.  $Mg_3N_2$ , b.  $CrSO_4$ .

**Problem Strategy** First, you need to identify the type of compound that you are dealing with. Because each of these compounds contains both metal and non-metal atoms, we expect them to be ionic, so we need to apply the rules for naming ionic compounds. When naming ionic compounds, start by writing the formulas of the cations and anions in the compound, then name the ions. Look first for any monatomic cations and anions whose charges are predictable. Use the rules given in the text to name the ions. For those metals having more than one cation, you will need to deduce the charge on the metal ion (say the ion of Cr in  $CrSO_4$ ) from the charge on the anion. You will need to memorize or have available the formulas and names of the polyatomic anions to be able to write them from the formula of the compound.

##### Solution

- a. Magnesium, a Group 2A metal, is expected to form only a  $2+$  ion ( $Mg^{2+}$ , the magnesium ion). Nitrogen (Group 5A) is expected to form an anion of charge equal to the group number minus 8 ( $N^{3-}$ , the nitride ion). You can check that these ions would give the formula  $Mg_3N_2$ . The name of the compound is **magnesium nitride** (the name of the cation followed by the name of the anion).
- b. Chromium is a transition element and, like most such elements, has more than one monatomic ion. You can find the charge on the Cr ion if you know the formula of the anion. From Table 2.6, you see that the  $SO_4$  in  $CrSO_4$  refers to the anion  $SO_4^{2-}$  (the sulfate ion). Therefore, the Cr cation must be  $Cr^{2+}$  to give electrical neutrality. The name of  $Cr^{2+}$  is chromium(II) ion, so the name of the compound is **chromium(II) sulfate**.

**Answer Check** Whenever you have to name a compound, you can check your answer to see if the name will lead you back to the correct formula.

**Exercise 2.5** Write the names of the following compounds:  
a.  $CaO$ , b.  $PbCrO_4$ .

See Problems 2.77 and 2.78.

**Example 2.5 Writing the Formula from the Name of an Ionic Compound****Gaining Mastery Toolbox****Critical Concept 2.5**

The name of the ionic compound provides the names of the ions that form the compound. In the formula the cation name will always be listed first, followed by the anion name. For metals that can have more than one charge, Roman numerals following the cation name indicate the charge.

**Solution Essentials:**

- Monatomic ions and charges
- Polyatomic ions and charges
- Cation names (monatomic and polyatomic)
- Anion names (monatomic and polyatomic)
- Ionic compound
- Example 2.3
- Metal and nonmetal
- Main group elements and transition metal

Write formulas for the following compounds: a. iron(II) phosphate, b. titanium (IV) oxide.

**Problem Strategy** As in all nomenclature problems, first determine the type of compound you are working with. The compounds presented in this problem contain both metal and nonmetal atoms, so they are ionic. Use the name of the compound, obtain the name of the ions, and then write the formulas of the ions. Finally, use the method of Example 2.3 to obtain the formula of the compound from the formulas of the ions.

**Solution**

- a. Iron(II) phosphate contains the iron(II) ion,  $\text{Fe}^{2+}$ , and the phosphate ion,  $\text{PO}_4^{3-}$ . (You will need to have memorized the formula of the phosphate ion, or have access to Table 2.6.) Once you know the formulas of the ions, you use the method of Example 2.3 to obtain the formula. The formula is  $\text{Fe}_3(\text{PO}_4)_2$ .
- b. Titanium(IV) oxide is composed of titanium(IV) ions,  $\text{Ti}^{4+}$ , and oxide ions,  $\text{O}^{2-}$ . The formula of titanium(IV) oxide is  $\text{TiO}_2$ .

**Answer Check** Whenever you have to write the formula of a compound from its name, make sure that the formula you have written will result in the correct name.

**Exercise 2.6** A compound has the name thallium(III) nitrate. What is its formula? The symbol of thallium is Tl.

See Problems 2.79 and 2.80.

**CONCEPT CHECK 2.6**

Which of the following are polyatomic ions?

Which of the following is a false statement regarding polyatomic ions?

- a Polyatomic ions must contain two or more atoms in their chemical formula.
- b Polyatomic ions must have either a positive or negative charge.
- c Polyatomic ions must have at least two different elements chemically bonded together.
- d Polyatomic ions can be combinations of metals and nonmetals.
- e Polyatomic ions can be oxoanions.

**Binary Molecular Compounds**

A **binary compound** is a compound composed of only two elements. Binary compounds composed of a metal and a nonmetal are usually ionic and are named as ionic compounds, as we have just discussed. (For example,  $\text{NaCl}$ ,  $\text{MgBr}_2$ , and  $\text{Al}_2\text{N}_3$  are all binary ionic compounds.) Binary compounds composed of two nonmetals or metalloids are usually molecular and are named using a prefix system. Examples of binary molecular compounds are  $\text{H}_2\text{O}$ ,  $\text{NH}_3$ , and  $\text{CCl}_4$ . Using this prefix system, you name the two elements using the order given by the formula of the compound.

**Order of Elements in the Formula** The order of elements in the formula of a binary molecular compound is established by convention. By this convention, the nonmetal

or metalloid occurring first in the following sequence is written first in the formula of the compound.

Element	B	Si	C	Sb	As	P	N	H	Te	Se	S	I	Br	Cl	O	F
Group	3A	4A		5A	5A	5A	5A		6A	6A	6A	7A	7A			

You can reproduce this order easily if you have a periodic table available. You arrange the nonmetals and metalloids in the order of the groups of the periodic table, listing the elements from the bottom of the group upward. Then you place H between Groups 5A and 6A, and move O so that it is just before F.

This order places the nonmetals and metalloids approximately in order of increasing nonmetallic character. Thus, in the formula, the first element is the more metallic and the second element is the more nonmetallic, similar to the situation with binary ionic compounds. For example, the compound whose molecule contains three fluorine atoms and one nitrogen atom is written  $\text{NF}_3$ , not  $\text{F}_3\text{N}$ .

**Rules for Naming Binary Molecular Compounds** Now let us look at the rules for naming binary molecular compounds by the *prefix system*.

1. The name of the compound usually has the elements in the order given in the formula.
2. You name the first element using the exact element name.
3. You name the second element by writing the stem name of the element with the suffix *-ide* (as if the element occurred as the anion).
4. You add a prefix, derived from the Greek, to each element name to denote the subscript of the element in the formula. (The Greek prefixes are listed in Table 2.7.) Generally, the prefix *mono-* is not used, unless it is needed to distinguish two compounds of the same two elements.

**Table 2.7** Greek Prefixes for Naming Compounds

Number	Prefix
1	mono-
2	di-
3	tri-
4	tetra-
5	penta-
6	hexa-
7	hepta-
8	octa-
9	nona-
10	deca-

Consider  $\text{N}_2\text{O}_3$ . This is a binary molecular compound, as you would predict because N and O are nonmetals. According to Rule 1, you name it after the elements, N before O, following the order of elements in the formula. By Rule 2, the N is named exactly as the element (nitrogen), and by Rule 3, the O is named as the anion (oxide). The compound is a nitrogen oxide. Finally, you add prefixes to denote the subscripts in the formula (Rule 4). As Table 2.7 shows, the prefix for two is *di-*, and the prefix for three is *tri-*. The name of the compound is dinitrogen trioxide.

Here are some examples to illustrate how the prefix *mono-* is used. There is only one compound of hydrogen and chlorine: HCl. It is called hydrogen chloride, not monohydrogen monochloride, since the prefix *mono-* is not generally written. On the other hand, there are two common compounds of carbon and oxygen: CO and  $\text{CO}_2$ . They are both carbon oxides. To distinguish one from the other, we name them carbon monoxide and carbon dioxide, respectively.

Here are some other examples of prefix names for binary molecular compounds.

$\text{SF}_4$	sulfur tetrafluoride	$\text{SF}_6$	sulfur hexafluoride
$\text{ClO}_2$	chlorine dioxide	$\text{Cl}_2\text{O}_7$	dichlorine hept(a)oxide

The final vowel in a prefix is often dropped before a vowel in a stem name, for ease in pronunciation. Tetraoxide, for instance, becomes tetroxide.

A few compounds have older, well-established names. The compound  $\text{H}_2\text{S}$  would be named dihydrogen sulfide by the prefix system, but is commonly called hydrogen sulfide. NO is still called nitric oxide, although its prefix name is nitrogen monoxide. The names water and ammonia are used for  $\text{H}_2\text{O}$  and  $\text{NH}_3$ , respectively.

**Example 2.6 Naming a Binary Compound from Its Formula****Gaining Mastery Toolbox****Critical Concept 2.6**

There are rules that can be applied to naming binary molecular compounds. These rules are specific to binary molecular compounds and do not apply to ionic compounds. Molecular compounds are combinations of nonmetal atoms.

**Solution Essentials:**

- Greek prefixes
- Binary molecular compound naming rules
- Naming order of elements
- Binary compound
- Periodic table
- Nonmetal

Name the following compounds: a.  $N_2O_4$ , b.  $P_4O_6$ .

**Problem Strategy** First, you need to determine the type of compound that you are dealing with: molecular or ionic. In this case the compound contains only nonmetals, so it is molecular. Molecular compounds require that you use the Greek prefixes (Table 2.7), naming the elements in the same order as in the formulas.

**Solution**

- a.  $N_2O_4$  contains two nitrogen atoms and four oxygen atoms. Consulting Table 2.7 reveals that the corresponding prefixes are *di-* and *tetra-*, so the name is ***dinitrogen tetroxide***.
- b.  $P_4O_6$  contains four phosphorus atoms and six oxygen atoms. Consulting Table 2.7 reveals that the corresponding prefixes are *tetra-* and *hexa-*, so the name is ***tetraphosphorus hexoxide***.

**Answer Check** Check to see whether the name leads back to the correct formula.

**Exercise 2.7** Name the following compounds:

- a.  $Cl_2O_6$ , b.  $PCl_3$ , c.  $PCl_5$ .

See Problems 2.83 and 2.84.

**Example 2.7 Writing the Formula from the Name of a Binary Compound****Gaining Mastery Toolbox****Critical Concept 2.7**

Greek prefixes are used to determine the correct formula of binary molecular compounds. The elements in the formula are written in the same order as they are presented in the name.

**Solution Essentials:**

- Greek prefixes
- Binary molecular compound naming rules
- Element symbols
- Periodic table
- Nonmetal

Give the formulas of the following compounds: a. disulfur dichloride, b. tetraphosphorus trisulfide.

**Problem Strategy** As always, first determine whether you are working with a molecular or ionic compound. Because these compounds contain only nonmetals, they must be molecular. Given that they are molecular, you will need to use the Greek prefixes in Table 2.7 to give you the corresponding names for each subscript.

**Solution** You change the names of the elements to symbols and translate the prefixes to subscripts. The formulas are a.  $S_2Cl_2$  and b.  $P_4S_3$ .

**Answer Check** Check to see whether the formula you have written will result in the correct name.

**Exercise 2.8** Give formulas for the following compounds:

- a. carbon disulfide, b. sulfur trioxide.

See Problems 2.85 and 2.86.

**Example 2.8 Naming a Binary Chemical Compound from Its Molecular Model****Gaining Mastery Toolbox****Critical Concept 2.8**

Models of molecular compounds depict the number and identity of each element in a single molecule. The molecular formula can be written directly from the information contained in the molecular model.

Name the chemical compounds shown in the margin at the top of the next page.

**Problem Strategy** After recognizing that these are molecular compounds, start by writing down the elements using subscripts to denote how many atoms of each element occur in the compound. Next, determine which element should be written first in the chemical formula. (The more metallic element is written first.)

(continued)

**Example 2.8** (continued)**Solution Essentials:**

- Element symbols
- Naming order of elements
- Example 2.6
- Molecular models

**Solution**

- a. The elements in the compound are O and N. There are two O atoms for each N atom, so the chemical formula could be  $O_2N$ . Applying the rule for writing the more metallic element first, the formula is rearranged to yield the correct formula,  $NO_2$ . Using Greek prefixes and naming the elements in the order in which they appear, we get the correct chemical formula: **nitrogen dioxide**.
- b. Following the same procedure as part a, we get **chlorine monofluoride**.

**Answer Check** Make sure that the answer reflects the correct number of each of the elements given in the molecular structure.

**Exercise 2.9** Using the molecular models, name the following chemical compounds:

See Problems 2.87 and 2.88

**Acids and Corresponding Anions**

Acids are an important class of compounds, and we will look closely at them in the next chapter. Here we want merely to see how we name these compounds and how they are related to the anions that we encounter in some ionic compounds. For our present purposes, an *acid* is a molecular compound that yields hydrogen ions,  $H^+$ , and an anion for each acid molecule when the acid dissolves in water. An example is nitric acid,  $HNO_3$ . The  $HNO_3$  molecule yields one  $H^+$  ion and one nitrate ion,  $NO_3^-$ , in aqueous (water) solution.

Nitric acid,  $HNO_3$ , is an oxoacid, or oxyacid (Figure 2.26). An **oxoacid** is an acid containing hydrogen, oxygen, and another element (often called the central atom). In water the oxoacid molecule yields one or more hydrogen ions,  $H^+$ , and an oxoanion. The names of the oxoacids are related to the names of the corresponding oxoanions. If you know the name of the oxoanion, you can obtain the name of the corresponding acid by replacing the suffix as follows:

**Anion Suffix**      **Acid Suffix**

-ate                      -ic  
-ite                      -ous

The following diagram illustrates how to apply this information to naming oxoacids.

**Figure 2.26** ▲  
Molecular model of nitric acid

Acid	Contains	Name
$HNO_3$	nitrate anion	therefore nitric acid
	ate	to ic
$HNO_2$	nitrite anion	therefore nitrous acid
	ite	to ous

Oxoanion		Oxoacid	
$\text{CO}_3^{2-}$	Carbonate ion	$\text{H}_2\text{CO}_3$	Carbonic acid
$\text{NO}_2^-$	Nitrite ion	$\text{HNO}_2$	Nitrous acid
$\text{NO}_3^-$	Nitrate ion	$\text{HNO}_3$	Nitric acid
$\text{PO}_4^{3-}$	Phosphate ion	$\text{H}_3\text{PO}_4$	Phosphoric acid
$\text{SO}_3^{2-}$	Sulfite ion	$\text{H}_2\text{SO}_3$	Sulfurous acid
$\text{SO}_4^{2-}$	Sulfate ion	$\text{H}_2\text{SO}_4$	Sulfuric acid
$\text{ClO}^-$	Hypochlorite ion	$\text{HClO}$	Hypochlorous acid
$\text{ClO}_2^-$	Chlorite ion	$\text{HClO}_2$	Chlorous acid
$\text{ClO}_3^-$	Chlorate ion	$\text{HClO}_3$	Chloric acid
$\text{ClO}_4^-$	Perchlorate ion	$\text{HClO}_4$	Perchloric acid

Table 2.8 lists some oxoanions and their corresponding oxoacids.

Some binary compounds of hydrogen and nonmetals yield acidic solutions when dissolved in water. These *solutions* are named like compounds by using the prefix *hydro-* and the suffix *-ic* with the stem name of the nonmetal, followed by the word *acid*. We denote the solution by the formula of the binary compound followed by *(aq)* for aqueous (water) solution. The corresponding binary compound can be distinguished from the solution by appending the state of the compound to the formula. Thus, when hydrogen chloride gas,  $\text{HCl}(g)$ , is dissolved in water, it forms hydrochloric acid,  $\text{HCl}(aq)$ .

Here are some other examples:

**Binary Compound**

$\text{HBr}(g)$ , hydrogen bromide

$\text{HF}(g)$ , hydrogen fluoride

**Acid Solution**

*hydrobromic acid*,  $\text{HBr}(aq)$

*hydrofluoric acid*,  $\text{HF}(aq)$

### Example 2.9 Writing the Name and Formula of an Anion from the Acid

#### Gaining Mastery Toolbox

##### Critical Concept 2.9

There are rules that can be applied to naming acids. Depending on the type of acid, there are two sets of rules: one for oxoacids and one for acids that are binary compounds of hydrogen and a nonmetal.

##### Solution Essentials:

- Recognition of the chemical formula of an acid
- Oxoacid
- Naming oxoacid from oxoanion name
- Polyatomic anion names

Selenium has an oxoacid,  $\text{H}_2\text{SeO}_4$ , called selenic acid. What is the formula and name of the corresponding anion?

**Problem Strategy** Knowing that  $\text{H}_2\text{SeO}_4$  is an oxyacid, we must first determine the oxoanion name from the examples provided in Table 2.8. From the oxoanion name you determine whether a prefix (*per-* or *hypo-*) is necessary and whether the proper suffix is *-ite* or *-ate*. You then name the anion.

**Solution** When you remove two  $\text{H}^+$  ions from  $\text{H}_2\text{SeO}_4$ , you obtain the  $\text{SeO}_4^{2-}$  ion. You name the ion from the acid by replacing *-ic* with *-ate*. The anion is called the **selenate ion**.

**Answer Check** Check to see whether the name you have written leads back to the correct formula.

**Exercise 2.10** What are the name and formula of the anion corresponding to perbromic acid,  $\text{HBrO}_4$ ?

See Problems 2.89 and 2.90.

Figure 2.27 ►

**Copper(II) sulfate** The hydrate  $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$  is blue; the anhydrous compound,  $\text{CuSO}_4$ , is white.

### Hydrates

A **hydrate** is a compound that contains water molecules weakly bound in its crystals. These substances are often obtained by evaporating an aqueous solution of the compound. Consider copper(II) sulfate. When an aqueous solution of this substance is evaporated, blue crystals form in which each formula unit of copper(II) sulfate,  $\text{CuSO}_4$ , is associated with five molecules of water. The formula of the hydrate is written  $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ , where a centered dot separates  $\text{CuSO}_4$  and  $5\text{H}_2\text{O}$ . When the blue crystals of the hydrate are heated, the water is driven off, leaving behind white crystals of copper(II) sulfate without associated water, a substance called *anhydrous* copper(II) sulfate (see Figure 2.27).

Hydrates are named from the anhydrous compound, followed by the word *hydrate* with a prefix to indicate the number of water molecules per formula unit of the compound. For example,  $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$  is known as copper(II) sulfate pentahydrate.

### Example 2.10 Naming a Hydrate from Its Formula

#### Gaining Mastery Toolbox

##### Critical Concept 2.10

Hydrates are ionic compounds that contain water molecules as part of the chemical formula. Naming hydrates requires that you first apply the rules of naming ionic compounds and then account for the number of water molecules in the chemical formula.

##### Solution Essentials:

- Recognition of the chemical formula of a hydrate
- Rules for naming hydrates
- Rules for naming ionic compounds
- Greek prefixes

Epsom salts has the formula  $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$ . What is the chemical name of the substance?

**Problem Strategy** You need to identify the type of compound that you are dealing with, ionic or molecular. Because this compound contains both metals and nonmetals, it is ionic. However, this compound has the additional feature that it contains water molecules. Therefore, you need to apply ionic naming rules and then use Greek prefixes (Table 2.7) to indicate the number of water molecules that are part of the formula. The word *hydrate* will be used to represent water in the name.

**Solution**  $\text{MgSO}_4$  is magnesium sulfate.  $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$  is **magnesium sulfate heptahydrate**.

**Answer Check** Make sure that the name leads back to the formula that you started with.

**Exercise 2.11** Washing soda has the formula  $\text{Na}_2\text{CO}_3 \cdot 10\text{H}_2\text{O}$ . What is the chemical name of this substance?

See Problems 2.91 and 2.92.

### Example 2.11 Writing the Formula from the Name of a Hydrate

#### Gaining Mastery Toolbox

##### Critical Concept 2.11

A hydrate formula has two parts: the formula of the ionic compound and the number of water molecules bound to the ionic compound. A centered dot is used to separate the two parts, and Greek prefixes are used to indicate the number of water molecules.

##### Solution Essentials:

- Rules for naming hydrates
- Rules for naming ionic compounds
- Greek prefixes

The mineral gypsum has the chemical name calcium sulfate dihydrate. What is the chemical formula of this substance?

**Problem Strategy** You need to identify the type of compound that you are dealing with, ionic or molecular. Because this compound contains both metals and nonmetals, it is ionic. However, this compound has the additional feature that it contains water molecules. Therefore, we need to apply ionic naming rules and then use Greek prefixes (Table 2.7) to indicate the number of water molecules that are part of the formula. The word *hydrate* will be used to represent water in the name.

**Solution** Calcium sulfate is composed of calcium ions ( $\text{Ca}^{2+}$ ) and sulfate ions ( $\text{SO}_4^{2-}$ ), so the formula of the anhydrous compound is  $\text{CaSO}_4$ . Since the mineral is a *dihydrate*, the formula of the compound is  **$\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$** .

(continued)

**Example 2.11** (continued)

**Answer Check** Make sure that the formula will result in the correct name that you started with.

**Exercise 2.12** Photographers' hypo, used to fix negatives during the development process, is sodium thiosulfate pentahydrate. What is the chemical formula of this compound?

See Problems 2.93 and 2.94

**CONCEPT CHECK 2.7**

You take a job with the U.S. Environmental Protection Agency (EPA) inspecting college chemistry laboratories. On the first day of the job while inspecting Generic University, you encounter a bottle with the formula  $Al_2Q_3$  that was used as an unknown compound in an experiment. Before you send the compound off to the EPA lab for analysis, you want to narrow down the possibilities for element Q. What are the likely (real element) candidates for element Q?

## ▶ Chemical Reactions: Equations

An important feature of atomic theory is its explanation of a chemical reaction as a rearrangement of the atoms of substances. The reaction of sodium metal with chlorine gas described in the chapter opening involves the rearrangement of the atoms of sodium and chlorine to give the new combination of atoms in sodium chloride. Such a rearrangement of atoms is conveniently represented by a chemical equation, which uses chemical formulas.

### 2.9 Writing Chemical Equations

A **chemical equation** is the symbolic representation of a chemical reaction in terms of chemical formulas. For example, the burning of sodium in chlorine to produce sodium chloride is written

The formulas on the left side of an equation (before the arrow) represent the reactants; a **reactant** is a starting substance in a chemical reaction. The arrow means “react to form” or “yield.” The formulas on the right side represent the products; a **product** is a substance that results from a reaction. Note the *coefficient* of 2 in front of the formula NaCl. Coefficients in front of the formula give the relative number of molecules or formula units involved in the reaction. When no coefficient is written, it is understood to be 1.

In many cases, it is useful to indicate the states or phases of the substances in an equation. You do this by placing appropriate labels indicating the phases within parentheses following the formulas of the substances. You use the following phase labels:

(g) = gas, (l) = liquid, (s) = solid, (aq) = aqueous (water) solution

When you use these labels, the previous equation becomes

You can also indicate in an equation the conditions under which a reaction takes place. If the reactants are heated to make the reaction go, you can indicate this by putting the symbol  $\Delta$  (capital Greek delta) over the arrow. For example, the equation

indicates that solid sodium nitrate,  $\text{NaNO}_3$ , decomposes when heated to give solid sodium nitrite,  $\text{NaNO}_2$ , and oxygen gas,  $\text{O}_2$ .

When an aqueous solution of hydrogen peroxide,  $\text{H}_2\text{O}_2$ , comes in contact with platinum metal, Pt, the hydrogen peroxide decomposes into water and oxygen gas. The platinum acts as a *catalyst*, a substance that speeds up a reaction without undergoing any net change itself. You write the equation for this reaction as follows. The catalyst, Pt, is written over the arrow. ◀

You also can combine the symbol  $\Delta$  with the formula of a catalyst, placing one above the arrow and the other below the arrow.

Platinum is a silvery-white metal used for jewelry. It is also valuable as a catalyst for many reactions, including those that occur in the catalytic converters of automobiles.

## 2.10 Balancing Chemical Equations

When the coefficients in a chemical equation are correctly given, the numbers of atoms of each element are equal on both sides of the arrow. The equation is then said to be *balanced*. That a chemical equation should be balanced follows from atomic theory. A chemical reaction involves simply a recombination of the atoms; none are destroyed and none are created. Consider the burning of natural gas, which is composed mostly of methane,  $\text{CH}_4$ . Using atomic theory, you describe this as the chemical reaction of one molecule of methane,  $\text{CH}_4$ , with two molecules of oxygen,  $\text{O}_2$ , to form one molecule of carbon dioxide,  $\text{CO}_2$ , and two molecules of water,  $\text{H}_2\text{O}$ .

Figure 2.28 represents the reaction in terms of molecular models.

Figure 2.28 ▶

**Representation of the reaction of methane with oxygen** Molecular models represent the reaction of  $\text{CH}_4$  with  $\text{O}_2$  to give  $\text{CO}_2$  and  $\text{H}_2\text{O}$ .

Before you can write a balanced chemical equation for a reaction, you must determine *by experiment* those substances that are reactants and those that are products. You must also determine the formulas of each substance. Once you know these things, you can write the balanced chemical equation.

As an example, consider the burning of propane gas (Figure 2.29). By experiment, you determine that propane reacts with oxygen in air to give carbon dioxide and water. You also determine from experiment that the formulas of propane, oxygen, carbon dioxide, and water are  $\text{C}_3\text{H}_8$ ,  $\text{O}_2$ ,  $\text{CO}_2$ , and  $\text{H}_2\text{O}$ , respectively. Then you can write

This equation is not balanced because the coefficients that give the relative number of molecules involved have not yet been determined. *To balance the equation, you select coefficients that will make the numbers of atoms of each element equal on both sides of the equation.*

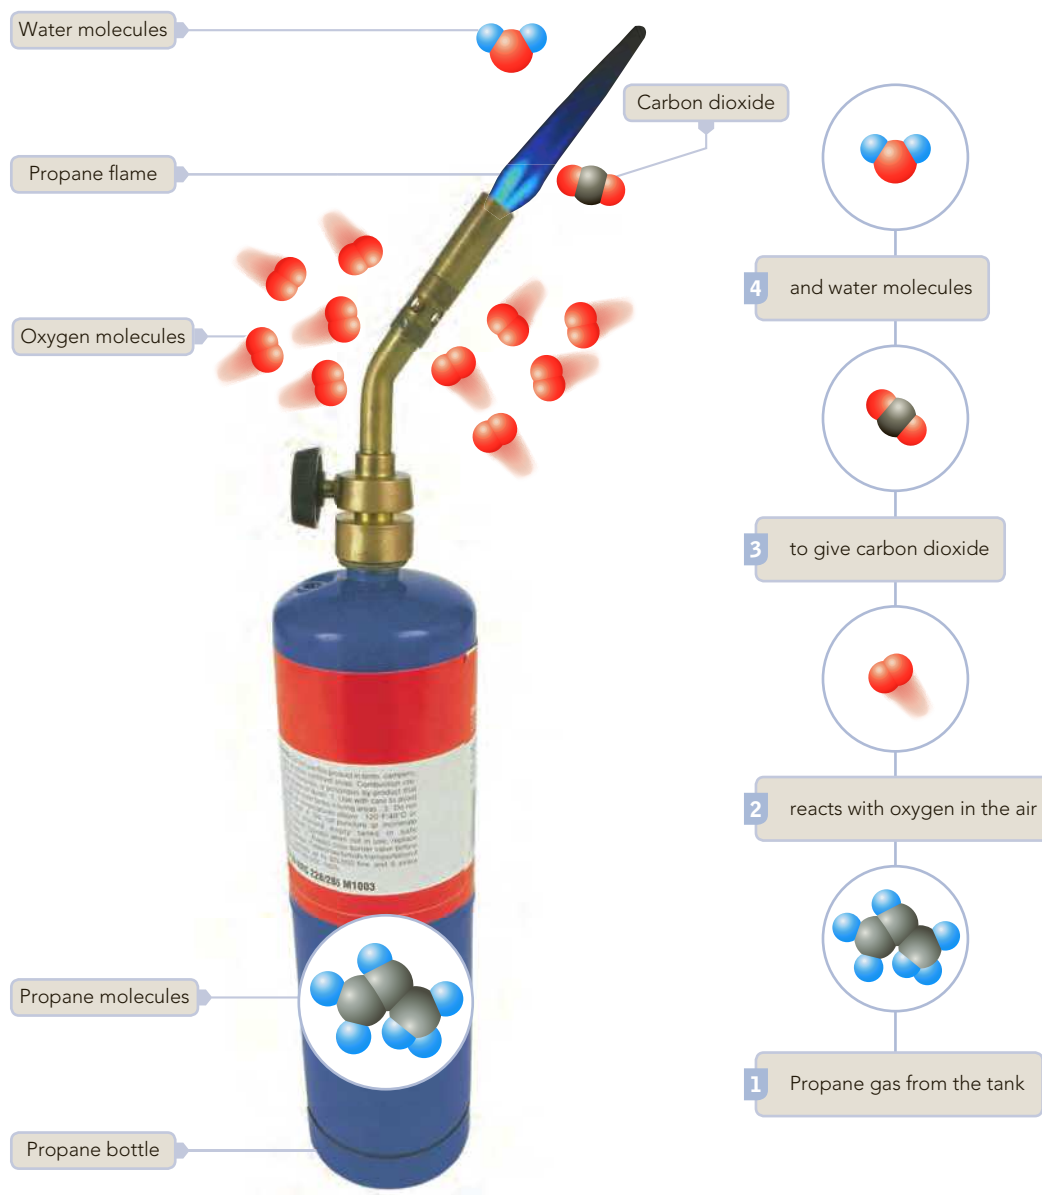

Figure 2.29 ◀

**The burning of propane gas** Propane gas, C<sub>3</sub>H<sub>8</sub>, from the tank burns by reacting with oxygen, O<sub>2</sub>, in air to give carbon dioxide, CO<sub>2</sub>, and water, H<sub>2</sub>O.

Comstock/Getty Images; ©Vladimir Breyberg/Shutterstock.com

Because there are three carbon atoms on the left side of the equation (C<sub>3</sub>H<sub>8</sub>), you must have three carbon atoms on the right. This is achieved by writing 3 for the coefficient of CO<sub>2</sub>.

(We have written the coefficient for C<sub>3</sub>H<sub>8</sub> to show that it is now determined; normally when the coefficient is 1, it is omitted.) Similarly, there are eight hydrogen atoms on the left (in C<sub>3</sub>H<sub>8</sub>), so you write 4 for the coefficient of H<sub>2</sub>O.

The coefficients on the right are now determined, and there are ten oxygen atoms on this side of the equation: 6 from the three CO<sub>2</sub> molecules and 4 from the four H<sub>2</sub>O molecules. You now write 5 for the coefficient of O<sub>2</sub>. We drop the coefficient 1 from C<sub>3</sub>H<sub>8</sub> and have the balanced equation.

It is a good idea to check your work by counting the number of atoms of each element on the left side and then on the right side of the equation.

The combustion of propane can be equally well represented by

in which the coefficients of the previous equation have been doubled. Usually, however, it is preferable to *write the coefficients so that they are the smallest whole numbers possible*. When we refer to a balanced equation, we will assume that this is the case unless otherwise specified.

The method we have outlined—called *balancing by inspection*—is essentially a trial-and-error method. ◀ It can be made easier, however, by observing the following rule:

Balance first the atoms for elements that occur in only one substance on each side of the equation.

The usefulness of this rule is illustrated in the next example. Remember that in any formula, such as  $\text{Fe}_2(\text{SO}_4)_3$ , a subscript to the right of the parentheses multiplies *each* subscript within the parentheses. Thus,  $\text{Fe}_2(\text{SO}_4)_3$  represents  $4 \times 3$  oxygen atoms. Remember also that you cannot change a subscript in any formula; only the coefficients can be altered to balance an equation.

Balancing equations this way is relatively quick for all but the most complicated equations. A special method for such equations is described in Chapter 19.

### Interactive Example 2.12 Balancing Simple Equations

#### Gaining Mastery Toolbox

##### Critical Concept 2.12

When a chemical reaction occurs, elements are neither created nor destroyed; they are rearranged. A balanced chemical equation is one that correctly represents the substances (elements and compounds) before and after a reaction. When the equation is balanced, the starting numbers of atoms of elements (reactants) equal those after the reaction (products).

##### Solution Essentials:

- Balancing chemical equations by inspection
- Balanced chemical equation
- Chemical equation
- Reactants
- Products

Balance the following equations.

- a.  $\text{H}_3\text{PO}_3 \longrightarrow \text{H}_3\text{PO}_4 + \text{PH}_3$       b.  $\text{Ca} + \text{H}_2\text{O} \longrightarrow \text{Ca}(\text{OH})_2 + \text{H}_2$   
 c.  $\text{Fe}_2(\text{SO}_4)_3 + \text{NH}_3 + \text{H}_2\text{O} \longrightarrow \text{Fe}(\text{OH})_3 + (\text{NH}_4)_2\text{SO}_4$

**Problem Strategy** Look at the chemical equation for atoms of elements that occur in only one substance on each side of the equation. Begin by balancing the equation in one of these atoms. Use the number of atoms on the left side of the arrow as the coefficient of the substance containing that element on the right side, and vice versa. After balancing one element in an equation, the rest become easier.

#### Solution

- a. Oxygen occurs in just one of the products ( $\text{H}_3\text{PO}_4$ ). It is therefore easiest to balance O atoms first. To do this, note that  $\text{H}_3\text{PO}_3$  has three O atoms; use 3 as the coefficient of  $\text{H}_3\text{PO}_4$  on the right side. There are four O atoms in  $\text{H}_3\text{PO}_4$  on the right side; use 4 as the coefficient of  $\text{H}_3\text{PO}_3$  on the left side.

This equation is now also balanced in P and H atoms. Thus, the balanced equation is

- b. The equation is balanced in Ca atoms as it stands.

O atoms occur in only one reactant and in only one product, so they are balanced next.

The equation is now also balanced in H atoms. Thus, the answer is

- a. To balance the equation in Fe atoms, you write

(continued)

**Example 2.12** (continued)

You balance the S atoms by placing the coefficient 3 for  $(\text{NH}_4)_2\text{SO}_4$ .

Now you balance the N atoms.

To balance the O atoms, you first count the number of O atoms on the right (18). Then you count the number of O atoms in substances on the left with known coefficients. There are 12 O's in  $\text{Fe}_2(\text{SO}_4)_3$ ; hence, the number of remaining O's (in  $\text{H}_2\text{O}$ ) must be  $18 - 12 = 6$ .

Finally, note that the equation is now balanced in H atoms. The answer is

**Answer Check** As a final step when balancing chemical equations, always count the number of atoms of each element on both sides of the equation to make certain that they are equal.

**Exercise 2.13** Find the coefficients that balance the following equations.

- $\text{O}_2 + \text{PCl}_3 \longrightarrow \text{POCl}_3$
- $\text{P}_4 + \text{N}_2\text{O} \longrightarrow \text{P}_4\text{O}_6 + \text{N}_2$
- $\text{As}_2\text{S}_3 + \text{O}_2 \longrightarrow \text{As}_2\text{O}_3 + \text{SO}_2$
- $\text{Ca}_3(\text{PO}_4)_2 + \text{H}_3\text{PO}_4 \longrightarrow \text{Ca}(\text{H}_2\text{PO}_4)_2$

See Problems 2.97 and 2.98.

## A Checklist for Review

### Summary of Facts and Concepts

*Atomic theory* is central to chemistry. According to this theory, all matter is composed of small particles, or *atoms*. Each *element* is composed of the same kind of atom, and a *compound* is composed of two or more elements chemically combined in fixed proportions. A *chemical reaction* consists of the rearrangement of the atoms present in the reacting substances to give new chemical combinations present in the substances formed by the reaction. Although Dalton considered atoms to be the ultimate particles of matter, we now know that atoms themselves have structure. An atom has a *nucleus* and *electrons*. These atomic particles were discovered by J. J. Thomson and Ernest Rutherford.

Thomson established that cathode rays consist of negatively charged particles, or electrons, that are constituents of all atoms. Thomson measured the mass-to-charge ratio of the electron, and later Millikan measured its charge. From these measurements, the electron was found to be more than 1800 times lighter than the lightest atom.

Rutherford proposed the nuclear model of the atom to account for the results of experiments in which alpha

particles were scattered from metal foils. According to this model, the atom consists of a central core, or nucleus, around which the electrons exist. The nucleus has most of the mass of the atom and consists of *protons* (with a positive charge) and *neutrons* (with no charge). Each chemically distinct atom has a nucleus with a specific number of protons (*atomic number*), and around the nucleus in the neutral atom are an equal number of electrons. The number of protons plus neutrons in a nucleus equals the *mass number*. Atoms whose nuclei have the same number of protons but different numbers of neutrons are called *isotopes*.

The *atomic weight* can be calculated from the isotopic masses and *fractional abundances* of the isotopes in a naturally occurring element. These data can be determined by the use of a mass spectrometer, which separates ions according to their mass-to-charge ratios.

The elements can be arranged in rows and columns by atomic number to form the *periodic table*. Elements in a given *group* (column) have similar properties. (A *period* is

a row in the periodic table.) Elements on the left and at the center of the table are *metals*; those on the right are *nonmetals*.

A *chemical formula* is a notation used to convey the relative proportions of the atoms of the different elements in a substance. If the substance is molecular, the formula gives the precise number of each kind of atom in the molecule. If the substance is ionic, the formula also gives the relative number of different ions in the compound.

Chemical nomenclature is the systematic naming of compounds based on their formulas or structures. Rules

are given for naming *ionic compounds*, *binary molecular compounds*, *acids*, and *hydrates*.

A chemical reaction occurs when the atoms in substances rearrange and combine into new substances. We represent a reaction by a *chemical equation*, writing a chemical formula for each reactant and product. The coefficients in the equation indicate the relative numbers of reactant and product molecules or formula units. Once the reactants and products and their formulas have been determined by experiment, we determine the coefficients by *balancing* the numbers of each kind of atom on both sides of the equation.

## Learning Objectives

## Important Terms

### 2.1 Atomic Theory of Matter

- List the postulates of atomic theory.
- Define *element*, *compound*, and *chemical reaction* in the context of these postulates.
- Recognize the atomic symbols of the elements.
- Explain the significance of the law of multiple proportions.

atomic theory  
atom  
element  
compound  
chemical reaction  
atomic symbol  
law of multiple proportions

### 2.2 The Structure of the Atom

- Describe Thomson's experiment in which he discovered the electron.
- Describe Rutherford's experiment that led to the nuclear model of the atom.

nucleus  
electron

### 2.3 Nuclear Structure; Isotopes

- Name and describe the nuclear particles making up the nucleus of the atom.
- Define *atomic number*, *mass number*, and *nuclide*.
- Write the nuclide symbol for a given nuclide.
- Define and provide examples of *isotopes* of an element.
- Write the nuclide symbol of an element. **Example 2.1**

proton  
atomic number ( $Z$ )  
neutron  
mass number ( $A$ )  
nuclide  
isotope

### 2.4 Atomic Weights

- Define *atomic mass unit* and *atomic weight*.
- Describe how a *mass spectrometer* can be used to determine the *fractional abundance* of the isotopes of an element.
- Determine the atomic weight of an element from the isotopic masses and fractional abundances. **Example 2.2**

atomic mass unit (amu)  
atomic weight  
fractional abundance

### 2.5 Periodic Table of the Elements

- Identify periods and groups on the periodic table.
- Find the *main-group* and *transition* elements on the periodic table.
- Locate the *alkali metal* and *halogen* groups on the periodic table.
- Recognize the portions of the periodic table that contain the *metals*, *nonmetals*, and *metalloids (semimetals)*.

periodic table  
period (of periodic table)  
group (of periodic table)  
metal  
nonmetal  
metalloid (semimetal)

<b>2.6 Chemical Formulas; Molecular and Ionic Substances</b>	
<ul style="list-style-type: none"> <li>Determine when the <i>chemical formula</i> of a compound represents a <i>molecule</i>.</li> <li>Determine whether a chemical formula is also a <i>molecular formula</i>.</li> <li>Define <i>ion</i>, <i>cation</i>, and <i>anion</i>.</li> <li>Classify compounds as <i>ionic</i> or <i>molecular</i>.</li> <li>Define and provide examples for the term <i>formula unit</i>.</li> <li>Specify the charge on all substances, ionic and molecular.</li> <li>Write an ionic formula, given the ions. <b>Example 2.3</b></li> </ul>	chemical formula molecule molecular formula polymer monomer ion anion cation ionic compound formula unit
<b>2.7 Organic Compounds</b>	
<ul style="list-style-type: none"> <li>List the attributes of molecular substances that make them <i>organic compounds</i>.</li> <li>Explain what makes a molecule a <i>hydrocarbon</i>.</li> <li>Recognize some <i>functional groups</i> of organic molecules.</li> </ul>	organic compound hydrocarbon functional group
<b>2.8 Naming Simple Compounds</b>	
<ul style="list-style-type: none"> <li>Recognize <i>inorganic compounds</i>.</li> <li>Learn the rules for predicting the charges of <i>monatomic ions</i> in ionic compounds.</li> <li>Apply the rules for naming monatomic ions.</li> <li>Learn the names and charges of common <i>polyatomic ions</i>.</li> <li>Name an ionic compound from its formula. <b>Example 2.4</b></li> <li>Write the formula of an ionic compound from its name. <b>Example 2.5</b></li> <li>Determine the order of elements in a <i>binary (molecular) compound</i>.</li> <li>Learn the rules for naming binary molecular compounds, including the Greek prefixes.</li> <li>Name a binary compound from its formula. <b>Example 2.6</b></li> <li>Write the formula of a binary compound from its name. <b>Example 2.7</b></li> <li>Name a binary molecular compound from its molecular model. <b>Example 2.8</b></li> <li>Recognize molecular compounds that are acids.</li> <li>Determine whether an acid is an <i>oxoacid</i>.</li> <li>Learn the approach for naming binary acids and oxoacids.</li> <li>Write the name and formula of an anion from the acid. <b>Example 2.9</b></li> <li>Recognize compounds that are <i>hydrates</i>.</li> <li>Learn the rules for naming hydrates.</li> <li>Name a hydrate from its formula. <b>Example 2.10</b></li> <li>Write the formula of a hydrate from its name. <b>Example 2.11</b></li> </ul>	chemical nomenclature inorganic compound monatomic ion polyatomic ion binary compound oxoacid hydrate

<ul style="list-style-type: none"> <li>Identify the <i>reactants</i> and <i>products</i> in a chemical equation.</li> <li>Write chemical equations using appropriate phase labels, symbols of reaction conditions, and the presence of a catalyst.</li> </ul>	chemical equation reactant product
<b>2.10 Balancing Chemical Equations</b>	
<ul style="list-style-type: none"> <li>Determine if a chemical reaction is balanced.</li> <li>Master the techniques for balancing chemical equations. <b>Example 2.12</b></li> </ul>	

## Questions and Problems

### Self-Assessment and Review Questions

**Key:** These questions test your understanding of the ideas you worked with in the chapter. These problems vary in difficulty and often can be used for the basis of discussion.

**2.1** Describe atomic theory and discuss how it explains the great variety of different substances. How does it explain chemical reactions?

**2.2** Two compounds of iron and chlorine, A and B, contain 1.270 g and 1.904 g of chlorine, respectively, for each gram of iron. Show that these amounts are in the ratio 2 : 3. Is this consistent with the law of multiple proportions? Explain.

**2.3** Explain the operation of a cathode-ray tube. Describe the deflection of cathode rays by electrically charged plates placed within the cathode-ray tube. What does this imply about cathode rays?

**2.4** Explain Millikan's oil-drop experiment.

**2.5** Describe the nuclear model of the atom. How does this model explain the results of alpha-particle scattering from metal foils?

**2.6** What are the different kinds of particles in the atom's nucleus? Compare their properties with each other and with those of an electron.

**2.7** Describe how protons and neutrons were discovered to be constituents of nuclei.

**2.8** Oxygen consists of three different \_\_\_\_\_, each having eight protons but different numbers of neutrons.

**2.9** Describe how Dalton obtained relative atomic weights.

**2.10** Briefly explain how a mass spectrometer works. What kinds of information does one obtain from the instrument?

**2.11** Define the term *atomic weight*. Why might the values of atomic weights on a planet elsewhere in the universe be different from those on earth?

**2.12** What is the name of the element in Group 4A and Period 5?

**2.13** Cite some properties that are characteristic of a metal.

**2.14** Ethane consists of molecules with two atoms of carbon and six atoms of hydrogen. Write the molecular formula for ethane.

**2.15** What is the difference between a molecular formula and a structural formula?

**2.16** What is the fundamental difference between an organic substance and an inorganic substance? Write chemical formulas of three inorganic molecules that contain carbon.

**2.17** Give an example of a binary compound that is ionic. Give an example of a binary compound that is molecular.

**2.18** Which of the following models represent a(n):

- a element
- b compound
- c mixture
- d ionic solid
- e gas made up of an element and a compound
- f mixture of elements
- g solid element
- h solid
- i liquid

**2.19** The compounds  $\text{CuCl}$  and  $\text{CuCl}_2$  were formerly called cuprous chloride and cupric chloride, respectively. What are their names using the Stock system of nomenclature? What are the advantages of the Stock system of nomenclature over the former one?

**2.20** Explain what is meant by the term *balanced chemical equation*.

**2.21** How many protons, neutrons, and electrons are in  $^{119}\text{Sn}^{2+}$ ?

- a 50 p, 69 n, 48  $e^-$
- b 50 p, 69 n, 50  $e^-$
- c 119 p, 50 n, 69  $e^-$
- d 69 p, 50 n, 69 e
- e 50 p, 119 n, 52  $e^-$

**2.22** The atomic weight of Ga is 69.72 amu. There are only two naturally occurring isotopes of gallium:  $^{69}\text{Ga}$ , with a mass of 69.0 amu, and  $^{71}\text{Ga}$ , with a mass of 71.0 amu. The natural abundance of the  $^{69}\text{Ga}$  isotope is approximately:

- a 15%
- b 30%
- c 50%
- d 65%
- e 80%

**2.23** In which of the following are the name and formula correctly paired?

- a sodium sulfite:  $\text{Na}_2\text{S}$
- b calcium carbonate:  $\text{Ca}(\text{CO}_3)_2$
- c magnesium hydroxide:  $\text{Mg}(\text{OH})_2$
- d nitrite:  $\text{NO}_2$
- e iron (III) oxide:  $\text{FeO}$

**2.24** A chunk of an unidentified element (let's call it element "X") is reacted with sulfur to form an ionic compound with the chemical formula  $\text{X}_2\text{S}$ . Which of the following elements is the most likely identity of X?

- a Mg
- b Li
- c Al
- d C
- e Cl

## Concept Explorations

**Key:** Concept explorations are comprehensive problems that provide a framework that will enable you to explore and learn many of the critical concepts and ideas in each chapter. If you master the concepts associated with these explorations, you will have a better understanding of many important chemistry ideas and will be more successful in solving all types of chemistry problems. These problems are well suited for group work and for use as in-class activities.

### 2.25 Average Atomic Weight

**Part 1:** Consider the four identical spheres below, each with a mass of 2.00 g.

Calculate the average mass of a sphere in this sample.

**Part 2:** Now consider a sample that consists of four spheres, each with a different mass: blue mass is 2.00 g, red mass is 1.75 g, green mass is 3.00 g, and yellow mass is 1.25 g.

- Calculate the average mass of a sphere in this sample.
- How does the average mass for a sphere in this sample compare with the average mass of the sample that consisted just of the blue spheres? How can such different samples have their averages turn out the way they did?

**Part 3:** Consider two jars. One jar contains 100 blue spheres, and the other jar contains 25 each of red, blue, green, and yellow colors mixed together.

- If you were to remove 50 blue spheres from the jar containing just the blue spheres, what would be the total mass of spheres left in the jar? (Note that the masses of the spheres are given in Part 2.)
- If you were to remove 50 spheres from the jar containing the mixture (assume you get a representative distribution of colors), what would be the total mass of spheres left in the jar?
- In the case of the mixture of spheres, does the average mass of the spheres *necessarily* represent the mass of an individual sphere in the sample?
- If you had 80.0 grams of spheres from the blue sample, how many spheres would you have?
- If you had 60.0 grams of spheres from the mixed-color sample, how many spheres would you have? What assumption did you make about your sample when performing this calculation?

**Part 4:** Consider a sample that consists of three green spheres and one blue sphere. The green mass is 3.00 g, and the blue mass is 1.00 g.

- Calculate the *fractional abundance* of each sphere in the sample.
- Use the fractional abundance to calculate the average mass of the spheres in this sample.
- How are the ideas developed in this Concept Exploration related to the atomic weights of the elements?

### 2.26 Model of the Atom

Consider the following depictions of two atoms, which have been greatly enlarged so you can see the subatomic particles.

- How many protons are present in atom A?
- What is the significance of the number of protons depicted in atom A or any atom?
- Can you identify the real element represented by the drawing of atom A? If so, what element does it represent?
- What is the charge on atom A? Explain how you arrived at your answer.
- Write the nuclide symbol of atom A.
- Write the atomic symbol and the atomic number of atom B.
- What is the mass number of atom B? How does this mass number compare with that of atom A?
- What is the charge on atom B?
- Write the nuclide symbol of atom B.
- Draw pictures like those above of  ${}^6_3\text{Li}^+$  and  ${}^6_3\text{Li}^-$  atoms. What are the mass number and atomic number of each of these atoms?
- Consider the two atoms depicted in this problem and the two that you just drew. What is the total number of lithium isotopes depicted? How did you make your decision?
- Is the mass number of an isotope of an atom equal to the mass of the isotope of the atom? Be sure to explain your answer.

## Conceptual Problems

**Key:** These problems are designed to check your understanding of the concepts associated with some of the main topics presented in each chapter. A strong conceptual understanding of chemistry is the foundation for both applying chemical knowledge and solving chemical problems.

These problems vary in level of difficulty and often can be used as a basis for group discussion.

**2.27** One of the early models of the atom proposed that atoms were wispy balls of positive charge with the electrons evenly distributed throughout. What would you expect to

observe if you conducted Rutherford's experiment and the atom had this structure?

2.28 A friend is trying to balance the following equation:

He presents you with his version of the "balanced" equation:

You immediately recognize that he has committed a serious error; however, he argues that there is nothing wrong, since the equation is balanced. What reason can you give to convince him that his "method" of balancing the equation is flawed?

2.29 Given that the periodic table is an organizational scheme for the elements, what might be some other logical ways in which to group the elements that would provide meaningful chemical information in a periodic table of your own devising?

2.30 You discover a new set of polyatomic anions that has the newly discovered element "X" combined with oxygen. Since you made the discovery, you get to choose the names for these new polyatomic ions. In developing the names, you want to pay attention to convention. A colleague in your lab has come up with a name that she really likes for one of the ions. How would you name the following in a way consistent with her name?

**Formula**      **Name**

2.31 You have the mythical metal element "X" that can exist as  $\text{X}^+$ ,  $\text{X}^{2+}$ , and  $\text{X}^{5+}$  ions.

a What would be the chemical formula for compounds formed from the combination of each of the X ions and  $\text{SO}_4^{2-}$ ?

b If the name of the element X is exy, what would be the names of each of the compounds from part a of this problem?

2.32 Match the molecular model with the correct chemical formula:  $\text{CH}_3\text{OH}$ ,  $\text{NH}_3$ ,  $\text{KCl}$ ,  $\text{H}_2\text{O}$ .

2.33 Consider a hypothetical case in which the charge on a proton is twice that of an electron. Using this hypothetical case, and the fact that atoms maintain a charge of 0, how many protons, neutrons, and electrons would a potassium-39 atom contain?

2.34 Currently, the atomic mass unit (amu) is based on being exactly one-twelfth the mass of a carbon-12 atom and is equal to  $1.66 \times 10^{-27}$  kg.

a If the amu were based on sodium-23 with a mass equal to exactly 1/23 of the mass of a sodium-23 atom, would the mass of the amu be different?

b If the new mass of the amu based on sodium-23 is  $1.67 \times 10^{-27}$  kg, how would the mass of a hydrogen atom, in amu, compare with the current mass of a hydrogen atom in amu?

2.35 For each of the following chemical reactions, write the correct element and/or compound symbols, formulas, and coefficients needed to produce complete, balanced equations. In all cases, the reactants are elements and the products are binary compounds.

2.36 You perform a chemical reaction using the hypothetical elements A and B. These elements are represented by their molecular models shown below:

The product of the reaction represented by molecular models is

a Using the molecular models and the boxes, present a balanced chemical equation for the reaction of elements A and B.

b Using the symbols A and  $\text{B}_2$  for the chemical reaction, write a balanced chemical equation.

c What are some real-element possibilities for element B?

## Practice Problems

**Key:** These problems are for practice in applying problem-solving skills. They are divided by topic, and some are keyed to exercises (see the ends of the exercises). The problems are arranged in matching pairs; the odd-numbered problem of each pair is listed first, and its answer is given in the back of the book.

2.37 What is the name of the element represented by each of the following atomic symbols?

a He      b H      c Pd      d Sr

2.38 For each atomic symbol, give the name of the element.

a Be      b Ag      c Si      d C

2.39 Give the atomic symbol for each of the following elements.

a potassium      b sulfur      c iron      d manganese

2.40 Give the atomic symbol for each of the following elements.

a copper      b calcium      c mercury      d tin

### Electrons, Protons, and Neutrons

**2.41** A student has determined the mass-to-charge ratio for an electron to be  $5.64 \times 10^{-12}$  kg/C. In another experiment, using Millikan's oil-drop apparatus, he found the charge on the electron to be  $1.605 \times 10^{-19}$  C. What would be the mass of the electron, according to these data?

**2.42** The mass-to-charge ratio for the positive ion  $F^+$  is  $1.97 \times 10^{-7}$  kg/C. Using the value of  $1.602 \times 10^{-19}$  C for the charge on the ion, calculate the mass of the fluorine atom. (The mass of the electron is negligible compared with that of the ion, so the ion mass is essentially the atomic weight.)

**2.43** The following table gives the number of protons and neutrons in the nuclei of various atoms. Which atom is the isotope of atom A? Which atom has the same mass number as atom A?

	<i>Protons</i>	<i>Neutrons</i>
Atom A	18	19
Atom B	16	19
Atom C	18	18
Atom D	17	20

**2.44** The following table gives the number of protons and neutrons in the nuclei of various atoms. Which atom is the isotope of atom A? Which atom has the same mass number as atom A?

	<i>Protons</i>	<i>Neutrons</i>
Atom A	32	39
Atom B	33	38
Atom C	38	50
Atom D	32	38

**2.45** Naturally occurring chlorine is a mixture of the isotopes Cl-35 and Cl-37. How many protons and how many neutrons are there in each isotope? How many electrons are there in the neutral atoms?

**2.46** Naturally occurring nitrogen is a mixture of  $^{14}\text{N}$  and  $^{15}\text{N}$ . Give the number of protons, neutrons, and electrons in the neutral atom of each isotope.

**2.47** What is the nuclide symbol for the nucleus that contains 11 protons and 12 neutrons?

**2.48** An atom contains 34 protons and 45 neutrons. What is the nuclide symbol for the nucleus?

### Atomic Weights

**2.49** Ammonia is a gas with a characteristic pungent odor. It is sold as a water solution for use in household cleaning. The gas is a compound of nitrogen and hydrogen in the atomic ratio 1 : 3. A sample of ammonia contains 7.933 g N and 1.712 g H. What is the atomic weight of N relative to H?

**2.50** Hydrogen sulfide is a gas with the odor of rotten eggs. The gas can sometimes be detected in automobile exhaust. It is a compound of hydrogen and sulfur in the atomic ratio 2 : 1. A sample of hydrogen sulfide contains 0.587 g H and 9.330 g S. What is the atomic weight of S relative to H?

**2.51** Calculate the atomic weight of an element with two naturally occurring isotopes, from the following data:

<i>Isotope</i>	<i>Isotopic Mass (amu)</i>	<i>Fractional Abundance</i>
X-63	62.930	0.6909
X-65	64.928	0.3091

What is the identity of element X?

**2.52** An element has two naturally occurring isotopes with the following masses and abundances:

<i>Isotopic Mass (amu)</i>	<i>Fractional Abundance</i>
49.9472	$2.500 \times 10^{-3}$
50.9440	0.9975

What is the atomic weight of this element? What is the identity of the element?

**2.53** An element has three naturally occurring isotopes with the following masses and abundances:

<i>Isotopic Mass (amu)</i>	<i>Fractional Abundance</i>
38.964	0.9326
39.964	$1.000 \times 10^{-4}$
40.962	0.0673

Calculate the atomic weight of this element. What is the identity of the element?

**2.54** An element has three naturally occurring isotopes with the following masses and abundances:

<i>Isotopic Mass (amu)</i>	<i>Fractional Abundance</i>
27.977	0.9221
28.976	0.0470
29.974	0.0309

Calculate the atomic weight of this element. What is the identity of the element?

**2.55** While traveling to a distant universe, you discover the hypothetical element "X." You obtain a representative sample of the element and discover that it is made up of two isotopes, X-23 and X-25. To help your science team calculate the atomic weight of the substance, you send the following drawing of your sample with your report.

In the report, you also inform the science team that the brown atoms are X-23, which have an isotopic mass of 23.02 amu, and the green atoms are X-25, which have an isotopic mass of 25.147 amu. What is the atomic weight of element X?

**2.56** While roaming a parallel universe, you discover the hypothetical element "Z." You obtain a representative sample of the element and discover that it is made up of two isotopes, Z-47 and Z-51. To help your science team calculate the atomic weight of the substance, you send the following drawing of your sample with your report.

In the report, you also inform the science team that the blue atoms are Z-47, which have an isotopic mass of 47.621 amu, and the orange atoms are Z-51, which have an isotopic mass of 51.217 amu. What is the atomic weight of element Z?

### Periodic Table

**2.57** Identify the group and period for each of the following. Refer to the periodic table (Figure 2.15 or inside front cover). Label each as a metal, nonmetal, or metalloid.

- a** C   **b** Po   **c** Cr   **d** Mg   **e** B

**2.58** Refer to the periodic table (Figure 2.15 or inside front cover) and obtain the group and period for each of the following elements. Also determine whether the element is a metal, nonmetal, or metalloid.

- a** V   **b** Rb   **c** B   **d** I   **e** He

**2.59** Refer to the periodic table (Figure 2.15 or inside front cover) and answer the following questions.

- a** What Group 6A element is a metalloid?  
**b** What is the Group 3A element in Period 3?

**2.60** Refer to the periodic table (Figure 2.15 or inside front cover) and answer the following questions.

- a** What Group 5A element is a metal?  
**b** What is the Group 2A element in Period 2?

**2.61** Give one example (atomic symbol and name) for each of the following.

- a** a main-group (representative) element in the second period  
**b** a halogen  
**c** a transition element in the fourth period  
**d** a lanthanide element

**2.62** Give one example (atomic symbol and name) for each of the following.

- a** a transition element in the fourth period  
**b** an alkali metal  
**c** a main-group (representative) element in the third period  
**d** an actinide element

### Molecular and Ionic Substances

**2.63** The normal form of the element sulfur is a brittle, yellow solid. This is a molecular substance,  $S_8$ . If this solid is vaporized, it first forms  $S_8$  molecules; but at high temperature,  $S_2$  molecules are formed. How do the molecules of the solid sulfur and of the hot vapor differ? How are the molecules alike?

**2.64** White phosphorus is available in sticks, which have a waxy appearance. This is a molecular substance,  $P_4$ . When this solid is vaporized, it first forms  $P_4$  molecules; but at high temperature,  $P_2$  molecules are formed. How do the molecules of white phosphorus and those of the hot vapor differ? How are the molecules alike?

**2.65** A 4.19-g sample of nitrous oxide (an anesthetic, sometimes called laughing gas) contains  $5.73 \times 10^{22}$   $N_2O$

molecules. How many nitrogen atoms are in this sample? How many nitrogen atoms are in 2.67 g of nitrous oxide?

**2.66** Nitric acid is composed of  $HNO_3$  molecules. A sample weighing 4.50 g contains  $4.30 \times 10^{22}$   $HNO_3$  molecules. How many nitrogen atoms are in this sample? How many oxygen atoms are in 61.0 g of nitric acid?

**2.67** A sample of ammonia,  $NH_3$ , contains  $1.2 \times 10^{23}$  hydrogen atoms. How many  $NH_3$  molecules are in this sample?

**2.68** A sample of ethanol (ethyl alcohol),  $C_2H_5OH$ , contains  $4.2 \times 10^{23}$  hydrogen atoms. How many  $C_2H_5OH$  molecules are in this sample?

**2.69** Give the molecular formula for each of the following structural formulas.

**2.70** What molecular formula corresponds to each of the following structural formulas?

**2.71** Write the molecular formula for each of the following compounds represented by molecular models.

2.72 Write the molecular formula for each of the following compounds represented by molecular models.

2.73 Iron(II) nitrate has the formula  $\text{Fe}(\text{NO}_3)_2$ . What is the ratio of iron atoms to oxygen atoms in this compound?

2.74 Ammonium phosphate,  $(\text{NH}_4)_3\text{PO}_4$ , has how many oxygen atoms for each nitrogen atom?

2.75 Write the formula for the compound of each of the following pairs of ions.

- a  $\text{Fe}^{3+}$  and  $\text{CN}^-$
- b  $\text{K}^+$  and  $\text{CO}_3^{2-}$
- c  $\text{Li}^+$  and  $\text{N}^{3-}$
- d  $\text{Ca}^{2+}$  and  $\text{P}^{3-}$

2.76 For each of the following pairs of ions, write the formula of the corresponding compound.

- a  $\text{Co}^{2+}$  and  $\text{N}^{3-}$
- b  $\text{NH}_4^+$  and  $\text{PO}_4^{3-}$
- c  $\text{Na}^+$  and  $\text{SO}_3^{2-}$
- d  $\text{Fe}^{3+}$  and  $\text{OH}^-$

### Chemical Nomenclature

2.77 Name the following compounds.

- a  $\text{Na}_2\text{SO}_4$
- b  $\text{Na}_3\text{N}$
- c  $\text{CuCl}$
- d  $\text{Cr}_2\text{O}_3$

2.78 Name the following compounds.

- a  $\text{CaO}$
- b  $\text{Mn}_2\text{O}_3$
- c  $\text{NH}_4\text{HCO}_3$
- d  $\text{Cu}(\text{NO}_3)_2$

2.79 Write the formulas of:

- a iron(III) phosphate
- b potassium sulfide
- c magnesium carbonate
- d manganese(II) sulfite

2.80 Write the formulas of:

- a sodium thiosulfate
- b copper(II) hydroxide
- c calcium hydrogen carbonate
- d chromium(III) phosphide

2.81 For each of the following binary compounds, decide whether the compound is expected to be ionic or molecular.

- a  $\text{SeF}_4$
- b  $\text{LiBr}$
- c  $\text{SiF}_4$
- d  $\text{Cs}_2\text{O}$

2.82 For each of the following binary compounds, decide whether the compound is expected to be ionic or molecular.

- a  $\text{H}_2\text{O}$
- b  $\text{As}_4\text{O}_6$
- c  $\text{ClF}_3$
- d  $\text{Fe}_2\text{O}_3$

2.83 Give systematic names to the following binary compounds.

- a  $\text{HI}$
- b  $\text{P}_2\text{O}_5$
- c  $\text{AsH}_3$
- d  $\text{ClO}_2$

2.84 Give systematic names to the following binary compounds.

- a  $\text{N}_2\text{F}_2$
- b  $\text{CF}_4$
- c  $\text{N}_2\text{O}_5$
- d  $\text{As}_4\text{O}_6$

2.85 Write the formulas of the following compounds.

- a nitrogen tribromide
- b xenon hexafluoride
- c carbon monoxide
- d dichlorine pentoxide

2.86 Write the formulas of the following compounds.

- a diphosphorus pentoxide
- b nitrogen dioxide
- c dinitrogen tetrafluoride
- d boron trifluoride

2.87 Write the systematic name for each of the following compounds represented by a molecular model.

2.88 Write the systematic name for each of the following molecules represented by a molecular model.

2.89 Give the name and formula of the acid corresponding to each of the following oxoanions.

- a sulfite ion,  $\text{SO}_3^{2-}$
- b hyponitrite ion,  $\text{N}_2\text{O}_2^{2-}$
- c disulfite ion,  $\text{S}_2\text{O}_5^{2-}$
- d arsenate ion,  $\text{AsO}_4^{3-}$

2.90 Give the name and formula of the acid corresponding to each of the following oxoanions.

- a selenite ion,  $\text{SeO}_3^{2-}$
- b chlorite ion,  $\text{ClO}_2^-$
- c hypoiodite ion,  $\text{IO}^-$
- d nitrate ion,  $\text{NO}_3^-$

2.91 Glauber's salt has the formula  $\text{Na}_2\text{SO}_4 \cdot 10\text{H}_2\text{O}$ . What is the chemical name of this substance?

2.92 Emerald-green crystals of the substance  $\text{NiSO}_4 \cdot 6\text{H}_2\text{O}$  are used in nickel plating. What is the chemical name of this compound?

2.93 Iron(II) sulfate heptahydrate is a blue-green, crystalline compound used to prepare other iron compounds. What is the formula of iron(II) sulfate heptahydrate?

**2.94** Cobalt(II) chloride hexahydrate has a pink color. It loses water on heating and changes to a blue-colored compound. What is the formula of cobalt(II) chloride hexahydrate?

### Chemical Equations

**2.95** For the balanced chemical equation  $\text{Ca}(\text{NO}_3)_2 + \text{Na}_2\text{CO}_3 \longrightarrow \text{CaCO}_3 + 2\text{NaNO}_3$ , how many oxygen atoms are on the left side?

**2.96** In the equation  $2\text{PbS} + \text{O}_2 \longrightarrow 2\text{PbO} + 2\text{SO}_2$ , how many oxygen atoms are there on the right side? Is the equation balanced as written?

**2.97** Balance the following equations.

**2.98** Balance the following equations.

**2.99** Solid calcium phosphate and aqueous sulfuric acid solution react to give calcium sulfate, which comes out of the solution as a solid. The other product is phosphoric acid, which remains in solution. Write a balanced equation for the reaction using complete formulas for the compounds with phase labels.

**2.100** Solid sodium metal reacts with water, giving a solution of sodium hydroxide and releasing hydrogen gas. Write a balanced equation for the reaction using complete formulas for the compounds with phase labels.

**2.101** An aqueous solution of ammonium chloride and barium hydroxide is heated, and the compounds react to give off ammonia gas. Barium chloride solution and water are also products. Write a balanced equation for the reaction using complete formulas for the compounds with phase labels; indicate that the reactants are heated.

**2.102** Lead metal is produced by heating solid lead(II) sulfide with solid lead(II) sulfate, resulting in liquid lead and sulfur dioxide gas. Write a balanced equation for the reaction using complete formulas for the compounds with phase labels; indicate that the reactants are heated.

## General Problems

**Key:** These problems provide more practice but are not divided by topic or keyed to exercises. Each section ends with essay questions, each of which is color coded to refer to the *A Chemist Looks at Frontiers* (purple) chapter essay on which it is based. Odd-numbered problems and the even-numbered problems that follow are similar; answers to all odd-numbered problems except the essay questions are given in the back of the book.

**2.103** Two samples of different compounds of nitrogen and oxygen have the following compositions. Show that the compounds follow the law of multiple proportions. What is the ratio of oxygen in the two compounds for a fixed amount of nitrogen?

	Amount N	Amount O
Compound A	1.206 g	2.755 g
Compound B	1.651 g	4.714 g

**2.104** Two samples of different compounds of sulfur and oxygen have the following compositions. Show that the compounds follow the law of multiple proportions. What is the ratio of oxygen in the two compounds for a fixed amount of sulfur?

	Amount S	Amount O
Compound A	1.210 g	1.811 g
Compound B	1.783 g	1.779 g

**2.105** In a series of oil-drop experiments, the charges measured on the oil drops were  $-4.80 \times 10^{-19}$  C,  $-6.40 \times 10^{-19}$  C,  $-9.60 \times 10^{-19}$  C, and  $-1.28 \times 10^{-18}$  C. What is the smallest difference in charge between any two drops? If this is assumed to be the charge on the electron, how many excess electrons are there on each drop?

**2.106** In a hypothetical universe, an oil-drop experiment gave the following measurements of charges on oil drops:  $-5.55 \times 10^{-19}$  C,  $-9.25 \times 10^{-19}$  C,  $-1.11 \times 10^{-18}$  C, and  $-1.48 \times 10^{-18}$  C. Assume that the smallest difference in charge equals the unit of negative charge in this universe. What is the value of this unit of charge? How many units of excess negative charge are there on each oil drop?

**2.107** Compounds of europium, Eu, are used to make color television screens. The europium nucleus has a charge of +63. How many electrons are there in the neutral atom? in the  $\text{Eu}^{3+}$  ion?

**2.108** Cesium, Cs, is used in photoelectric cells ("electric eyes"). The cesium nucleus has a charge of +55. What is the number of electrons in the neutral atom? in the  $\text{Cs}^+$  ion?

**2.109** A nucleus of mass number 81 contains 46 neutrons. An atomic ion of this element has 36 electrons in it. Write the symbol for this atomic ion (give the symbol for the nucleus and give the ionic charge as a right superscript).

**2.110** One isotope of a metallic element has mass number 74 and has 51 neutrons in the nucleus. An atomic ion has 18 electrons. Write the symbol for this ion (give the symbol for the nucleus and give the ionic charge as a right superscript).

**2.111** Obtain the fractional abundances for the two naturally occurring isotopes of europium. The masses of the isotopes are  $^{151}\text{Eu}$ , 150.9196 amu;  $^{153}\text{Eu}$ , 152.9209 amu. The atomic weight is 151.9641 amu.

**2.112** Silver has two naturally occurring isotopes, one of mass 106.91 amu and the other of mass 108.90 amu. Find the fractional abundances for these two isotopes. The atomic weight is 107.87 amu.

**2.113** Identify the following elements, giving their name and atomic symbol.

- a a nonmetal that is normally a liquid
- b a normally gaseous element in Group 1A
- c a transition element in Group 5B, Period 5
- d the halogen in Period 2

**2.114** Identify the following elements, giving their name and atomic symbol.

- a a normally liquid element in Group 7A
- b a metal that is normally a liquid
- c a main-group element in Group 3A, Period 3
- d the alkali metal in Period 4

**2.115** Give the names of the following ions.

- a  $\text{Cr}^{3+}$
- b  $\text{Pb}^{4+}$
- c  $\text{Ti}^{2+}$
- d  $\text{Cu}^{2+}$

**2.116** Give the names of the following ions.

- a  $\text{Mn}^{2+}$
- b  $\text{Ni}^{2+}$
- c  $\text{Co}^{2+}$
- d  $\text{Fe}^{3+}$

**2.117** Write formulas for all the ionic compounds that can be formed by combinations of these ions:  $\text{Na}^+$ ,  $\text{Co}^{2+}$ ,  $\text{SO}_4^{2-}$ , and  $\text{Cl}^-$ .

**2.118** Write formulas for all the ionic compounds that can be formed by combinations of these ions:  $\text{Mg}^{2+}$ ,  $\text{Cr}^{3+}$ ,  $\text{S}^{2-}$ , and  $\text{NO}_3^-$ .

**2.119** Name the following compounds.

- a  $\text{Sn}_3(\text{PO}_4)_2$
- b  $\text{NH}_4\text{NO}_2$
- c  $\text{Mg}(\text{OH})_2$
- d  $\text{NiSO}_3$

**2.120** Name the following compounds.

- a  $\text{Cu}(\text{NO}_2)_2$
- b  $(\text{NH}_4)_3\text{P}$
- c  $\text{K}_2\text{SO}_3$
- d  $\text{Hg}_3\text{N}_2$

**2.121** Give the formulas for the following compounds.

- a mercury(I) sulfide
- b cobalt(III) sulfite
- c ammonium dichromate
- d aluminum fluoride

**2.122** Give the formulas for the following compounds.

- a hydrogen peroxide
- b magnesium phosphate
- c lead(IV) phosphide
- d calcium carbonate

**2.123** Name the following molecular compounds.

- a  $\text{AsBr}_3$
- b  $\text{H}_2\text{Te}$
- c  $\text{P}_2\text{O}_5$
- d  $\text{SiO}_2$

**2.124** Name the following molecular compounds.

- a  $\text{ClF}_4$
- b  $\text{CS}_2$
- c  $\text{PF}_3$
- d  $\text{SF}_6$

**2.125** Balance the following equations.

- a  $\text{C}_2\text{H}_6 + \text{O}_2 \longrightarrow \text{CO}_2 + \text{H}_2\text{O}$
- b  $\text{P}_4\text{O}_6 + \text{H}_2\text{O} \longrightarrow \text{H}_3\text{PO}_3$
- c  $\text{KClO}_3 \longrightarrow \text{KCl} + \text{KClO}_4$
- d  $(\text{NH}_4)_2\text{SO}_4 + \text{NaOH} \longrightarrow \text{NH}_3 + \text{H}_2\text{O} + \text{Na}_2\text{SO}_4$
- e  $\text{NBr}_3 + \text{NaOH} \longrightarrow \text{N}_2 + \text{NaBr} + \text{HOBr}$

**2.126** Balance the following equations.

- a  $\text{NaOH} + \text{H}_2\text{CO}_3 \longrightarrow \text{Na}_2\text{CO}_3 + \text{H}_2\text{O}$
- b  $\text{SiCl}_4 + \text{H}_2\text{O} \longrightarrow \text{SiO}_2 + \text{HCl}$
- c  $\text{Ca}_3(\text{PO}_4)_2 + \text{C} \longrightarrow \text{Ca}_3\text{P}_2 + \text{CO}$
- d  $\text{H}_2\text{S} + \text{O}_2 \longrightarrow \text{SO}_2 + \text{H}_2\text{O}$
- e  $\text{N}_2\text{O}_5 \longrightarrow \text{NO}_2 + \text{O}_2$

**2.127** A monatomic ion has a charge of +4. The nucleus of the ion has a mass number of 235. The number of neutrons in the nucleus is 1.55 times that of the number of protons. How many electrons are in the ion? What is the name of the element?

**2.128** A monatomic ion has a charge of +1. The nucleus of the ion has a mass number of 85. The number of neutrons in the nucleus is 1.30 times that of the number of protons. How many electrons are in the ion? What is the name of the element?

**2.129** Natural carbon, which has an atomic weight of 12.011 amu, consists of carbon-12 and carbon-13 isotopes. Given that the mass of carbon-13 is 13.00335 amu, what would be the average atomic weight (in amu) of a carbon sample prepared by mixing equal numbers of carbon atoms from a sample of natural carbon and a sample of pure carbon-13?

**2.130** A sample of natural chlorine, has an atomic weight of 35.4527 amu, consists of chlorine-35 and chlorine-37 isotopes. Given that the mass of chlorine-35 is 34.96885 amu, what is the average atomic weight (in amu) of a chlorine sample prepared by mixing equal numbers of chlorine atoms from a sample of natural chlorine and a sample of pure chlorine-35?

**2.131** What is the provisional name for the element 117? How is this name arrived at? When would this name be replaced with a permanent name?

**2.132** Elements beyond fermium have been produced by bombarding a target element with a beam of another element. What target element and what beam element were used to produce element 117?

## Strategy Problems

**Key:** As noted earlier, all of the practice and general problems are matched pairs. This section is a selection of problems that are not in matched-pair format. These challenging problems require that you employ many of the concepts and strategies that were developed in the chapter. In some cases, you will have to integrate several concepts and operational skills in order to solve the problem successfully.

**2.133** Correct any mistakes in the naming of the following compounds or ions.

- $\text{SO}_3$ : sulfite
- $\text{NO}_2$ : nitrate

$\text{PO}_4^{3-}$ : phosphite ion

$\text{N}_2$ : nitride

$\text{Mg}(\text{OH})_2$ : manganese dihydroxide

**2.134** An unknown metal (let's call it "M") is reacted with sulfur to produce a compound with the chemical formula  $\text{MS}$ . What is the charge on the metal in the compound  $\text{MS}$ ? Name a metal that could be metal M.

**2.135** Aluminum is reacted with oxygen to form a binary compound. Write the balanced chemical reaction and write the name of the compound formed by the reaction.

**2.136** Ammonia gas reacts with molecular oxygen gas to form nitrogen monoxide gas and liquid water. Write the complete balanced reaction with all proper state symbols.

**2.137** A hypothetical element X is found to have an atomic weight of 37.45 amu. Element X has only two isotopes, X-37 and X-38. The X-37 isotope has a fractional abundance of 0.7721 and an isotopic mass of 37.24. What is the isotopic mass of the other isotope?

**2.138** A monatomic ion has a charge of +3. The nucleus of the ion has a mass number of 27. The number of neutrons in the nucleus is equal to the number of electrons in a  $S^{2+}$  ion. Identify the element and indicate the number of protons, neutrons, and electrons.

**2.139** A small crystal of  $CaCl_2$  that weighs 0.12 g contains  $6.5 \times 10^{20}$  formula units of  $CaCl_2$ . What is the total number of ions (cations and anions) that make up this crystal?

**2.140** Write the formulas and names for all the ionic compounds that can form by combinations of the following ions:  $Mg^{2+}$ ,  $Cr^{3+}$ , the carbonate anion, and the nitride anion.

**2.141** Name the following compounds:

**2.142** The  $IO_3^-$  anion is called iodate. There are three related ions:  $IO^-$ ,  $IO_2^-$ , and  $IO_4^-$ . Using what you have learned about similar groups of anions, write the name for each of the following compounds:

**2.143** Write out in words the following chemical equations:

**2.144** From the following written description, write the balanced chemical equation for the reaction including state symbols. A diatomic gaseous molecule that contains 17 protons per atom is reacted with a solid element that has an atomic number of 19 to yield an ionic compound.

**2.145** An 18-mL sample of water contains  $6.0 \times 10^{23}$  water molecules. Assuming that this sample consists only of the Hydrogen-1 and Oxygen-16 isotopes, calculate the number of neutrons, protons, and electrons in this water sample.

**2.146** Name the following compounds:

**2.147** During nuclear decay a  $^{238}U$  atom can break apart into a helium-4 atom and one other atom. Assuming that no subatomic particles are destroyed during this decay process, what is the other element produced?

**2.148** Write the balanced chemical equation for the reaction of an aqueous oxacid that contains the phosphate anion with solid magnesium hydroxide. The reaction produces liquid dihydrogen monoxide and a solid ionic compound formed from the combination of magnesium cations and phosphate anions.

## Capstone Problems

**Key:** The problems under this heading combine skills, strategies, and concepts learned in previous chapters with those introduced in the current one.

**2.149** There are  $2.619 \times 10^{22}$  atoms in 1.000 g of sodium. Assume that sodium atoms are spheres of radius 1.86 Å and that they are lined up side by side. How many miles in length is the line of sodium atoms?

**2.150** There are  $1.699 \times 10^{22}$  atoms in 1.000 g of chlorine. Assume that chlorine atoms are spheres of radius 0.99 Å and that they are lined up side by side in a 0.5-g sample. How many miles in length is the line of chlorine atoms in the sample?

**2.151** A sample of green crystals of nickel(II) sulfate heptahydrate was heated carefully to produce the bluish green nickel(II) sulfate hexahydrate. What are the formulas of the hydrates? If 8.753 g of the heptahydrate produces 8.192 g of the hexahydrate, how many grams of anhydrous nickel(II) sulfate could be obtained?

**2.152** Cobalt(II) sulfate heptahydrate has pink-colored crystals. When heated carefully, it produces cobalt(II)

sulfate monohydrate, which has red crystals. What are the formulas of these hydrates? If 3.548 g of the heptahydrate yields 2.184 g of the monohydrate, how many grams of the anhydrous cobalt(II) sulfate could be obtained?

**2.153** A sample of metallic element X, weighing 3.177 g, combines with 0.6015 L of  $O_2$  gas (at normal pressure and 20.0°C) to form the metal oxide with the formula XO. If the density of  $O_2$  gas under these conditions is 1.330 g/L, what is the mass of this oxygen? The atomic weight of oxygen is 15.999 amu. What is the atomic weight of X? What is the identity of X?

**2.154** A sample of metallic element X, weighing 4.315 g, combines with 0.4810 L of  $Cl_2$  gas (at normal pressure and 20.0°C) to form the metal chloride with the formula XCl. If the density of  $Cl_2$  gas under these conditions is 2.948 g/L, what is the mass of the chlorine? The atomic weight of chlorine is 35.45 amu. What is the atomic weight of X? What is the identity of X?

**2.155**

**a** Complete the following table for an isotopically labeled atom or ion:

Name or Group # of Element	Element Name	Metal, Metalloid, or Nonmetal?	Symbol (example ${}_{15}^{31}\text{P}^{3-}$ )	Mass Number	Atomic Number	Number of ${}^0_0n$ in Nucleus	Number of ${}^+_1p$ in Nucleus	Number of $e^-$	Net Charge
				73				32	0
			${}_{53}^{131}\text{I}^-$						

**b** Complete the following table for an isotopically labeled atom or ion:

Name or Group # of Element	Element Name	Metal, Metalloid, or Nonmetal?	Symbol (example ${}_{15}^{31}\text{P}^{3-}$ )	Mass Number	Atomic Number	Number of ${}^0_0n$ in Nucleus	Number of ${}^+_1p$ in Nucleus	Number of $e^-$	Net Charge
					34	46			2-
2A			${}_{--}^{138} --$					54	2+

**2.156** A mixture is made up of 4 molecules of  $\text{CH}_3\text{CH}_2\text{CH}_2\text{OH}$  and 5 formula units of  $\text{Pb}_3(\text{PO}_4)_4 \cdot 6\text{H}_2\text{O}$ .

Why are the terms “molecules” and “formula units” used for the two substances?

- Molecules contain only covalent bonds, whereas formula units may contain ionic and/or covalent bonds.
- Molecules contain only ionic bonds, whereas formula units contain only covalent bonds.
- Molecules may contain covalent and/or ionic bonds, whereas formula units contain only ionic bonds.

How many total atoms are in the mixture? \_\_\_\_\_

How many protons are in the mixture? \_\_\_\_\_

How many electrons are in the mixture? \_\_\_\_\_

Give the theoretical maximum number of  $\text{O}_3$  molecules that could be made from the mixture. \_\_\_\_\_

How many potassium atoms are in the mixture? \_\_\_\_\_

How many lead atoms are in this mixture? \_\_\_\_\_

Give the correct name of  $\text{Pb}_3(\text{PO}_4)_4 \cdot 6\text{H}_2\text{O}$ . \_\_\_\_\_

Give the name and formula of the acid corresponding to the oxoanion present in  $\text{Pb}_3(\text{PO}_4)_4 \cdot 6\text{H}_2\text{O}$ .

Name \_\_\_\_\_ Formula \_\_\_\_\_

**2.157** A power plant is driven by the combustion of a complex fossil fuel having the formula  $\text{C}_{11}\text{H}_7\text{S}$ . Assume the air supply has a  $\text{N}_2/\text{O}_2$  molecular ratio of 3.76:1.00 and the  $\text{N}_2$  remains unreacted. In addition to the water produced, assume the fuel's C is completely converted to  $\text{CO}_2$  and its sulfur content is converted to  $\text{SO}_2$ .

- Including  $\text{N}_2$  supplied in the air, write a balanced combustion equation for the complex fuel, assuming 100% stoichiometric combustion (i.e., when there is no excess oxygen in the products). Except in the case of  $\text{N}_2$ , use only integer coefficients.
- Including  $\text{N}_2$  supplied in the air, write a balanced combustion equation for the complex fuel, assuming 133% stoichiometric combustion (i.e., when there is excess oxygen present in the products). Except in the case of  $\text{N}_2$ , use only integer coefficients.

**2.158** The element europium exists in nature as two isotopes:  ${}^{151}\text{Eu}$  has a mass of 150.9196 amu, and  ${}^{153}\text{Eu}$  has a mass of 152.9209 amu. The average atomic mass of europium is 151.96 amu.

- Calculate the relative abundance of the two europium isotopes.
- Graph each fractional abundance value as a y-axis value in association with its corresponding mass value on the x-axis. Starting from each x-axis value, where  $y = 0$ , draw a vertical line up to the fractional abundance value. The result will approximate the type of visual graph a mass spectrometer would yield for europium in the 150–155 amu range.

**2.159** Starting from ground level with the graduation of Atomic University's Class of 2018, strings of Au atoms (diameter = 288 pm) are to be bonded to one another in a vertical fashion until the top of the campus flagpole is reached. As a rite of passage, each graduate from an average class of 225 graduates is allowed to add one string containing exactly 10,000,000 Au atoms at the end of each commencement. Which graduating class will have the honor of reaching the top of the flagpole first?

**2.160**

- Complete and balance the following reactions:
  - The complete combustion of  $\text{C}_4\text{H}_{10}\text{O}$  with  $\text{O}_2$ :  

$$\text{C}_4\text{H}_{10}\text{O} + \text{_____} \longrightarrow \text{_____} + \text{_____}$$
  - $\text{Pb(s)} + \text{_____} \longrightarrow \text{_____}$   
 lead(IV) nitride
- Complete and balance the following reactions:
  - The complete combustion of  $\text{C}_7\text{H}_{16}\text{O}$  with  $\text{O}_2$ :  

$$\text{C}_8\text{H}_{18}\text{O}_2 + \text{_____} \longrightarrow \text{_____} + \text{_____}$$
  - $\text{_____} + \text{_____} \text{P}_4 \longrightarrow \text{_____}$   
 mercury(I) phosphide

## 3

# Calculations with Chemical Formulas and Equations

Zinc and iodine react to produce zinc iodide, a solution used to find flaws in composite airplane wings. Zinc iodide solution sprayed on a wing will fill a crack, if present, which shows up on an X ray as an opaque area (from the absorption of X rays by iodine ions).

Charles D. Winters/Science Source

## CONTENTS AND CONCEPTS

### Mass and Moles of Substance

Here we will establish a critical relationship between the mass of a chemical substance and the quantity of that substance (in moles).

- 3.1** Molecular Weight and Formula Weight
- 3.2** The Mole Concept

### Determining Chemical Formulas

Explore how the percentage composition and mass percentage of the elements in a chemical substance can be used to determine the chemical formula.

- 3.3** Mass Percentages from the Formula

- 3.4** Elemental Analysis: Percentages of Carbon, Hydrogen, and Oxygen

- 3.5** Determining Formulas

### Stoichiometry: Quantitative Relations in Chemical Reactions

Develop a molar interpretation of chemical equations, which then allows for calculation of the quantities of reactants and products.

- 3.6** Molar Interpretation of a Chemical Equation

- 3.7** Amounts of Substances in a Chemical Reaction

- 3.8** Limiting Reactant; Theoretical and Percentage Yields

**A**cetic acid (ah-see'-tik acid) is a colorless liquid with a sharp, vinegary odor. In fact, vinegar contains acetic acid, which accounts for vinegar's odor and sour taste. The name *vinegar* derives from the French word *vinaigre*, meaning "sour wine." Vinegar results from the fermentation of wine or cider by certain bacteria. These bacteria require oxygen, and the overall chemical change is the reaction of ethanol (alcohol) in wine with oxygen to give acetic acid (Figure 3.1).

Laboratory preparation of acetic acid may also start from ethanol, which reacts with oxygen in two steps. First, ethanol reacts with oxygen to yield a compound called acetaldehyde, in addition to water. In the second step, the acetaldehyde reacts with more oxygen to produce acetic acid. (The human body also produces acetaldehyde and then acetic acid from alcohol, as it attempts to eliminate alcohol from the system.)

This chapter focuses on two basic questions, which we can illustrate using these compounds: How do you determine the chemical formula of a substance such as acetic acid (or acetaldehyde)? How much acetic acid can you prepare from a given quantity of ethanol (or a given quantity of acetaldehyde)? These types of questions are very important in chemistry. You must know the formulas of all the substances involved in a reaction before you can write the chemical equation, and you need the balanced chemical equation to determine the quantitative relationships among the different substances in the reaction. We begin by discussing how you relate number of atoms or molecules to grams of substance, because this is the key to answering both questions.

**Figure 3.1** ▲  
**Electrostatic potential map of acetic acid molecule (CH<sub>3</sub>COOH)** Acetic acid is the compound responsible for the sour taste and smell of vinegar.

## ► Mass and Moles of Substance

You buy a quantity of groceries in several ways. You often purchase items such as oranges and lemons by counting out a particular number. Some things, such as eggs and soda, can be purchased in a “package” that represents a known quantity—for example, a dozen or a case. Bulk foods, such as peanuts or hard candy, are usually purchased by mass, because it is too tedious to count them out, and because we know that a given mass yields a certain quantity of the item. All three of these methods are used by chemists to determine the quantity of matter: counting, using a package that represents a quantity, and measuring the mass. For a chemist, it is a relatively easy matter to weigh a substance to obtain the mass. However, the number of atoms or molecules in even a seemingly minute amount is much too large to count. (You may recall from Section 2.6 that a billionth of a drop of water contains  $2 \times 10^{12}$  H<sub>2</sub>O molecules.) Nevertheless, chemists are interested in knowing such numbers. How many atoms of carbon are there in one molecule of acetic acid? How many molecules of acetic acid can be obtained from one molecule of ethanol? Before we look at how chemists solve this problem of measuring numbers of atoms, molecules, and ions, we must look at the concept of molecular weight (or molecular mass) and formula weight (or formula mass) and introduce the package chemists call the mole.

### 3.1 Molecular Weight and Formula Weight

In Chapter 2 (Section 2.4), we discussed the concept of atomic mass. We can easily extend this idea to include molecular mass. The **molecular weight** (MW) of a substance is *the sum of the atomic weights of all the atoms in a molecule of the substance*. It is, therefore, the average mass of a molecule of that substance, expressed in atomic mass units. For example, the molecular weight of water, H<sub>2</sub>O, is 18.0 amu ( $2 \times 1.0$  amu from two H atoms plus 16.0 amu from one O atom). If the molecular formula for the substance is not known, you can determine the molecular weight experimentally by means of a mass spectrometer. In later chapters, we will discuss simple, inexpensive methods for determining molecular weight.

Some chemists use the term *molecular weight* in a less strict sense for ionic as well as molecular compounds.

The **formula weight (FW)** of a substance is *the sum of the atomic weights of all atoms in a formula unit of the compound*, whether molecular or not. Sodium chloride, with the formula unit NaCl, has a formula weight of 58.44 amu (22.99 amu from Na plus 35.45 amu from Cl). NaCl is ionic, so strictly speaking the expression “molecular weight of NaCl” has no meaning. On the other hand, the molecular weight and the formula weight calculated from the molecular formula of a substance are identical. ◀

### Example 3.1 Calculating the Formula Weight from a Formula

#### Gaining Mastery Toolbox

##### Critical Concept 3.1

The formula weight of a compound is based on the number and type of each element in the compound. The formula weight is calculated by summing the weights of all atoms in the chemical formula.

##### Solution Essentials:

- Formula weight
- Atomic weight
- Atomic mass unit
- Periodic table
- Rules for significant figures and rounding

Calculate the formula weight of each of the following to three significant figures, using a table of atomic weights (AW): a. chloroform,  $\text{CHCl}_3$ ; b. iron(III) sulfate,  $\text{Fe}_2(\text{SO}_4)_3$ .

**Problem Strategy** Identify the number and type of atoms in the chemical formula. Use the periodic table to obtain the atomic weight of each of the elements present in the compounds. Taking into account the number of each atom present in the formula, sum the masses. If atoms in the formula are enclosed within parentheses as in part b, the number of each element within the parentheses should be multiplied by the subscript that follows the final, or closing, parenthesis.

#### Solution

a. The calculation is

$$\begin{array}{rcl} 1 \times \text{AM of C} & = & 12.0 \text{ amu} \\ 1 \times \text{AM of H} & = & 1.0 \text{ amu} \\ 3 \times \text{AM of Cl} & = & 3 \times 35.45 \text{ amu} = 106.4 \text{ amu} \\ \text{FM of CHCl}_3 & = & 119.4 \text{ amu} \end{array}$$

The answer rounded to three significant figures is **119 amu**.

b. The calculation is

$$\begin{array}{rcl} 2 \times \text{AM of Fe} & = & 2 \times 55.8 \text{ amu} = 111.6 \text{ amu} \\ 3 \times \text{AM of S} & = & 3 \times 32.1 \text{ amu} = 96.3 \text{ amu} \\ 3 \times 4 \times \text{AM of O} & = & 12 \times 16.00 \text{ amu} = 192.0 \text{ amu} \\ \text{FM of Fe}_2(\text{SO}_4)_3 & = & 399.9 \text{ amu} \end{array}$$

The answer rounded to three significant figures is  **$4.00 \times 10^2$  amu**.

**Answer Check** The most common error when calculating formula weights is not correctly accounting for those atoms that are enclosed in parentheses.

**Exercise 3.1** Calculate the formula weights of the following compounds, using a table of atomic weights. Give the answers to three significant figures. a. nitrogen dioxide,  $\text{NO}_2$ ; b. glucose,  $\text{C}_6\text{H}_{12}\text{O}_6$ ; c. sodium hydroxide, NaOH; d. magnesium hydroxide,  $\text{Mg}(\text{OH})_2$ .

See Problems 3.27 and 3.28.

### Example 3.2 Calculating the Formula Weight from Molecular Models

#### Gaining Mastery Toolbox

##### Critical Concept 3.2

A molecular model depicts the number and type of each atom present in the molecular compound. Molecular models can be used to determine the chemical formula of a molecular compound.

For the following two compounds, write the molecular formula and calculate the formula weight to four significant figures:

(continued)

**Example 3.2** (continued)**Solution Essentials:**

- Formula weight
- Atomic weight
- Atomic mass unit
- Periodic table
- Molecular model
- Rules for significant figures and rounding

**Problem Strategy** In order to calculate the formula weight, you need to have the total number of each type of atom present in the structure, so look at the structure and keep a tally of all the atoms present.

**Solution**

- a. This molecular model is of a molecule that is composed of two O and two H atoms. For inorganic compounds, the elements in a chemical formula are written in order such that the most metallic element is listed first. (Even though H is not metallic, it is positioned in the periodic table in such a way that it is considered to be a metal when writing formulas.) Hence, the chemical formula is  $\text{H}_2\text{O}_2$ . Using the same approach as Example 3.1, calculating the formula weight yields **34.02 amu**.
- b. This molecular model represents a molecule made up of one N atom, three O atoms, and one H atom. The chemical formula is then  $\text{HNO}_3$ . The formula weight is **63.01 amu**.

**Answer Check** Always make sure that your answer is reasonable. If you obtain a molecular weight of more than 200 amu for a simple molecular compound (this is possible but not typical), it is advisable to check your work closely.

**Exercise 3.2** For the following compounds, write the molecular formula and calculate the formula weight to three significant figures.

See Problems 3.29 and 3.30.

## 3.2 The Mole Concept

When we prepare a compound industrially or even study a reaction in the laboratory, we deal with tremendous numbers of molecules or ions. Suppose you wish to prepare acetic acid, starting from 10.0 g of ethanol. This small sample (less than 3 tea-spoonful) contains  $1.31 \times 10^{23}$  molecules, a truly staggering number. Imagine a device that counts molecules at the rate of one million per second. It would take more than four billion years—nearly the age of the earth—for this device to count that many molecules! Chemists have adopted the *mole concept* as a convenient way to deal with the enormous numbers of molecules or ions in the samples they work with.

### Definition of Mole and Molar Mass

A **mole** (symbol **mol**) is defined as *the quantity of a given substance that contains as many molecules or formula units as the number of atoms in exactly 12 g of carbon-12*. One mole of ethanol, for example, contains the same number of ethanol molecules as there are carbon atoms in 12 g of carbon-12.

The number of atoms in a 12-g sample of carbon-12 is called **Avogadro's number** (to which we give the symbol  $N_A$ ). Recent measurements of this number give the value  $6.0221367 \times 10^{23}$ , which to three significant figures is  $6.02 \times 10^{23}$ .

A mole of a substance contains Avogadro's number ( $6.02 \times 10^{23}$ ) of molecules (or formula units). The term *mole*, like a dozen or a gross, thus refers to a

© Cengage Learning/Melissa Kelly Photography

Figure 3.2 ▲

## One mole each of various substances

Sodium carbonate,  $\text{Na}_2\text{CO}_3$ , is a white, crystalline solid known commercially as soda ash. Large amounts of soda ash are used in the manufacture of glass. The hydrated compound,  $\text{Na}_2\text{CO}_3 \cdot 10\text{H}_2\text{O}$ , is known as washing soda.

particular number of things. A dozen eggs equals 12 eggs, a gross of pencils equals 144 pencils, and a mole of ethanol equals  $6.02 \times 10^{23}$  ethanol molecules.

In using the term *mole* for ionic substances, we mean the number of formula units of the substance. For example, a mole of sodium carbonate,  $\text{Na}_2\text{CO}_3$ , is a quantity containing  $6.02 \times 10^{23}$   $\text{Na}_2\text{CO}_3$  units. But each formula unit of  $\text{Na}_2\text{CO}_3$  contains two  $\text{Na}^+$  ions and one  $\text{CO}_3^{2-}$  ion. Therefore, a mole of  $\text{Na}_2\text{CO}_3$  also contains  $2 \times 6.02 \times 10^{23}$   $\text{Na}^+$  ions and  $1 \times 6.02 \times 10^{23}$   $\text{CO}_3^{2-}$  ions. ◀

When using the term *mole*, it is important to specify the formula of the unit to avoid any misunderstanding. For example, a mole of oxygen atoms (with the formula O) contains  $6.02 \times 10^{23}$  O atoms. A mole of oxygen molecules (formula  $\text{O}_2$ ) contains  $6.02 \times 10^{23}$   $\text{O}_2$  molecules—that is,  $2 \times 6.02 \times 10^{23}$  O atoms.

The **molar mass** of a substance is *the mass of one mole of the substance*. Carbon-12 has a molar weight of exactly 12 g/mol, by definition.

For all substances, the molar mass in grams per mole is numerically equal to the formula weight in atomic weight units.

Ethanol, whose molecular formula is  $\text{C}_2\text{H}_6\text{O}$  (frequently written as the condensed structural formula  $\text{C}_2\text{H}_5\text{OH}$ ), has a molecular weight of 46.1 amu and a molar mass of 46.1 g/mol. Figure 3.2 shows molar amounts of different substances.

### Example 3.3 Calculating the Mass of an Atom or Molecule

#### Gaining Mastery Toolbox

##### Critical Concept 3.3

The mass of one mole ( $6.022 \times 10^{23}$  units) of a substance is the molar mass of a substance. The units of molar mass are grams per mole (g/mol). The molar mass of each element can be found on the periodic table and the inside back cover of the text.

##### Solution Essentials:

- Mole (mol)
- Avogadro's number ( $6.022 \times 10^{23}$ )
- Molar mass
- Periodic table
- Rules for significant figures and rounding

- What is the mass in grams of a chlorine atom, Cl?
- What is the mass in grams of a hydrogen chloride molecule, HCl?

**Problem Strategy** In order to solve this type of problem, we need to consider using molar mass and the relationship between the number of atoms or molecules and the molar mass.

##### Solution

- The atomic weight of Cl is 35.5 amu, so the molar mass of Cl is 35.5 g/mol. Dividing 35.5 g (per mole) by  $6.02 \times 10^{23}$  (Avogadro's number) gives the mass of one atom.

$$\text{Mass of a Cl atom} = \frac{35.5 \text{ g}}{6.02 \times 10^{23}} = 5.90 \times 10^{-23} \text{ g}$$

- The molecular weight of HCl equals the AW of H plus the AW of Cl, or 1.01 amu + 35.5 amu = 36.5 amu. Therefore, 1 mol HCl contains 36.5 g HCl and

$$\text{Mass of an HCl molecule} = \frac{36.5 \text{ g}}{6.02 \times 10^{23}} = 6.06 \times 10^{-23} \text{ g}$$

(continued)

**Example 3.3** (continued)

**Answer Check** As you know, individual atoms and molecules are incredibly small. Therefore, whenever you are asked to calculate the mass of a few atoms or molecules, you should expect a very small mass.

**Exercise 3.3** a. What is the mass in grams of a calcium atom, Ca? b. What is the mass in grams of an ethanol molecule, C<sub>2</sub>H<sub>5</sub>OH?

See Problems 3.33, 3.34, 3.35, and 3.36.

**Mole Calculations**

Now that you know how to find the mass of one mole of a substance, there are two important questions to ask. First, how much does a given number of moles of a substance weigh? Second, how many moles of a given formula unit does a given mass of substance contain? Both questions are easily answered using dimensional analysis, or the conversion-factor method. ▶

To illustrate, consider the conversion of grams of ethanol, C<sub>2</sub>H<sub>5</sub>OH, to moles of ethanol. The molar mass of ethanol is 46.1 g/mol, so we write

Thus, the factor converting grams of ethanol to moles of ethanol is 1 mol C<sub>2</sub>H<sub>5</sub>OH/46.1 g C<sub>2</sub>H<sub>5</sub>OH. To convert moles of ethanol to grams of ethanol, we simply invert the conversion factor (46.1 g C<sub>2</sub>H<sub>5</sub>OH/1 mol C<sub>2</sub>H<sub>5</sub>OH). Note that the unit you are converting *from* is on the bottom of the conversion factor; the unit you are converting *to* is on the top.

Again, suppose you are going to prepare acetic acid from 10.0 g of ethanol, C<sub>2</sub>H<sub>5</sub>OH. How many moles of C<sub>2</sub>H<sub>5</sub>OH is this? You convert 10.0 g C<sub>2</sub>H<sub>5</sub>OH to moles C<sub>2</sub>H<sub>5</sub>OH by multiplying by the appropriate conversion factor.

$$10.0 \text{ g C}_2\text{H}_5\text{OH} \times \frac{1 \text{ mol C}_2\text{H}_5\text{OH}}{46.1 \text{ g C}_2\text{H}_5\text{OH}} = 0.217 \text{ mol C}_2\text{H}_5\text{OH}$$

Diagramming this solution (recall that the  $\Rightarrow$  indicates a conversion factor).

The following examples further illustrate this conversion-factor technique.

Alternatively, because the molar mass is the mass per mole, you can relate mass and moles by means of the formula

$$\text{Molar mass} = \text{mass/moles}$$

**Example 3.4 Converting Moles of Substance to Grams****Gaining Mastery Toolbox****Critical Concept 3.4**

Molar mass is a conversion factor. This conversion factor can be used with dimensional analysis to convert from grams of substance to moles of substance.

**Solution Essentials:**

- Molar mass
- Mole (mol)
- Conversion factor
- Dimensional analysis
- Rules for significant figures and rounding

Zinc iodide, ZnI<sub>2</sub>, can be prepared by the direct combination of elements (Figure 3.3). A chemist determines from the amounts of elements that 0.0654 mol ZnI<sub>2</sub> can form. How many grams of zinc iodide is this?

**Figure 3.3** ▶

**Reaction of zinc and iodine**  
Heat from the reaction of the elements causes some iodine to vaporize (violet vapor).

© Cengage Learning

(continued)

**Example 3.4** (continued)

**Problem Strategy** Use the molar mass to write the factor that converts from mol  $\text{ZnI}_2$  to g  $\text{ZnI}_2$ . Note that the unit you are converting from (mol  $\text{ZnI}_2$ ) is on the bottom of the conversion factor, and the unit you are converting to (g  $\text{ZnI}_2$ ) is on the top.

The problem strategy is diagrammed as

**Solution** The molar mass of  $\text{ZnI}_2$  is 319 g/mol. (The formula weight is 319 amu, which is obtained by summing the atomic weights in the formula.) Therefore,

$$0.0654 \text{ mol } \cancel{\text{ZnI}_2} \times \frac{319 \text{ g } \text{ZnI}_2}{1 \text{ mol } \cancel{\text{ZnI}_2}} = \mathbf{20.9 \text{ g } \text{ZnI}_2}$$

**Answer Check** Whenever you solve a problem of this type, be sure to write all units, making certain that they will cancel. This “built-in” feature of dimensional analysis ensures that you are correctly using the conversion factors.

**Exercise 3.4** Hydrogen peroxide,  $\text{H}_2\text{O}_2$ , is a colorless liquid. A concentrated solution of it is used as a source of oxygen for rocket propellant fuels. Dilute aqueous solutions are used as a bleach. Analysis of a solution shows that it contains 0.909 mol  $\text{H}_2\text{O}_2$  in 1.00 L of solution. What is the mass of hydrogen peroxide in this volume of solution?

See Problems 3.37, 3.38, 3.39, and 3.40.

**Example 3.5** Converting Grams of Substance to Moles**Gaining Mastery Toolbox****Critical Concept 3.5**

Molar mass is a conversion factor. This conversion factor can be used with dimensional analysis to convert from moles of substance to mass of substance.

**Solution Essentials:**

- Molar mass
- Mole (mol)
- Conversion factor
- Dimensional analysis
- Rules for significant figures and rounding

Lead(II) chromate,  $\text{PbCrO}_4$ , is a yellow paint pigment (called chrome yellow) prepared by a precipitation reaction (Figure 3.4). In a preparation, 45.6 g of lead(II) chromate is obtained as a precipitate. How many moles of  $\text{PbCrO}_4$  is this?

**Problem Strategy** Since we are starting with a mass of  $\text{PbCrO}_4$ , we need the conversion factor for grams of  $\text{PbCrO}_4$  to moles of  $\text{PbCrO}_4$ . The molar mass of  $\text{PbCrO}_4$  will provide this information.

The problem strategy is diagrammed as

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. WCN 02-200-203

**Solution** The molar mass of  $\text{PbCrO}_4$  is 323 g/mol. That is,

$$1 \text{ mol } \text{PbCrO}_4 = 323 \text{ g } \text{PbCrO}_4$$

Therefore,

$$45.6 \text{ g } \cancel{\text{PbCrO}_4} \times \frac{1 \text{ mol } \text{PbCrO}_4}{323 \text{ g } \cancel{\text{PbCrO}_4}} = \mathbf{0.141 \text{ mol } \text{PbCrO}_4}$$

**Answer Check** Note that the given amount of material in this problem (45.6 g  $\text{PbCrO}_4$ ) is much less than its molar mass (323 g/mol). Therefore, we would expect the number of moles of  $\text{PbCrO}_4$  to be much less than 1, which is the case here. Quick, alert comparisons such as this can be very valuable in checking for calculation errors.

(continued)

**Example 3.5** (continued)

**Exercise 3.5** Nitric acid,  $\text{HNO}_3$ , is a colorless, corrosive liquid used in the manufacture of nitrogen fertilizers and explosives. In an experiment to develop new explosives for mining operations, a sample containing 28.5 g of nitric acid was poured into a beaker. How many moles of  $\text{HNO}_3$  are there in this sample of nitric acid?

See Problems 3.41 and 3.42.

**Figure 3.4** ▶

**Preparation of lead(II) chromate** When lead(II) nitrate solution (colorless) is added to potassium chromate solution (clear yellow), bright yellow solid lead(II) chromate forms (giving a cloudlike formation of fine crystals).

© Cengage Learning

**Example 3.6** Calculating the Number of Molecules in a Given Mass**Gaining Mastery Toolbox****Critical Concept 3.6**

Avogadro's number is a conversion factor. Whenever you are required to know "how many" atoms, elements, molecules, etc., use the conversion factor  $1 \text{ mol} = 6.022 \times 10^{23}$ .

**Solution Essentials:**

- Molar mass
- Avogadro's number ( $6.022 \times 10^{23}$ )
- Mole (mol)
- Conversion factor
- Dimensional analysis
- Rules for significant figures and rounding

How many molecules are there in a 3.46-g sample of hydrogen chloride,  $\text{HCl}$ ?

**Problem Strategy** The number of molecules in a sample is related to moles of compound ( $1 \text{ mol HCl} = 6.02 \times 10^{23} \text{ HCl molecules}$ ). Therefore, if you first convert grams  $\text{HCl}$  to moles, then you can convert moles to number of molecules.

This problem strategy that requires two conversion factors is diagrammed as

**Solution** Here is the calculation:

$$3.46 \text{ g HCl} \times \frac{1 \text{ mol HCl}}{36.5 \text{ g HCl}} \times \frac{6.02 \times 10^{23} \text{ HCl molecules}}{1 \text{ mol HCl}} = 5.71 \times 10^{22} \text{ HCl molecules}$$

Note how the units in the numerator of a factor are canceled by the units in the denominator of the following factor.

**Answer Check** A very common mistake made when solving this type of problem is to use an incorrect conversion factor, such as  $1 \text{ mol HCl} = 6.02 \times 10^{23} \text{ g HCl}$ . If this statement were true, the mass of  $\text{HCl}$  contained in a mole would be far more than the mass of all the matter in the Milky Way galaxy! Therefore, if you end up with a gigantic mass for an answer, or get stuck on how to use the quantity  $6.02 \times 10^{23}$  as a conversion factor, improper unit assignment is a likely culprit.

**Exercise 3.6** Hydrogen cyanide,  $\text{HCN}$ , is a volatile, colorless liquid with the odor of certain fruit pits (such as peach and cherry pits). The compound is highly poisonous. How many molecules are there in 56 mg  $\text{HCN}$ , the average toxic dose?

See Problems 3.45, 3.46, 3.47, and 3.48.

**CONCEPT CHECK 3.1**

You have 1.5 moles of tricycles.

- How many moles of seats do you have?
- How many moles of tires do you have?
- How could you use parts a and b as an analogy to teach a friend about the number of moles of  $\text{OH}^-$  ions in 1.5 moles of  $\text{Mg}(\text{OH})_2$ ?

## ▶ Determining Chemical Formulas

When a chemist has discovered a new compound, the first question to answer is, What is the formula? To answer, you begin by analyzing the compound to determine amounts of the elements for a given amount of compound. This is conveniently expressed as **percentage composition**—that is, as *the mass percentages of each element in the compound*. You then determine the formula from this percentage composition. If the compound is a molecular substance, you must also find the molecular weight of the compound in order to determine the molecular formula.

The next section describes the calculation of mass percentages. Then, in two following sections, we describe how to determine a chemical formula.

### 3.3 Mass Percentages from the Formula

Suppose that *A* is a part of something—that is, part of a whole. It could be an element in a compound or one substance in a mixture. We define the **mass percentage** of *A* as *the parts of A per hundred parts of the total, by mass*. That is,

$$\text{Mass\% } A = \frac{\text{mass of } A \text{ in the whole}}{\text{mass of the whole}} \times 100\%$$

You can look at the mass percentage of *A* as the number of grams of *A* in 100 g of the whole.

The next example will provide practice with the concept of mass percentage. In this example we will start with a compound (formaldehyde,  $\text{CH}_2\text{O}$ ) whose formula is given and obtain the percentage composition.

#### Example 3.7 Calculating the Percentage Composition from the Formula

##### Gaining Mastery Toolbox

##### Critical Concept 3.7

You assume that you have one mole of compound. Making this assumption, you then know the total mass of the compound (molar mass), and from the chemical formula, the number of moles of each element in the compound.

##### Solution Essentials:

- Percentage composition
- Mass percentage
- Molar mass
- Rules for significant figures and rounding

Formaldehyde,  $\text{CH}_2\text{O}$ , is a toxic gas with a pungent odor. Large quantities are consumed in the manufacture of plastics (Figure 3.5), and a water solution of the compound is used to preserve biological specimens. Calculate the mass percentages of the elements in formaldehyde (give answers to three significant figures).

**Problem Strategy** To calculate mass percentage, you need the mass of an element in a given mass of compound. You can get this information by interpreting the formula in molar terms and then converting moles to masses, using a table of atomic weights. Thus, 1 mol  $\text{CH}_2\text{O}$  has a mass of 30.0 g and contains 1 mol C (12.0 g), 2 mol H ( $2 \times 1.01$  g), and 1 mol O (16.0 g). You divide each mass of element by the molar mass, then multiply by 100, to obtain the mass percentage.

**Solution** Here are the calculations:

$$\% \text{ C} = \frac{12.0 \text{ g}}{30.0 \text{ g}} \times 100\% = \mathbf{40.0\%}$$

$$\% \text{ H} = \frac{2 \times 1.01 \text{ g}}{30.0 \text{ g}} \times 100\% = \mathbf{6.73\%}$$

You can calculate the percentage of O in the same way, but it can also be found by subtracting the percentages of C and H from 100%:

$$\% \text{ O} = 100\% - (40.0\% + 6.73\%) = \mathbf{53.3\%}$$

(continued)

**Example 3.7** (continued)

The clear solution contains formaldehyde,  $\text{CH}_2\text{O}$ , and resorcinol,  $\text{C}_6\text{H}_4(\text{OH})_2$ . The formation of the plastic is started by adding several drops of potassium hydroxide.

**Figure 3.5** ◀  
Preparing resorcinol-formaldehyde plastic

The red plastic has formed in the beaker.

© Cengage Learning

**Answer Check** A typical mistake when working a mass percentage problem is to forget to account for the number of moles of each element given in the chemical formula. An example would be to answer this question as though the formula were  $\text{CHO}$  instead of  $\text{CH}_2\text{O}$ .

**Exercise 3.7** Ammonium nitrate,  $\text{NH}_4\text{NO}_3$ , which is prepared from nitric acid, is used as a nitrogen fertilizer. Calculate the mass percentages of the elements in ammonium nitrate (to three significant figures).

See Problems 3.57, 3.58, 3.59, and 3.60.

**Example 3.8** Calculating the Mass of an Element in a Given Mass of Compound**Gaining Mastery Toolbox****Critical Concept 3.8**

The percentage composition of an element is the mass percentage of the element. The mass percentage of an element can be used to calculate the mass of that element in a sample.

**Solution Essentials:**

- Percentage composition
- Mass percentage
- Rules for significant figures and rounding

How many grams of carbon are there in 83.5 g of formaldehyde,  $\text{CH}_2\text{O}$ ? Use the percentage composition obtained in the previous example (40.0% C, 6.73% H, 53.3% O).

**Problem Strategy** Solving this type of problem requires that you first calculate the mass percentage of the element of interest, carbon in this case (as noted in the problem, this was done in Example 3.7). Multiplying of this percentage, expressed as a decimal, times the mass of formaldehyde in the sample, will yield the mass of carbon present.

(continued)

**Example 3.8** (continued)

**Solution**  $\text{CH}_2\text{O}$  is 40.0% C, so the mass of carbon in 83.5 g  $\text{CH}_2\text{O}$  is

$$83.5 \text{ g} \times 0.400 = \mathbf{33.4 \text{ g}}$$

**Answer Check** Make sure that you have converted the percent to a decimal prior to multiplication. An answer that is more than the starting mass of material is an indication that you probably made this mistake.

**Exercise 3.8** How many grams of nitrogen, N, are there in a fertilizer containing 48.5 g of ammonium nitrate and no other nitrogen-containing compound? See Exercise 3.7 for the percentage composition of  $\text{NH}_4\text{NO}_3$ .

See Problems 3.61 and 3.62.

### 3.4 Elemental Analysis: Percentages of Carbon, Hydrogen, and Oxygen

Suppose you have a newly discovered compound whose formula you wish to determine. The first step is to obtain its percentage composition. As an example, consider the determination of the percentages of carbon, hydrogen, and oxygen in compounds containing only these three elements. The basic idea is this: You burn a sample of the compound of known mass and get  $\text{CO}_2$  and  $\text{H}_2\text{O}$ . Next you relate the masses of  $\text{CO}_2$  and  $\text{H}_2\text{O}$  to the masses of carbon and hydrogen. Then you calculate the mass percentages of C and H. You find the mass percentage of O by subtracting the mass percentages of C and H from 100.

Figure 3.6 shows an apparatus used to find the amount of carbon and hydrogen in a compound. The compound is burned in a stream of oxygen gas. The vapor of the compound and its combustion products pass over copper pellets coated with copper(II) oxide,  $\text{CuO}$ , which supplies additional oxygen and ensures that the compound is completely burned. As a result of the combustion, every mole of carbon (C) in the compound ends up as a mole of carbon dioxide ( $\text{CO}_2$ ), and every mole of hydrogen (H) ends up as one-half mole of water ( $\text{H}_2\text{O}$ ). The water is collected by a drying agent, a substance that has a strong affinity for water. The carbon dioxide is collected by chemical reaction with sodium hydroxide,  $\text{NaOH}$ . ◀ By weighing the U-tubes containing the drying agent and the sodium hydroxide before and after combustion, it is possible to determine the masses of water and carbon

Sodium hydroxide reacts with carbon dioxide according to the following equations:

**Figure 3.6** ▼

**Combustion method for determining the percentages of carbon and hydrogen in a compound**

dioxide produced. From these data, you can calculate the percentage composition of the compound.

The chapter opened with a discussion of acetic acid. The next example shows how to determine the percentage composition of this substance from combustion data. We will use this percentage composition later in Example 3.12 to determine the formula of acetic acid.

### Example 3.9 Calculating the Percentages of C and H by Combustion

#### Gaining Mastery Toolbox

##### Critical Concept 3.9

The mass percentages of carbon and hydrogen can be calculated from the masses of  $\text{CO}_2$  and  $\text{H}_2\text{O}$ . During the reaction, *all* of the carbon atoms in the sample end up in the  $\text{CO}_2$  and *all* of the hydrogen atoms end up in the  $\text{H}_2\text{O}$ . Therefore, the mass of carbon in the  $\text{CO}_2$  is equal to the mass of carbon in the sample, and the mass of hydrogen in the  $\text{H}_2\text{O}$  is equal to the mass of hydrogen in the sample. We *cannot* make the statement that the mass of oxygen in the  $\text{H}_2\text{O}$  and  $\text{CO}_2$  is equal to the mass of oxygen in the sample because oxygen is both in the sample and is a reactant.

##### Solution Essentials:

- Elemental analysis
- Percentage composition
- Mass percentage
- Molar mass
- Dimensional analysis
- Rules for significant figures and rounding

Acetic acid contains only C, H, and O. A 4.24-mg sample of acetic acid is completely burned. It gives 6.21 mg of carbon dioxide and 2.54 mg of water. What is the mass percentage of each element in acetic acid?

**Problem Strategy** Note that in the products of the combustion, all of the carbon from the sample ends up in the  $\text{CO}_2$ , all of the hydrogen ends up in the  $\text{H}_2\text{O}$ , and the oxygen is in both compounds. Because of this, you should concentrate first on the carbon and hydrogen and worry about the oxygen last. If we can determine the mass of carbon and hydrogen in the original sample, we should then be able to determine the percentage of each of these elements present in the compound. Once we know the mass percentages of carbon and hydrogen in the original compound, the remaining mass percentage (100% total) must be due to oxygen. Let's start by determining the mass of carbon that was originally contained in the compound. You first convert the mass of  $\text{CO}_2$  to moles of  $\text{CO}_2$ . Then you convert this to moles of C, noting that 1 mol C produces 1 mol  $\text{CO}_2$ . Finally, you convert to mass of C. Similarly, for hydrogen, you convert the mass of  $\text{H}_2\text{O}$  to mol  $\text{H}_2\text{O}$ , then to mol H, and finally to mass of H. (Remember that 1 mol  $\text{H}_2\text{O}$  produces 2 mol H.) Once you have the masses of C and H, you can calculate the mass percentages. Subtract from 100% to get % O.

**Solution** Following is the calculation of grams C:

$$6.21 \times 10^{-3} \text{ g } \text{CO}_2 \times \frac{1 \text{ mol } \text{CO}_2}{44.0 \text{ g } \text{CO}_2} \times \frac{1 \text{ mol C}}{1 \text{ mol } \text{CO}_2} \times \frac{12.0 \text{ g C}}{1 \text{ mol C}} \\ = 1.69 \times 10^{-3} \text{ g C (or 1.69 mg C)}$$

For hydrogen, you note that 1 mol  $\text{H}_2\text{O}$  yields 2 mol H, so you write

$$2.54 \times 10^{-3} \text{ g } \text{H}_2\text{O} \times \frac{1 \text{ mol } \text{H}_2\text{O}}{18.0 \text{ g } \text{H}_2\text{O}} \times \frac{2 \text{ mol H}}{1 \text{ mol } \text{H}_2\text{O}} \times \frac{1.01 \text{ g H}}{1 \text{ mol H}} \\ = 2.85 \times 10^{-4} \text{ g H (or 0.285 mg H)}$$

You can now calculate the mass percentages of C and H in acetic acid.

$$\text{Mass\% C} = \frac{1.69 \text{ mg}}{4.24 \text{ mg}} \times 100\% = 39.9\%$$

$$\text{Mass\% H} = \frac{0.285 \text{ mg}}{4.24 \text{ mg}} \times 100\% = 6.72\%$$

You find the mass percentage of oxygen by subtracting the sum of these percentages from 100%:

$$\text{Mass\% O} = 100\% - (39.9\% + 6.72\%) = 53.4\%$$

Thus, the percentage composition of acetic acid is **39.9% C, 6.72% H, and 53.4% O**.

**Answer Check** The most common error for this type of problem is not taking into account the fact that each mole of water contains two moles of hydrogen.

**Exercise 3.9** A 3.87-mg sample of ascorbic acid (vitamin C) gives 5.80 mg  $\text{CO}_2$  and 1.58 mg  $\text{H}_2\text{O}$  on combustion. What is the percentage composition of this compound (the mass percentage of each element)? Ascorbic acid contains only C, H, and O.

See Problems 3.63 and 3.64.

### ✓ CONCEPT CHECK 3.2

You perform combustion analysis on a compound that contains only C and H.

- Considering the fact that the combustion products  $\text{CO}_2$  and  $\text{H}_2\text{O}$  are colorless, how can you tell if some of the product got trapped in the  $\text{CuO}$  pellets (see Figure 3.6)?
- Would your calculated results of mass percentage of C and H be affected if some of the combustion products got trapped in the  $\text{CuO}$  pellets? If your answer is yes, how might your results differ from the expected values for the compound?

The formula of sodium peroxide, an ionic compound of  $\text{Na}^+$  and  $\text{O}_2^{2-}$ , is  $\text{Na}_2\text{O}_2$ . Its empirical formula is  $\text{NaO}$ .

© Cengage Learning/Melissa Kelly Photography

Figure 3.7 ▲

**Molecular model of hydrogen peroxide ( $\text{H}_2\text{O}_2$ )** Hydrogen peroxide has the empirical formula  $\text{HO}$  and the molecular formula  $\text{H}_2\text{O}_2$ . In order to arrive at the correct structure of molecular compounds like  $\text{H}_2\text{O}_2$  shown here, chemists must have the molecular formula.

## 3.5 Determining Formulas

The percentage composition of a compound leads directly to its empirical formula. An **empirical formula** (or **simplest formula**) for a compound is *the formula of a substance written with the smallest integer (whole number) subscripts*. For most ionic substances, the empirical formula is the formula of the compound. ◀ This is often not the case for molecular substances. For example, hydrogen peroxide has the molecular formula  $\text{H}_2\text{O}_2$ . The molecular formula, you may recall, tells you the precise number of atoms of different elements in a molecule of the substance. The empirical formula, however, merely tells you the ratio of numbers of atoms in the compound. The empirical formula of hydrogen peroxide ( $\text{H}_2\text{O}_2$ ) is  $\text{HO}$  (Figure 3.7).

Compounds with different molecular formulas can have the same empirical formula, and such substances will have the same percentage composition. An example is acetylene,  $\text{C}_2\text{H}_2$ , and benzene,  $\text{C}_6\text{H}_6$ . Acetylene is a gas used as a fuel and also in welding. Benzene, in contrast, is a liquid that is used in the manufacture of plastics and is a component of gasoline. Table 3.1 illustrates how these two compounds, with the same empirical formula, but different molecular formulas, also have different chemical structures. Because the empirical formulas of acetylene and benzene are the same, they have the same percentage composition: 92.3% C and 7.7% H, by mass.

To obtain the molecular formula of a substance, you need two pieces of information: (1) as in the previous section, the percentage composition, from which the empirical formula can be determined; and (2) the molecular weight. The molecular weight allows you to choose the correct multiple of the empirical formula for the molecular formula. We will illustrate these steps in the next three examples.

### Empirical Formula from the Composition

The empirical formula of a compound shows the ratios of numbers of atoms in the compound. You can find this formula from the composition of the compound by converting masses of the elements to moles. The next two examples show these calculations in detail.

Table 1.3 Molecular Models of Two Compounds That Have the Empirical Formula  $\text{CH}$

Although benzene and acetylene have the same empirical formula, they do not have the same molecular formula or structure.

Compound	Empirical Formula	Molecular Formula	Molecular Model
Acetylene	$\text{CH}$	$\text{C}_2\text{H}_2$	
Benzene	$\text{CH}$	$\text{C}_6\text{H}_6$	

## Instrumental Methods

# Mass Spectrometry and Molecular Formula

Some very sophisticated instruments have become indispensable to modern chemical research. One such instrument is the **mass spectrometer**, which measures the masses of positive ions produced from an extremely small sample of a substance, displaying the data as a *mass spectrum*. Figure 3.8 shows a modern benchtop mass spectrometer and the mass spectrum of methylene chloride,  $\text{CH}_2\text{Cl}_2$ . Each of the positive ions produced in the spectrometer from the substance is shown as a bar or line (called a *peak*) at the mass of the ion, in amu. (Strictly speaking, each peak appears at the mass-to-charge ratio of the ion, but the ion charge is usually one.) The height of each peak is proportional to the relative abundance of the ion. The mass spectrum of a substance can be used to identify it or, if the substance is a new one, to obtain its molecular formula. The spectrum may also give information about the structure of the molecule.

Figure 2.11 on page 41 shows a simplified diagram of a mass spectrometer, used there to separate atomic neon into its three isotopic ions. Neon gas (which consists of neon atoms) enters the spectrometer, where the atoms are ionized by bombarding them with a beam of high-energy electrons. (An electron from the beam strikes a neon atom, knocking out one of neon's electrons.) The positive ions are accelerated by a negative plate into the field of a magnet, which bends the path of each ion depending on its mass-to-charge ratio. The less massive ions are bent more strongly than the heavier ones for the same charge. In modern spectrometers, the ions fall on an electronic detector, whose current is recorded and displayed as the mass spectrum on a computer screen.

The spectrum of a molecular substance is more complicated than that of an atom. Consider methylene chloride,  $\text{CH}_2\text{Cl}_2$ . When its molecule is struck by an electron of sufficient energy, it may lose one of its own electrons (now giving two free electrons), leaving behind a positive ion:

The ion gains a great deal of energy from the collision of the molecule with an electron, and it may lose this energy by breaking into smaller pieces. For example:

Thus, the original molecule, even one as simple as  $\text{CH}_2\text{Cl}_2$ , can give rise to a number of ions. In addition, each ion may consist of atoms having more than one natural isotope, so

that each ion may occur in the spectrum as a group of several peaks. Note that the mass spectrum of methylene chloride shown in Figure 3.8 displays four prominent peaks and many smaller ones. A larger molecule can give an even more complicated mass spectrum, oftentimes yielding a “fingerprint” useful in identification. Only methylene chloride has exactly the spectrum shown in Figure 3.8. Thus, by comparing the mass spectrum of an unknown substance with those in a catalog of mass spectra of known compounds, you can determine its identity. The more information you have about the compound, the shorter the search through the catalog of spectra.

The mass spectrum itself contains a wealth of information about molecular structure. Some experience is needed to analyze the spectrum of a compound, but you can get an idea of how it is done by looking at Figure 3.8. Suppose you do not know the identity of the compound. The most intense peaks at the greatest mass usually correspond to the ion from the original molecule and give you the molecular weight. Thus, you would expect the peaks at mass 84 and mass 86 to be from the original molecular ion, so the molecular weight is approximately 84 to 86.

An elemental analysis is also possible. The two most intense peaks in Figure 3.8 are at 84 amu and 49 amu. They differ by 35 amu. Perhaps the original molecule that gives the peak at 84 amu contains a chlorine-35 atom, which is lost to give the peak at 49 amu. If this is true, you should expect another peak at mass 86, corresponding to the original molecular ion with chlorine-37 in place of a chlorine-35 atom. This is indeed what you see.

The relative heights of the peaks, which depend on the natural abundances of atoms, are also important, because they give you additional information about the elements present. The relative heights can also tell you how many atoms of a given element are in the original molecule. Naturally occurring chlorine is 75.8% chlorine-35 and 24.2% chlorine-37. If the original molecule contained only one Cl atom, the peaks at 84 amu and 86 amu would be in the ratio 0.758 : 0.242. That is, the peak at 86 amu would be about one-third the height of the one at 84 amu. In fact, the relative height is twice this value. This means that the molecular ion contains two chlorine atoms, because the chance that any such ion contains one chlorine-37 atom is then twice as great. Thus, simply by comparing relative peak heights, you can confirm the presence of particular elements.

## Instrumental Methods (continued)

INSADCO Photography/Alamy

Figure 3.8 ◀

**Mass spectrometer and the mass spectrum of methylene chloride,  $\text{CH}_2\text{Cl}_2$**  The mass spectrometer produces a mass spectrum. In the mass spectrum of  $\text{CH}_2\text{Cl}_2$ , the lines (*peaks*) at higher mass correspond to the ions  $\text{CH}_2\text{Cl}_2^+$  with different isotopes, produced by the loss of a single electron from the original  $\text{CH}_2\text{Cl}_2$  molecule. (The spectrum is from the NIST Chemistry WebBook, <http://webbook.nist.gov/chemistry/>.)

The spectrum in Figure 3.8 shows the peaks at nearest whole-number masses. There are mass spectrometers, however, that can obtain the masses of moderate-sized molecules to perhaps four decimal places. With this high resolution, you can in principle obtain the molecular formula of a substance. For example, the  $\text{CH}_2\text{Cl}_2$  molecule composed of the most abundant isotopes has a whole-number molecular mass of 84 amu (the largest peak at the right in Figure 3.8), but its mass to four decimals is 83.9534 amu. There are several other molecules with whole-number

masses of 84 amu. One of these is hexene,  $\text{C}_6\text{H}_{12}$  (the species composed of the more abundant isotopes); but, its more exact mass is 84.0939 amu. In general, molecules with different molecular formulas will have different masses, so you can turn this problem around. Given a molecular weight, you can use special computer programs to obtain the molecular formula.

■ See Problems 3.115 and 3.116.

**Example 3.10 Determining the Empirical Formula from Masses of Elements (Binary Compound)****Gaining Mastery Toolbox****Critical Concept 3.10**

The mole ratio of elements in the compound is the same ratio as the element subscripts in the empirical formula. The subscripts of the compound must be written as whole (integer) numbers. In some cases the empirical formula is the same as the molecular formula.

**Solution Essentials:**

- Empirical formula
- Molar mass
- Dimensional analysis
- Rules for significant figures and rounding

A compound of nitrogen and oxygen is analyzed, and a sample weighing 1.587 g is found to contain 0.483 g N and 1.104 g O. What is the empirical formula of the compound?

**Problem Strategy** This compound has the formula  $N_xO_y$ , where  $x$  and  $y$  are whole numbers that we need to determine. Masses of N and O are given in the problem. If we convert the masses of each of these elements to moles, they will be proportional to the subscripts in the empirical formula. The formula must be the smallest integer ratio of the elements. To obtain the smallest integers from the moles, we divide each by the smallest one. If the results are all whole numbers, they will be the subscripts in the formula. (Otherwise, you will need to multiply by some factor, as illustrated in Example 3.11.)

**Solution** You convert the masses to moles:

$$0.483 \text{ g-N} \times \frac{1 \text{ mol N}}{14.0 \text{ g-N}} = 0.0345 \text{ mol N}$$

$$1.104 \text{ g-O} \times \frac{1 \text{ mol O}}{16.00 \text{ g-O}} = 0.06900 \text{ mol O}$$

In order to obtain the smallest integers, you divide each mole number by the smaller one (0.0345 mol). For N, you get 1.00; for O, you get 2.00. Thus, the ratio of the number of N atoms to the number of O atoms is 1 to 2. Hence, the empirical formula is  $\text{NO}_2$ .

**Answer Check** Keep in mind that the empirical formula determined by this type of calculation is not necessarily the molecular formula of the compound. The only information that it provides is the smallest whole-number ratio of the elements.

**Exercise 3.10** A sample of compound weighing 83.5 g contains 33.4 g of sulfur. The rest is oxygen. What is the empirical formula? | See Problems 3.65 and 3.66.

**Example 3.11 Determining the Empirical Formula from Percentage Composition (General)****Gaining Mastery Toolbox****Critical Concept 3.11**

You assume that you are starting with 100 g of substance. By making this assumption, it simplifies the process of determining the relative masses of each element in the substance.

**Solution Essentials:**

- Empirical formula
- Percentage composition
- Molar mass
- Dimensional analysis
- Rules for significant figures and rounding

Chromium forms compounds of various colors. (The word *chromium* comes from the Greek *khroma*, meaning “color”; see Figure 3.9.) Sodium dichromate is the most important commercial chromium compound, from which many other chromium compounds are manufactured. It is a bright orange, crystalline substance. An analysis of sodium dichromate gives the following mass percentages: 17.5% Na, 39.7% Cr, and 42.8% O. What is the empirical formula of this compound? (Sodium dichromate is ionic, so it has no molecular formula.)

**Problem Strategy** Here we need to determine the whole-number values for  $x$ ,  $y$ , and  $z$  in the compound  $\text{Na}_x\text{Cr}_y\text{O}_z$ . The first task is to use the percent composition data to determine the moles of Na, Cr, and O in the compound. Then we can use mole ratios of these elements to determine the empirical formula. Assume for the purposes of this calculation that you have 100.0 g of substance. Then the mass of each element in the sample equals the numerical value of the percentage. For example, the quantity of sodium in 100 g of sodium dichromate is 17.5 g, since the substance is 17.5% Na. Now convert the masses to moles and divide each mole number by the smallest. In this example, you do not obtain a series of integers, or whole numbers, from this division. You will need to find a whole-number factor to multiply these results by to obtain integers. Normally this factor will be 2 or 3, though it might be larger.

(continued)

**Example 3.11** (continued)

© Cengage Learning

**Figure 3.9** ▲**Chromium compounds of different colors**

**Solution** Of the 100.0 g of sodium dichromate, 17.5 g is Na, 39.7 g is Cr, and 42.8 g is O. You convert these amounts to moles.

$$17.5 \text{ g Na} \times \frac{1 \text{ mol Na}}{23.0 \text{ g Na}} = 0.761 \text{ mol Na}$$

$$39.7 \text{ g Cr} \times \frac{1 \text{ mol Cr}}{52.0 \text{ g Cr}} = 0.763 \text{ mol Cr}$$

$$42.8 \text{ g O} \times \frac{1 \text{ mol O}}{16.0 \text{ g O}} = 2.68 \text{ mol O}$$

Now you divide all the mole numbers by the smallest one.

$$\text{For Na: } \frac{0.761 \text{ mol}}{0.761 \text{ mol}} = 1.00$$

$$\text{For Cr: } \frac{0.763 \text{ mol}}{0.761 \text{ mol}} = 1.00$$

$$\text{For O: } \frac{2.68 \text{ mol}}{0.761 \text{ mol}} = 3.52$$

You must decide whether these numbers are integers (whole numbers), within experimental error. If you round off the last digit, which is subject to experimental error, you get  $\text{Na}_{1.0}\text{Cr}_{1.0}\text{O}_{3.5}$ . In this case, the subscripts are not all integers. However, they can be made into integers by multiplying each one by 2; you get  $\text{Na}_{2.0}\text{Cr}_{2.0}\text{O}_{7.0}$ . Thus, the empirical formula is  **$\text{Na}_2\text{Cr}_2\text{O}_7$** .

**Answer Check** If you are working this type of problem and are not arriving at an answer that is readily converted to integers, it might be that you did not use enough significant figures throughout the calculation and/or that you rounded intermediate calculations.

**Exercise 3.11** Benzoic acid is a white, crystalline powder used as a food preservative. The compound contains 68.8% C, 5.0% H, and 26.2% O, by mass. What is its empirical formula?

See Problems 3.67, 3.68, 3.69, and 3.70.

**Molecular Formula from Empirical Formula**

The molecular formula of a compound is a multiple of its empirical formula. For example, the molecular formula of acetylene,  $\text{C}_2\text{H}_2$ , is equivalent to  $(\text{CH})_2$ , and the molecular formula of benzene,  $\text{C}_6\text{H}_6$ , is equivalent to  $(\text{CH})_6$ . Therefore, the molecular weight is some multiple of the empirical formula weight, which is obtained by summing the atomic weights of the atoms in the empirical formula. For any molecular compound, you can write

$$\text{Molecular weight} = n \times \text{empirical formula weight}$$

where  $n$  is the number of empirical formula units in the molecule. You get the molecular formula by multiplying the subscripts of the empirical formula by  $n$ , which you calculate from the equation

$$n = \frac{\text{molecular weight}}{\text{empirical formula weight}}$$

Once you determine the empirical formula for a compound, you can calculate its empirical formula weight. If you have an experimental determination of its molecular weights, you can calculate  $n$  and then the molecular formula. The next example illustrates how you use percentage composition and molecular weight to determine the molecular formula of acetic acid.

### Example 3.12 Determining the Molecular Formula from Percentage Composition and Molecular Weight

#### Gaining Mastery Toolbox

##### Critical Concept 3.12

The molecular weight of a compound is a multiple of the empirical formula weight. The multiple is an integer and can be used to determine the molecular formula of the compound from the empirical formula.

##### Solution Essentials:

- Empirical formula
- Empirical formula weight
- Molecular weight
- Percentage composition
- Dimensional analysis
- Rules for significant figures and rounding

In Example 3.9, we found the percentage composition of acetic acid to be 39.9% C, 6.72% H, and 53.4% O. Determine the empirical formula. The molecular weight of acetic acid was determined by experiment to be 60.0 amu. What is its molecular formula?

**Problem Strategy** This problem employs the same general strategy as Example 3.11, with a few additional steps. In this case the compound is composed of C, H, and O. After determining the empirical formula of the compound, you calculate the empirical formula weight. You then determine how many times more massive the molecular compound is than the empirical compound by dividing the molecular weight by the empirical formula weight. You now have a factor by which the subscripts of the empirical formula need to be multiplied to arrive at the molecular formula.

**Solution** A sample of 100.0 g of acetic acid contains 39.9 g C, 6.72 g H, and 53.4 g O. Converting these masses to moles gives 3.33 mol C, 6.67 mol H, and 3.34 mol O. Dividing the mole numbers by the smallest one gives 1.00 for C, 2.00 for H, and 1.00 for O. **The empirical formula of acetic acid is CH<sub>2</sub>O.** (You may have noted that the percentage composition of acetic acid is, within experimental error, the same as that of formaldehyde—see Example 3.7—so they must have the same empirical formula.) The empirical formula weight is 30.0 amu. Dividing the empirical formula weight into the molecular weight gives the number by which the subscripts in CH<sub>2</sub>O must be multiplied.

$$n = \frac{\text{molecular weight}}{\text{empirical formula weight}} = \frac{60.0 \text{ amu}}{30.0 \text{ amu}} = 2.00$$

**The molecular formula of acetic acid is (CH<sub>2</sub>O)<sub>2</sub>, or C<sub>2</sub>H<sub>4</sub>O<sub>2</sub>.** (A molecular model of acetic acid is shown in Figure 3.10.)

**Answer Check** Calculate the molecular weight of your answer. It should agree with the molecular weight of the compound given in the problem.

**Exercise 3.12** The percentage composition of acetaldehyde is 54.5% C, 9.2% H, and 36.3% O, and its molecular weight is 44 amu. Obtain the molecular formula of acetaldehyde.

**Figure 3.10** ▲  
Molecular model of acetic acid

See Problems 3.73, 3.74, 3.75, and 3.76.

The condensed structural formula for acetaldehyde is  $\text{CH}_3\text{CHO}$ . Its structural formula is

Determining this structural formula requires additional information.

The formula of acetic acid is often written  $\text{HC}_2\text{H}_3\text{O}_2$  to indicate that one of the hydrogen atoms is acidic (lost easily), while the other three are not (Figure 3.10). Now that you know the formulas of acetic acid and acetaldehyde (determined from the data in Exercise 3.12 to be  $\text{C}_2\text{H}_4\text{O}$ ), you can write the equations for the preparation of acetic acid described in the chapter opener. ◀ The first step consists of reacting ethanol with oxygen to obtain acetaldehyde and water. If you write the chemical equation and balance it, you obtain

In practice, the reaction is carried out with the reactants as gases (gas phase) at about  $400^\circ\text{C}$  using silver as a catalyst.

The second step consists of reacting acetaldehyde with oxygen to obtain acetic acid. Acetaldehyde liquid is mixed with a catalyst—manganese(II) acetate—and air is bubbled through it. The balanced equation is

Once you have this balanced equation, you are in a position to answer quantitative questions such as, How much acetic acid can you obtain from a 10.0-g sample of acetaldehyde? You will see how to answer such questions in the next sections.

### ✓ CONCEPT CHECK 3.3

A friend has some questions about empirical formulas and molecular formulas. You can assume that he is good at performing the calculations.

- For a problem that asked him to determine the empirical formula, he came up with the answer  $\text{C}_2\text{H}_8\text{O}_2$ . Is this a possible answer to the problem? If not, what guidance would you offer your friend?
- For another problem he came up with the answer  $\text{C}_{1.5}\text{H}_4$  as the empirical formula. Is this answer correct? Once again, if it isn't correct, what could you do to help your friend?
- Since you have been a big help, your friend asks one more question. He completed a problem of the same type as Example 3.12. His answers indicate that the compound had an empirical formula of  $\text{C}_3\text{H}_8\text{O}$  and the molecular formula  $\text{C}_3\text{H}_8\text{O}$ . Is this result possible?

## ► Stoichiometry: Quantitative Relations in Chemical Reactions

In Chapter 2, we described a chemical equation as a representation of what occurs when molecules react. We will now study chemical equations more closely to answer questions about the stoichiometry of reactions. **Stoichiometry** (pronounced “stoy-key-om'-e-tree”) is *the calculation of the quantities of reactants and products involved in a chemical reaction*. It is based on the chemical equation and on the relationship between mass and moles. Such calculations are fundamental to most quantitative work in chemistry. In the next sections, we will use the industrial Haber process for the production of ammonia to illustrate stoichiometric calculations.

### 3.6 Molar Interpretation of a Chemical Equation

In the Haber process for producing ammonia,  $\text{NH}_3$ , nitrogen (from the atmosphere) reacts with hydrogen at high temperature and pressure.

Hydrogen is usually obtained from natural gas or petroleum and so is relatively expensive. For this reason, the price of hydrogen partly determines the price of ammonia. Thus, an important question to answer is, How much hydrogen is required to give a particular quantity of ammonia? For example, how much hydrogen would be needed to produce one ton (907 kg) of ammonia? Similar kinds of questions arise throughout chemical research and industry.

To answer such quantitative questions, you must first look at the balanced chemical equation: one  $\text{N}_2$  molecule and three  $\text{H}_2$  molecules react to produce two  $\text{NH}_3$  molecules (see models above). A similar statement involving multiples of these numbers of molecules is also correct. For example,  $6.02 \times 10^{23}$   $\text{N}_2$  molecules react with  $3 \times 6.02 \times 10^{23}$   $\text{H}_2$  molecules, giving  $2 \times 6.02 \times 10^{23}$   $\text{NH}_3$  molecules. This last statement can be put in molar terminology: one mole of  $\text{N}_2$  reacts with three moles of  $\text{H}_2$  to give two moles of  $\text{NH}_3$ .

You may interpret a chemical equation either in terms of numbers of molecules (or ions or formula units) or in terms of numbers of moles, depending on your needs.

Because moles can be converted to mass, you can also give a mass interpretation of a chemical equation. The molar masses of  $\text{N}_2$ ,  $\text{H}_2$ , and  $\text{NH}_3$  are 28.0, 2.02, and 17.0 g/mol, respectively. Therefore, 28.0 g of  $\text{N}_2$  reacts with  $3 \times 2.02$  g of  $\text{H}_2$  to yield  $2 \times 17.0$  g of  $\text{NH}_3$ .

We summarize these three interpretations as follows:

Suppose you ask how many grams of atmospheric nitrogen will react with 6.06 g ( $3 \times 2.02$  g) of hydrogen. You see from the last equation that the answer is 28.0 g  $\text{N}_2$ . We formulated this question for one mole of atmospheric nitrogen. Recalling the question posed earlier, you may ask how much hydrogen (in kg) is needed to yield 907 kg of ammonia in the Haber process. The solution to this problem depends on the fact that *the number of moles involved in a reaction is proportional to the coefficients in the balanced chemical equation*. In the next section, we will describe a procedure for solving such problems.

**Exercise 3.13** In an industrial process, hydrogen chloride,  $\text{HCl}$ , is prepared by burning hydrogen gas,  $\text{H}_2$ , in an atmosphere of chlorine,  $\text{Cl}_2$ . Write the chemical equation for the reaction. Below the equation, give the molecular, molar, and mass interpretations.

See Problems 3.77 and 3.78.

### 3.7 Amounts of Substances in a Chemical Reaction

You see from the preceding discussion that a balanced chemical equation relates the amounts of substances in a reaction. The coefficients in the equation can be given a molar interpretation, and using this interpretation you can, for example, calculate the moles of product obtained from any given moles of reactant. Also, you can extend this type of calculation to answer questions about masses of reactants and products.

Again consider the Haber process for producing ammonia gas. Suppose you have a mixture of  $\text{H}_2$  and  $\text{N}_2$ , and 4.8 mol  $\text{H}_2$  in this mixture reacts with  $\text{N}_2$  to produce  $\text{NH}_3$ . How many moles of  $\text{NH}_3$  can you produce from this quantity of  $\text{H}_2$ ?

In asking questions like this, you assume that the mixture contains a sufficient quantity of the other reactant ( $N_2$ , in this case).

The balanced chemical equation for the Haber process tells you that 3 mol  $H_2$  produce 2 mol  $NH_3$ . You can express this as a conversion factor: ◀

$$\frac{2 \text{ mol } NH_3}{3 \text{ mol } H_2}$$

Converts from  
mol  $H_2$  to mol  $NH_3$

This conversion factor simply expresses the fact that the mole ratio of  $NH_3$  to  $H_2$  in the reaction is 2 to 3.

Multiplying any quantity of  $H_2$  by this conversion factor mathematically converts that quantity of  $H_2$  to the quantity of  $NH_3$  as specified by the balanced chemical equation. Note that you write the conversion factor with the quantity you are converting *from* on the bottom (3 mol  $H_2$ ), and the quantity you are converting *to* on the top (2 mol  $NH_3$ ).

To calculate the quantity of  $NH_3$  produced from 4.8 mol  $H_2$ , you write 4.8 mol  $H_2$  and multiply this by the preceding conversion factor:

$$4.8 \text{ mol } H_2 \times \frac{2 \text{ mol } NH_3}{3 \text{ mol } H_2} = 3.2 \text{ mol } NH_3$$

Note how the unit mol  $H_2$  cancels to give the answer in mol  $NH_3$ .

In this calculation, you converted moles of reactant to moles of product.

Moles reactant  $\longrightarrow$  moles product

It is just as easy to calculate the moles of reactant needed to obtain the specified moles of product. You mathematically convert moles of product to moles of reactant.

Moles product  $\longrightarrow$  moles reactant

To set up the conversion factor, you refer to the balanced chemical equation and place the quantity you are converting from on the bottom and the quantity you are converting to on the top.

$$\frac{3 \text{ mol } H_2}{2 \text{ mol } NH_3}$$

Converts from  
mol  $NH_3$  to mol  $H_2$

Now consider the problem asked in the previous section: How much hydrogen (in kg) is needed to yield 907 kg of ammonia by the Haber process? The balanced chemical equation directly relates moles of substances, not masses. Therefore, you must first convert the mass of ammonia to moles of ammonia, then convert moles of ammonia to moles of hydrogen. Finally, you convert moles of hydrogen to mass of hydrogen.

Mass  $NH_3 \longrightarrow$  mol  $NH_3 \longrightarrow$  mol  $H_2 \longrightarrow$  mass  $H_2$

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. WCN 02-200-203

You learned how to convert mass to moles, and vice versa, in Section 3.2.

The calculation to convert 907 kg  $NH_3$ , or  $9.07 \times 10^5$  g  $NH_3$ , to mol  $NH_3$  is as follows:

$$9.07 \times 10^5 \text{ g } NH_3 \times \frac{1 \text{ mol } NH_3}{17.0 \text{ g } NH_3} = 5.34 \times 10^4 \text{ mol } NH_3$$

Converts from  
g  $NH_3$  to mol  $NH_3$

Now you convert from moles  $NH_3$  to moles  $H_2$ .

$$5.34 \times 10^4 \text{ mol } NH_3 \times \frac{3 \text{ mol } H_2}{2 \text{ mol } NH_3} = 8.01 \times 10^4 \text{ mol } H_2$$

Converts from  
mol  $NH_3$  to mol  $H_2$

Finally, you convert moles  $\text{H}_2$  to grams  $\text{H}_2$ .

$$8.01 \times 10^4 \text{ mol H}_2 \times \underbrace{\frac{2.02 \text{ g H}_2}{1 \text{ mol H}_2}}_{\text{Converts from mol H}_2 \text{ to g H}_2} = 1.62 \times 10^5 \text{ g H}_2$$

The result says that to produce 907 kg  $\text{NH}_3$ , you need  $1.62 \times 10^5 \text{ g H}_2$ , or 162 kg  $\text{H}_2$ .

Once you feel comfortable with the individual conversions, you can do this type of calculation in a single step by multiplying successively by conversion factors, as follows:

$$9.07 \times 10^5 \text{ g NH}_3 \times \frac{1 \text{ mol NH}_3}{17.0 \text{ g NH}_3} \times \frac{3 \text{ mol H}_2}{2 \text{ mol NH}_3} \times \frac{2.02 \text{ g H}_2}{1 \text{ mol H}_2} = 1.62 \times 10^5 \text{ g H}_2 \text{ (or 162 kg H}_2\text{)}$$

Note that the unit in the denominator of each conversion factor cancels the unit in the numerator of the preceding factor. Figure 3.11 illustrates this calculation diagrammatically.

Figure 3.11 ◀

**Steps in a stoichiometric calculation** You convert the mass of substance A in a reaction to moles of substance A, then to moles of another substance B, and finally to mass of substance B.

The following two examples illustrate additional variations of this type of calculation.

### Example 3.13 Relating the Quantity of Reactant to Quantity of Product

#### Gaining Mastery Toolbox

##### Critical Concept 3.13

The coefficients in a balanced chemical equation represent molar relationships between the reactants and products. These relationships can be used as conversion factors when performing calculations.

##### Solution Essentials:

- Molar interpretation of a balanced chemical equation
- Molar mass
- Balanced chemical equation
- Dimensional analysis
- Rules for significant figures and rounding

Hematite,  $\text{Fe}_2\text{O}_3$ , is an important ore of iron; see Figure 3.12. (An ore is a natural substance from which the metal can be profitably obtained.) The free metal is obtained by reacting hematite with carbon monoxide,  $\text{CO}$ , in a blast furnace. Carbon monoxide is formed in the furnace by partial combustion of carbon. The reaction is

How many grams of iron can be produced from 1.00 kg  $\text{Fe}_2\text{O}_3$ ?

© Cengage Learning

Figure 3.12 ▲

**Hematite** The name of this iron mineral stems from the Greek word for blood, which alludes to the color of certain forms of the mineral.

**Problem Strategy** This calculation involves the conversion of a quantity of  $\text{Fe}_2\text{O}_3$  to a quantity of  $\text{Fe}$ . In performing this calculation, we assume that there is enough  $\text{CO}$  for the complete reaction of the  $\text{Fe}_2\text{O}_3$ . An essential feature of this type of calculation is that you must use the information from the balanced chemical equation to convert from the moles of a given substance to the moles of another substance. Therefore, you first convert the mass of  $\text{Fe}_2\text{O}_3$  ( $1.00 \text{ kg Fe}_2\text{O}_3 = 1.0 \times 10^3 \text{ g Fe}_2\text{O}_3$ ) to moles of  $\text{Fe}_2\text{O}_3$ . Then, using the relationship from the balanced chemical equation, you convert moles of  $\text{Fe}_2\text{O}_3$  to moles of  $\text{Fe}$ . Finally, you convert the moles of  $\text{Fe}$  to grams of  $\text{Fe}$ .

The problem strategy is diagrammed as

(continued)

**Example 3.13** (continued)

**Solution** The calculation is as follows:

$$1.00 \times 10^3 \text{ g Fe}_2\text{O}_3 \times \frac{1 \text{ mol Fe}_2\text{O}_3}{160 \text{ g Fe}_2\text{O}_3} \times \frac{2 \text{ mol Fe}}{1 \text{ mol Fe}_2\text{O}_3} \times \frac{55.8 \text{ g Fe}}{1 \text{ mol Fe}} = 698 \text{ g Fe}$$

**Answer Check** When calculating the mass of product produced in a chemical reaction such as this, keep in mind that the total mass of reactants must equal the total mass of products. Because of this, you should be suspicious of any calculation where you find that a few grams of reactant produces a large mass of product.

**Exercise 3.14** Sodium is a soft, reactive metal that instantly reacts with water to give hydrogen gas and a solution of sodium hydroxide, NaOH. How many grams of sodium metal are needed to give 7.81 g of hydrogen by this reaction? (Remember to write the balanced equation first.)

See Problems 3.83, 3.84, 3.85, and 3.86.

**Example 3.14** Relating the Quantities of Two Reactants (or Two Products)**Gaining Mastery Toolbox****Critical Concept 3.14**

The coefficients in a balanced chemical equation represent molar relationships between any two substances in the chemical equation. In addition to the conversion factors between products and reactants, there are conversion factors relating reactants to other reactants and products to other products.

**Solution Essentials:**

- Molar interpretation of a balanced chemical equation
- Molar mass
- Balanced chemical equation
- Dimensional analysis
- Rules for significant figures and rounding

Today chlorine is prepared from sodium chloride by electrochemical decomposition. Formerly chlorine was produced by heating hydrochloric acid with pyrolusite (manganese dioxide,  $\text{MnO}_2$ ), a common manganese ore. Small amounts of chlorine may be prepared in the laboratory by the same reaction (see Figure 3.13):

How many grams of HCl react with 5.00 g of manganese dioxide, according to this equation?

**Figure 3.13** ►

**Preparation of chlorine** Concentrated hydrochloric acid was added to manganese dioxide in the beaker. Note the formation of yellowish green gas (chlorine), which is depicted by molecular models.

© Cengage Learning

**Problem Strategy** When starting a problem like this, determine and note which quantities in the balanced chemical equation are being related. Here you are looking at the two reactants, and the relationship is that 4 mol HCl reacts with 1 mol  $\text{MnO}_2$ . Answer this problem following the same strategy as outlined in Example 3.13, only this time use the relationship between the HCl and  $\text{MnO}_2$ .

The problem strategy is diagrammed as

**Solution** You write what is given (5.00 g  $\text{MnO}_2$ ) and convert this to moles, then to moles of what is desired (mol HCl). Finally you convert this to mass (g HCl). The calculation is:

$$5.00 \text{ g MnO}_2 \times \frac{1 \text{ mol MnO}_2}{86.9 \text{ g MnO}_2} \times \frac{4 \text{ mol HCl}}{1 \text{ mol MnO}_2} \times \frac{36.5 \text{ g HCl}}{1 \text{ mol HCl}} = 8.40 \text{ g HCl}$$

(continued)

**Example 3.14** (continued)

**Answer Check** To avoid incorrect answers, before starting any stoichiometry problem, make sure that the chemical equation is complete and balanced and that the chemical formulas are correct.

**Exercise 3.15** Sphalerite is a zinc sulfide (ZnS) mineral and an important commercial source of zinc metal. The first step in the processing of the ore consists of heating the sulfide with oxygen to give zinc oxide, ZnO, and sulfur dioxide, SO<sub>2</sub>. How many kilograms of oxygen gas combine with  $5.00 \times 10^3$  g of zinc sulfide in this reaction? (You must first write the balanced chemical equation.)

See Problems 3.87 and 3.88.

**Exercise 3.16** The British chemist Joseph Priestley prepared oxygen in 1774 by heating mercury(II) oxide, HgO. Mercury metal is the other product. If 6.47 g of oxygen is collected, how many grams of mercury metal are also produced?

See Problems 3.89 and 3.90.

**CONCEPT CHECK 3.4**

The main reaction of a charcoal grill is  $C(s) + O_2(g) \longrightarrow CO_2(g)$ . Which of the statements below are incorrect? Why?

- a** 1 atom of carbon reacts with 1 molecule of oxygen to produce 1 molecule of CO<sub>2</sub>.
- b** 1 g of C reacts with 1 g of O<sub>2</sub> to produce 2 grams of CO<sub>2</sub>.
- c** 1 g of C reacts with 0.5 g of O<sub>2</sub> to produce 1 g of CO<sub>2</sub>.
- d** 12 g of C reacts with 32 g of O<sub>2</sub> to produce 44 g of CO<sub>2</sub>.
- e** 1 mol of C reacts with 1 mol of O<sub>2</sub> to produce 1 mol of CO<sub>2</sub>.
- f** 1 mol of C reacts with 0.5 mol of O<sub>2</sub> to produce 1 mol of CO<sub>2</sub>.

**3.8 Limiting Reactant; Theoretical and Percentage Yields**

Often reactants are added to a reaction vessel in amounts different from the molar proportions given by the chemical equation. In such cases, only one of the reactants may be completely consumed at the end of the reaction, whereas some amounts of other reactants will remain unreacted. The **limiting reactant** (or **limiting reagent**) is *the reactant that is entirely consumed when a reaction goes to completion*. A reactant

that is not completely consumed is often referred to as an *excess reactant*. Once one of the reactants is used up, the reaction stops. This means that:

The moles of product are always determined by the starting moles of limiting reactant.

A couple of analogies may help you understand the limiting reactant problem. Suppose you want to make some cheese sandwiches. Each is made from two slices of bread and a slice of cheese. Let's write that in the form of a chemical equation:

You look in the kitchen and see that you have six slices of bread and two slices of cheese. The six slices of bread would be enough to make three sandwiches if you had enough cheese. The two slices of cheese would be enough to make two sandwiches if you had enough bread. How many sandwiches can you make? What you will find is that once you have made two sandwiches, you will be out of cheese (Figure 3.14). Cheese is the “limiting reactant” in the language of chemistry. If you look at each “reactant,” and ask how much “product” you can make from it, the reactant that limits your amount of product is called the limiting reactant.

Here is another analogy. Suppose you are supervising the assembly of automobiles. Your plant has in stock 300 steering wheels and 900 tires, plus an excess of every other needed component. How many autos can you assemble from this stock? Here is the “balanced equation” for the auto assembly:

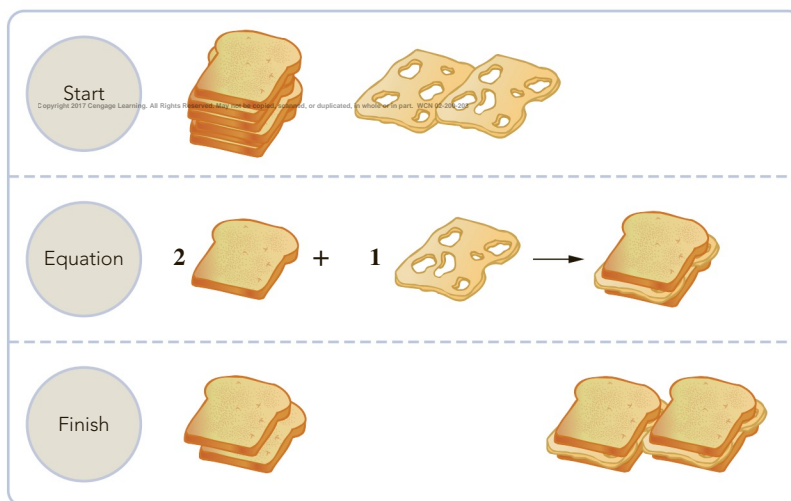

One way to solve this problem is to calculate the number of autos that you could assemble from each component. In this case, you only need to concentrate on the effects of the steering wheels and tires since production will not be limited by the other, excess components. Looking at the equation, you can determine that from 300 steering wheels, you could assemble 300 autos; from 900 tires you could assemble  $900 \div 4 = 225$  autos.

How many autos can you produce, 225 or 300? Note that by the time you have assembled 225 autos, you will have exhausted your stock of tires, so no more autos can be assembled. Tires are the “limiting reactant,” since they limit the number of automobiles that you can actually assemble (225).

**Figure 3.14** ▶

**Limiting reactant analogy using cheese sandwiches** Start with six slices of bread, two slices of cheese, and the sandwich-making equation. Even though you have extra bread, you are limited to making two sandwiches by the amount of cheese you have on hand. Cheese is the limiting reactant.

You can set up these calculations in the same way for a chemical reaction. First, you calculate the numbers of autos you could assemble from the number of steering wheels and from the number of tires available, and then you compare the results. From the balanced equation, you can see that one steering wheel is equivalent to one auto, and four tires are equivalent to one auto. Therefore:

$$300 \text{ steering wheels} \times \frac{1 \text{ auto}}{1 \text{ steering wheel}} = 300 \text{ autos}$$

$$900 \text{ tires} \times \frac{1 \text{ auto}}{4 \text{ tires}} = 225 \text{ autos}$$

Comparing the numbers of autos produced (225 autos versus 300 autos), you conclude that tires are the limiting component. (The component producing the fewer autos is the limiting component.) Note that apart from the units (or factor labels), the calculation is identical with what was done previously.

Now consider a chemical reaction, the burning of hydrogen in oxygen.

Suppose you put 1 mol  $\text{H}_2$  and 1 mol  $\text{O}_2$  into a reaction vessel. How many moles of  $\text{H}_2\text{O}$  will be produced? First, you note that 2 mol  $\text{H}_2$  produces 2 mol  $\text{H}_2\text{O}$  and that 1 mol  $\text{O}_2$  produces 2 mol  $\text{H}_2\text{O}$ . Now you calculate the moles of  $\text{H}_2\text{O}$  that you could produce from each quantity of reactant, assuming that there is sufficient other reactant.

$$1 \text{ mol H}_2 \times \frac{2 \text{ mol H}_2\text{O}}{2 \text{ mol H}_2} = 1 \text{ mol H}_2\text{O}$$

$$1 \text{ mol O}_2 \times \frac{2 \text{ mol H}_2\text{O}}{1 \text{ mol O}_2} = 2 \text{ mol H}_2\text{O}$$

Comparing these results, you see that hydrogen,  $\text{H}_2$ , yields the least amount of product, so it must be the limiting reactant. By the time 1 mol  $\text{H}_2\text{O}$  is produced, all of the hydrogen is used up; the reaction stops. Oxygen,  $\text{O}_2$ , is the excess reactant. Figure 3.15 depicts this reaction from a molecular viewpoint.

**Figure 3.15** ◀

**Molecular view of  $2\text{H}_2 + \text{O}_2 \longrightarrow 2\text{H}_2\text{O}$  reaction with  $\text{H}_2$  as the limiting reactant**

When an equal number of moles of  $\text{H}_2$  and  $\text{O}_2$  are reacted according to the equation  $2\text{H}_2 + \text{O}_2 \longrightarrow 2\text{H}_2\text{O}$ , all of the  $\text{H}_2$  completely reacts, whereas only half of the  $\text{O}_2$  is consumed. In this case, the  $\text{H}_2$  is the limiting reactant and the  $\text{O}_2$  is the excess reactant.

We can summarize the limiting-reactant problem as follows. Suppose you are given the amounts of reactants added to a vessel, and you wish to calculate the amount of product obtained when the reaction is complete. Unless you know that the reactants have been added in the molar proportions given by the chemical equation, the problem is twofold: (1) you must first identify the limiting reactant; (2) you then calculate the amount of product from the amount of limiting reactant. The next examples illustrate the steps.

 **CONCEPT CHECK 3.5**

Solid  $\text{ReO}_3$  is a material that is an extremely good conductor of electricity. It can be formed by the chemical reaction  $\text{Re}(s) + 3\text{Re}_2\text{O}_7(s) \longrightarrow 7\text{ReO}_3(s)$ . If 3 mol of Re and 3 mol of  $\text{Re}_2\text{O}_7$  are placed in a reaction vessel and the reaction proceeds, 7 mol of  $\text{ReO}_3$  are produced. Which of the following statements is the best reason that 7 mol of  $\text{ReO}_3$  are produced during the chemical reaction?

- a** According to the balanced chemical equation, 7 mol of  $\text{ReO}_3$  will always be formed regardless of the starting amounts of the reactants.
- b** Re is the limiting reactant.
- c**  $\text{Re}_2\text{O}_7$  is the limiting reactant.
- d**  $\text{Re}_2\text{O}_7$  is the excess reactant.
- e** The 3 mol of Re completely reacts producing 7 mol of  $\text{ReO}_3$ .

### Example 3.15 Calculating with a Limiting Reactant (Involving Moles)

#### Gaining Mastery Toolbox

##### Critical Concept 3.15

During a chemical reaction, after any one of the reactants is completely consumed, no additional products are formed. In order to calculate the amount of product formed during a chemical reaction, one must first identify the reactant—the limiting reactant—that would be used up prior to the other reactants.

##### Solution Essentials:

- Limiting reactant
- Molar interpretation of a balanced chemical equation
- Molar mass
- Balanced chemical equation
- Dimensional analysis
- Rules for significant figures and rounding

Zinc metal reacts with hydrochloric acid by the following reaction:

If 0.30 mol Zn is added to hydrochloric acid containing 0.52 mol HCl, how many moles of  $\text{H}_2$  are produced?

#### Problem Strategy

**Step 1:** Which is the limiting reactant? To answer this, using the relationship from the balanced chemical equation, you take each reactant in turn and ask how much product ( $\text{H}_2$ ) would be obtained if each were totally consumed. The reactant that gives the smaller amount of product is the limiting reactant. (Remember how you obtained the limiting component in the auto-assembly analogy.)

**Step 2:** You obtain the amount of product actually obtained from the amount of limiting reactant.

#### Solution

##### Step 1:

$$0.30 \text{ mol Zn} \times \frac{1 \text{ mol H}_2}{1 \text{ mol Zn}} = 0.30 \text{ mol H}_2$$

$$0.52 \text{ mol HCl} \times \frac{1 \text{ mol H}_2}{2 \text{ mol HCl}} = 0.26 \text{ mol H}_2$$

You see that hydrochloric acid must be the limiting reactant and that some zinc must be left unconsumed. (Zinc is the excess reactant.)

**Step 2:** Since HCl is the limiting reactant, the amount of  $\text{H}_2$  produced must be **0.26 mol**.

(continued)

**Example 3.15** (continued)

**Answer Check** A common assumption that often leads to errors in solving a problem of this type is to assume that whichever reactant is present in the least quantity (in mass or moles of material) is automatically the limiting reactant. Note how that assumption would have led to an incorrect answer in this problem. Always be sure to account for the stoichiometry of the balanced chemical equation.

**Exercise 3.17** Aluminum chloride,  $\text{AlCl}_3$ , is used as a catalyst in various industrial reactions. It is prepared from hydrogen chloride gas and aluminum metal shavings.

See Problems 3.91 and 3.92.

Suppose a reaction vessel contains 0.15 mol Al and 0.35 mol HCl. How many moles of  $\text{AlCl}_3$  can be prepared from this mixture?

**Example 3.16** Calculating with a Limiting Reactant (Involving Masses)**Gaining Mastery Toolbox****Critical Concept 3.16**

The amount (mol) of each reactant decreases during a chemical reaction. After the reaction is complete, the limiting reactant is completely consumed, and the other reactants are partially consumed.

**Solution Essentials:**

- Limiting reactant
- Molar interpretation of a balanced chemical equation
- Molar mass
- Balanced chemical equation
- Dimensional analysis
- Rules for significant figures and rounding

In a process for producing acetic acid, oxygen gas is bubbled into acetaldehyde,  $\text{CH}_3\text{CHO}$ , containing manganese(II) acetate (catalyst) under pressure at  $60^\circ\text{C}$ .

In a laboratory test of this reaction, 20.0 g  $\text{CH}_3\text{CHO}$  and 10.0 g  $\text{O}_2$  were put into a reaction vessel. a. How many grams of acetic acid can be produced by this reaction from these amounts of reactants? b. How many grams of the excess reactant remain after the reaction is complete?

**Problem Strategy**

- a. This part is similar to the preceding example, but now you must convert grams of each reactant (acetaldehyde and oxygen) to moles of product (acetic acid). From these results, you decide which is the limiting reactant and the moles of product obtained, which you convert to grams of product.
- b. In order to calculate the amount of excess reactant remaining after the reaction is complete, you need to know the identity of the excess reactant and how much of this excess reactant was needed for the reaction. The result from Step 1 provides the identity of the limiting reactant, so you will know which reactant was in excess. From the moles of product produced by the limiting reactant, you calculate the grams of the excess reactant needed in the reaction. You now know how much of this excess reactant was consumed, so subtracting the amount consumed from the starting amount will yield the amount of excess reactant that remains.

**Solution**

a. How much acetic acid is produced?

**Step 1:** To determine which reactant is limiting, you convert grams of each reactant (20.0 g  $\text{CH}_3\text{CHO}$  and 10.0 g  $\text{O}_2$ ) to moles of product,  $\text{HC}_2\text{H}_3\text{O}_2$ . Acetaldehyde has a molar mass of 44.1 g/mol, and oxygen has a molar mass of 32.0 g/mol.

$$20.0 \text{ g } \text{CH}_3\text{CHO} \times \frac{1 \text{ mol } \text{CH}_3\text{CHO}}{44.1 \text{ g } \text{CH}_3\text{CHO}} \times \frac{2 \text{ mol } \text{HC}_2\text{H}_3\text{O}_2}{2 \text{ mol } \text{CH}_3\text{CHO}} = 0.454 \text{ mol } \text{HC}_2\text{H}_3\text{O}_2$$

$$10.0 \text{ g } \text{O}_2 \times \frac{1 \text{ mol } \text{O}_2}{32.0 \text{ g } \text{O}_2} \times \frac{2 \text{ mol } \text{HC}_2\text{H}_3\text{O}_2}{1 \text{ mol } \text{O}_2} = 0.625 \text{ mol } \text{HC}_2\text{H}_3\text{O}_2$$

Thus, acetaldehyde,  $\text{CH}_3\text{CHO}$ , is the limiting reactant, so 0.454 mol  $\text{HC}_2\text{H}_3\text{O}_2$  was produced.

(continued)

**Example 3.16** (continued)

**Step 2:** You convert 0.454 mol HC<sub>2</sub>H<sub>3</sub>O<sub>2</sub> to grams of HC<sub>2</sub>H<sub>3</sub>O<sub>2</sub>.

$$0.454 \text{ mol HC}_2\text{H}_3\text{O}_2 \times \frac{60.1 \text{ g HC}_2\text{H}_3\text{O}_2}{1 \text{ mol HC}_2\text{H}_3\text{O}_2} = 27.3 \text{ g HC}_2\text{H}_3\text{O}_2$$

b. How much of the excess reactant (oxygen) was left over? You convert the moles of acetic acid to grams of oxygen (the quantity of oxygen needed to produce this amount of acetic acid).

$$0.454 \text{ mol HC}_2\text{H}_3\text{O}_2 \times \frac{1 \text{ mol O}_2}{2 \text{ mol HC}_2\text{H}_3\text{O}_2} \times \frac{32.0 \text{ g O}_2}{1 \text{ mol O}_2} = 7.26 \text{ g O}_2$$

You started with 10.0 g O<sub>2</sub>, so the quantity remaining is

$$(10.0 - 7.26) \text{ g O}_2 = 2.7 \text{ g O}_2 \quad (\text{mass remaining})$$

**Answer Check** Whenever you are confronted with a stoichiometry problem you should always determine if you are going to have to solve a limiting reactant problem like this one, or a problem like Example 3.13 that involves a single reactant and one reactant in excess. A good rule of thumb is that when two or more reactant quantities are specified, you should approach the problem as was done here.

**Exercise 3.18** In an experiment, 7.36 g of zinc was heated with 6.45 g of sulfur (Figure 3.16). Assume that these substances react according to the equation

What amount of zinc sulfide was produced?

**Figure 3.16** ▶

**Reaction of zinc and sulfur** When a hot nail is stuck into a pile of zinc and sulfur, a fiery reaction occurs and zinc sulfide forms.

© Cengage Learning

See Problems 3.93 and 3.94.

The **theoretical yield** of product is *the maximum amount of product that can be obtained by a reaction from given amounts of reactants*. It is the amount that you calculate from the stoichiometry based on the limiting reactant. In Example 3.16, the theoretical yield of acetic acid is 27.3 g. In practice, the **actual yield** of a product may be much less for several possible reasons. First, some product may be lost during the process of separating it from the final reaction mixture. Second, there may be other, competing reactions that occur simultaneously with the reactant on which the theoretical yield is based. Finally, many reactions appear to stop before they reach completion; they give mixtures of reactants and products. ◀

It is important to know the actual yield from a reaction in order to make economic decisions about a preparation method. The reactants for a given method may not be too costly per kilogram, but if the actual yield is very low, the final cost can be very high. The **percentage yield** of product is *the actual yield (experimentally determined) expressed as a percentage of the theoretical yield (calculated)*.

$$\text{Percentage yield} = \frac{\text{actual yield}}{\text{theoretical yield}} \times 100\%$$

Such reactions reach chemical equilibrium. We will discuss equilibrium quantitatively in Chapter 14.

To illustrate the calculation of percentage yield, recall that the theoretical yield of acetic acid calculated in Example 3.16 was 27.3 g. If the actual yield of acetic acid obtained in an experiment, using the amounts of reactants given in Example 3.16, is 23.8 g, then

$$\text{Percentage yield of HC}_2\text{H}_3\text{O}_2 = \frac{23.8 \text{ g}}{27.3 \text{ g}} \times 100\% = 87.2\%$$

**Exercise 3.19** New industrial plants for acetic acid react liquid methanol with carbon monoxide in the presence of a catalyst.

In an experiment, 15.0 g of methanol and 10.0 g of carbon monoxide were placed in a reaction vessel. What is the theoretical yield of acetic acid? If the actual yield is 19.1 g, what is the percentage yield?

See Problems 3.97 and 3.98.

### CONCEPT CHECK 3.6

You perform the hypothetical reaction of an element,  $\text{X}_2(g)$ , with another element,  $\text{Y}(g)$ , to produce  $\text{XY}(g)$ .

- Write the balanced chemical equation for the reaction.
- If  $\text{X}_2$  and  $\text{Y}$  were mixed in the quantities shown in the container on the left below and allowed to react, which of the three options is the correct representation of the contents of the container after the reaction has occurred?

Before reaction:

After reaction:

- Using the information presented in Part b, identify the limiting reactant.

## A Checklist for Review

### Summary of Facts and Concepts

A *formula weight* equals the sum of the atomic masses of the atoms in the formula of a compound. If the formula corresponds to that of a molecule, this sum of atomic masses equals the *molecular weight* of the compound. The mass of *Avogadro's number* ( $6.02 \times 10^{23}$ ) of formula units—that is, the mass of one *mole* of substance—equals the mass in grams that corresponds to the numerical value of the formula mass in amu. This mass is called the *molar mass*.

The *empirical formula* (*simplest formula*) of a compound is obtained from the *percentage composition* of the substance, which is expressed as *mass percentages* of the elements. To calculate the empirical formula, you convert mass percentages to ratios of moles, which, when expressed in smallest whole numbers, give the subscripts in the formula. A molecular formula is a multiple of the empirical formula; this multiple is determined from the experimental value of the molecular weight.

A chemical equation may be interpreted in terms of moles of reactants and products, as well as in terms of molecules. Using this *molar interpretation*, you can convert from the mass of one substance in a chemical equation to

the mass of another. The maximum amount of product from a reaction is determined by the *limiting reactant*, the reactant that is completely used up; the other reactants are in excess.

## Learning Objectives

## Important Terms

### 3.1 Molecular Weight and Formula Weight

- Define the terms *molecular weight* and *formula weight* of a substance.
- Calculate the formula weight from a formula.  
**Example 3.1**
- Calculate the formula weight from molecular models.  
**Example 3.2**

**molecular weight**  
**formula weight**

### 3.2 The Mole Concept

- Define the quantity called the *mole*.
- Learn *Avogadro's number*.
- Understand how the *molar mass* is related to the formula weight of a substance.
- Calculate the mass of atoms and molecules. **Example 3.3**
- Perform calculations using the mole.
- Convert from moles of substance to grams of substance. **Example 3.4**
- Convert from grams of substance to moles of substance. **Example 3.5**
- Calculate the number of molecules in a given mass of substance. **Example 3.6**

**mole (mol)**  
**Avogadro's number ( $N_A$ )**  
**molar mass**

### 3.3 Mass Percentages from the Formula

- Define *mass percentage*.
- Calculate the percentage composition of the elements in a compound. **Example 3.7**
- Calculate the mass of an element in a given mass of compound. **Example 3.8**

**percentage composition**  
**mass percentage**

### 3.4 Elemental Analysis: Percentage of Carbon, Hydrogen, and Oxygen

- Describe how C, H, and O combustion analysis is performed.
- Calculate the percentage of C, H, and O from combustion data. **Example 3.9**

### 3.5 Determining Formulas

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. WCN 02-200-203

- Define *empirical formula*.
- Determine the empirical formula of a binary compound from the masses of its elements.  
**Example 3.10**
- Determine the empirical formula from the percentage composition. **Example 3.11**
- Understand the relationship between the molecular weight of a substance and its *empirical formula weight*.
- Determine the molecular formula from the percentage composition and molecular weight. **Example 3.12**

**empirical (simplest) formula**

### 3.6 Molar Interpretation of a Chemical Equation

- Relate the coefficients in a balanced chemical equation to the number of molecules or moles (*molar interpretation*).

**stoichiometry**

**3.7 Amounts of Substances in a Chemical Reaction**

- Use the coefficients in a chemical reaction to perform calculations.
- Relate the quantities of reactant to the quantity of product. **Example 3.13**
- Relate the quantities of two reactants or two products. **Example 3.14**

**3.8 Limiting Reactant; Theoretical and Percentage Yields**

- Understand how a *limiting reactant* or *limiting reagent* determines the moles of product formed during a chemical reaction and how much *excess reactant* remains.
- Calculate with a limiting reactant involving moles. **Example 3.15**
- Calculate with a limiting reactant involving masses. **Example 3.16**
- Define and calculate the *theoretical yield* of chemical reactions.
- Determine the *percentage yield* of a chemical reaction.

**limiting reactant (reagent)**  
**theoretical yield**  
**percentage yield**

**Key Equations**

$$\text{Mass\% } A = \frac{\text{mass of } A \text{ in the whole}}{\text{mass of the whole}} \times 100\%$$

$$\text{Percentage yield} = \frac{\text{actual yield}}{\text{theoretical yield}} \times 100\%$$

$$n = \frac{\text{molecular weight}}{\text{empirical formula weight}}$$

**Questions and Problems****Self-Assessment and Review Questions**

**Key:** These questions test your understanding of the ideas you worked with in the chapter. These problems vary in difficulty and often can be used for the basis of discussion.

**3.1** What is the difference between a formula weight and a molecular weight? Could a given substance have both a formula weight and a molecular weight?

**3.2** Describe in words how to obtain the formula weight of a compound from the formula.

**3.3** One mole of  $\text{N}_2$  contains how many  $\text{N}_2$  molecules? How many N atoms are there in one mole of  $\text{N}_2$ ? One mole of iron(III) sulfate,  $\text{Fe}_2(\text{SO}_4)_3$ , contains how many moles of  $\text{SO}_4^{2-}$  ions? How many moles of O atoms?

**3.4** Explain what is involved in determining the composition of a compound of C, H, and O by combustion.

**3.5** Explain what is involved in obtaining the empirical formula from the percentage composition.

**3.6** A substance has the molecular formula  $\text{C}_6\text{H}_{12}\text{O}_2$ . What is its empirical formula?

**3.7** Hydrogen peroxide has the empirical formula HO and an empirical formula weight of 17.0 amu. If the molecular weight is 34.0 amu, what is the molecular formula?

**3.8** Describe in words the meaning of the equation

using a molecular, a molar, and then a mass interpretation.

**3.9** Explain how a chemical equation can be used to relate the masses of different substances involved in a reaction.

**3.10** What is a limiting reactant in a reaction mixture? Explain how it determines the amount of product.

**3.11** Come up with some examples of limiting reactants that use the concept but don't involve chemical reactions.

**3.12** Explain why it is impossible to have a theoretical yield of more than 100%.

**3.13** How many grams of  $\text{NH}_3$  will have the same number of molecules as 15.0 g of  $\text{C}_6\text{H}_6$ ?

- a** 3.27      **b** 1.92      **c** 15.0  
**d** 17.0      **e** 14.2

**3.14** Which of the following has the largest number of molecules?

- a** 1 g of benzene,  $\text{C}_6\text{H}_6$   
**b** 1 g of formaldehyde,  $\text{CH}_2\text{O}$   
**c** 1 g of TNT,  $\text{C}_7\text{H}_5\text{N}_3\text{O}_6$   
**d** 1 g of naphthalene,  $\text{C}_{10}\text{H}_8$   
**e** 1 g of glucose,  $\text{C}_6\text{H}_{12}\text{O}_6$

**3.15** How many atoms are present in 123 g of magnesium cyanide?

- a**  $9.7 \times 10^{23}$       **b**  $2.91 \times 10^{24}$       **c**  $2.83 \times 10^{28}$   
**d**  $4.85 \times 10^{24}$       **e**  $5.65 \times 10^{27}$

## 101a

## Calculations with Chemical Formulas and Equations

**3.16** When 2.56 g of a compound containing only carbon, hydrogen, and oxygen is burned completely, 3.84 g of  $\text{CO}_2$  and 1.05 g of  $\text{H}_2\text{O}$  are produced. What is the empirical formula of the compound?

## Concept Explorations

**Key:** Concept explorations are comprehensive problems that provide a framework that will enable you to explore and learn many of the critical concepts and ideas in each chapter. If you master the concepts associated with these explorations, you will have a better understanding of many important chemistry ideas and will be more successful in solving all types of chemistry problems. These problems are well suited for group work and for use as in-class activities.

### 3.17 Moles and Molar Mass

**Part 1:** The mole provides a convenient package where we can make a connection between the mass of a substance and the number (count) of that substance. This is a familiar concept if you have ever bought pieces of bulk hard candy, where you purchase candy by mass rather than count. Typically, there is a scale provided for weighing the candy. For example, a notice placed above the candy bin might read, "For the candy in the bin below, there are 500 pieces of candy per kg." Using this conversion factor, perform the following calculations.

- a How many candies would you have if you had 0.2 kg?
- b If you had 10 dozen candies, what would be their mass?
- c What is the mass of one candy piece?
- d What is the mass of 2.0 moles of candies?

**Part 2:** The periodic table provides information about each element that serves somewhat the same purpose as the label on the candy bin described in Part 1, only in this case, the mass (molar mass) of each element is the number of grams of the element that contain  $6.02 \times 10^{23}$  atoms or molecules of the element. As you are aware, the quantity  $6.02 \times 10^{23}$  is called the mole.

- a If you had 0.2 kg of helium, how many helium atoms would you have?
- b If you had 10 dozen helium atoms, what would be their mass?
- c What is the mass of one helium atom?
- d What is the mass of 2.0 moles of helium atoms?

**Part 3:** Say there is a newly defined "package" called the binkle. One binkle is defined as being exactly  $3 \times 10^{12}$ .

- a If you had 1.0 kg of nails and 1.0 kg of helium atoms, would you expect them to have the same number of binkles? Using complete sentences, explain your answer.

- b If you had 3.5 binkles of nails and 3.5 binkles of helium atoms, which quantity would have more (count) and which would have more mass? Using complete sentences, explain your answers.
- c Which would contain more atoms, 3.5 g of helium or 3.5 g of lithium? Using complete sentences, explain your answer.

### 3.18 Moles within Moles and Molar Mass

#### Part 1:

- a How many hydrogen and oxygen atoms are present in 1 molecule of  $\text{H}_2\text{O}$ ?
- b How many moles of hydrogen and oxygen atoms are present in 1 mol  $\text{H}_2\text{O}$ ?
- c What are the masses of hydrogen and oxygen in 1.0 mol  $\text{H}_2\text{O}$ ?
- d What is the mass of 1.0 mol  $\text{H}_2\text{O}$ ?

**Part 2:** Two hypothetical ionic compounds are discovered with the chemical formulas  $\text{XCl}_2$  and  $\text{YCl}_2$ , where X and Y represent symbols of the imaginary elements. Chemical analysis of the two compounds reveals that 0.25 mol  $\text{XCl}_2$  has a mass of 100.0 g and 0.50 mol  $\text{YCl}_2$  has a mass of 125.0 g.

- a What are the molar masses of  $\text{XCl}_2$  and  $\text{YCl}_2$ ?
- b If you had 1.0-mol samples of  $\text{XCl}_2$  and  $\text{YCl}_2$ , how would the number of chloride ions compare?
- c If you had 1.0-mol samples of  $\text{XCl}_2$  and  $\text{YCl}_2$ , how would the masses of elements X and Y compare?
- d What is the mass of chloride ions present in 1.0 mol  $\text{XCl}_2$  and 1.0 mol  $\text{YCl}_2$ ?
- e What are the molar masses of elements X and Y?
- f How many moles of X ions and chloride ions would be present in a 200.0-g sample of  $\text{XCl}_2$ ?
- g How many grams of Y ions would be present in a 250.0-g sample of  $\text{YCl}_2$ ?
- h What would be the molar mass of the compound  $\text{YBr}_3$ ?

**Part 3:** A minute sample of  $\text{AlCl}_3$  is analyzed for chlorine. The analysis reveals that there are 12 chloride ions present in the sample. How many aluminum ions must be present in the sample?

- a What is the total mass of  $\text{AlCl}_3$  in this sample?
- b How many moles of  $\text{AlCl}_3$  are in this sample?

## Conceptual Problems

**Key:** These problems are designed to check your understanding of the concepts associated with some of the main topics presented in each chapter. A strong conceptual understanding of chemistry is the foundation for both

applying chemical knowledge and solving chemical problems. These problems vary in level of difficulty and often can be used as a basis for group discussion.

**3.19** You react nitrogen and hydrogen in a container to produce ammonia,  $\text{NH}_3(g)$ . The following figure depicts the contents of the container after the reaction is complete.

- Write a balanced chemical equation for the reaction.
  - What is the limiting reactant?
  - How many molecules of the limiting reactant would you need to add to the container in order to have a complete reaction (convert all reactants to products)?
- 3.20** Propane,  $\text{C}_3\text{H}_8$ , is the fuel of choice in a gas barbecue. When burning, the balanced equation is

- What is the limiting reactant in cooking with a gas grill?
  - If the grill will not light and you know that you have an ample flow of propane to the burner, what is the limiting reactant?
  - When using a gas grill you can sometimes turn the gas up to the point at which the flame becomes yellow and smokey. In terms of the chemical reaction, what is happening?
- 3.21** A critical point to master in becoming proficient at solving problems is evaluating whether or not your answer is reasonable. A friend asks you to look over her homework to see if she has done the calculations correctly. Shown below are descriptions of some of her answers. Without using your calculator or doing calculations on paper, see if you can judge the answers below as being reasonable or ones that will require her to go back and work the problems again.

- 0.33 mol of an element has a mass of  $1.0 \times 10^{-3}$  g.
- The mass of one molecule of water is  $1.80 \times 10^{-10}$  g.
- There are  $3.01 \times 10^{23}$  atoms of Na in 0.500 mol of Na.
- The molar mass of  $\text{CO}_2$  is 44.0 kg/mol.

**3.22** An exciting, and often loud, chemical demonstration involves the simple reaction of hydrogen gas and oxygen gas to produce water vapor:

The reaction is carried out in soap bubbles or balloons that are filled with the reactant gases. We get the reaction to proceed by igniting the bubbles or balloons. The more  $\text{H}_2\text{O}$  that is formed during the reaction, the bigger the bang. Explain the following observations.

- A bubble containing just  $\text{H}_2$  makes a quiet “fffft” sound when ignited.
- When a bubble containing equal amounts of  $\text{H}_2$  and  $\text{O}_2$  is ignited, a sizable bang results.
- When a bubble containing a ratio of 2 to 1 in the amounts of  $\text{H}_2$  and  $\text{O}_2$  is ignited, the loudest bang results.
- When a bubble containing just  $\text{O}_2$  is ignited, virtually no sound is made.

**3.23** High cost and limited availability of a reactant often dictate which reactant is limiting in a particular process. Identify the limiting reactant when the reactions below are run, and come up with a reason to support your decision.

- Burning charcoal on a grill:

- Burning a chunk of Mg in water:

- The Haber process of ammonia production:

**3.24** A few hydrogen and oxygen molecules are introduced into a container in the quantities depicted in the following drawing. The gases are then ignited by a spark, causing them to react and form  $\text{H}_2\text{O}$ .

- What is the maximum number of water molecules that can be formed in the chemical reaction?
  - Draw a molecular level representation of the container's contents after the chemical reaction.
- 3.25** A friend asks if you would be willing to check several homework problems to see if she is on the right track. Following are the problems and her proposed solutions. When you identify the problem with her work, make the appropriate correction.

- Calculate the number of moles of calcium in 27.0 g of Ca.

$$27.0 \text{ g Ca} \times \frac{1 \text{ mol Ca}}{6.022 \times 10^{23} \text{ g Ca}} = ?$$

- Calculate the number of potassium ions in 2.5 mol of  $\text{K}_2\text{SO}_4$ .

$$2.5 \text{ mol K}_2\text{SO}_4 \times \frac{1 \text{ mol K}^+ \text{ ions}}{1 \text{ mol K}_2\text{SO}_4} \times \frac{6.022 \times 10^{23} \text{ K}^+ \text{ ions}}{1 \text{ mol K}^+ \text{ ions}} = ?$$

- Sodium reacts with water according to the following chemical equation.

Assuming complete reaction, calculate the number of moles of water required to react with 0.50 mol of Na.

$$0.50 \text{ mol Na} \times \frac{1 \text{ mol H}_2\text{O}}{2 \text{ mol Na}} = ?$$

**3.26** A friend is doing his chemistry homework and is working with the following chemical reaction.

## 101c

## Calculations with Chemical Formulas and Equations

He tells you that if he reacts 2 moles of  $C_2H_2$  with 4 moles of  $O_2$ , then the  $C_2H_2$  is the limiting reactant since there are fewer moles of  $C_2H_2$  than  $O_2$ .

- How would you explain to him where he went wrong with his reasoning (what concept is he missing)?
- After providing your friend with the explanation from part a, he still doesn't believe you because he *had* a homework problem where 2 moles of calcium

were reacted with 4 moles of sulfur and he needed to determine the limiting reactant. The reaction is

He obtained the correct answer, Ca, by reasoning that since there were fewer moles of calcium reacting, calcium *had* to be the limiting reactant. How would you explain his reasoning flaw and why he got "lucky" in choosing the answer that he did?

## Practice Problems

**Key:** These problems are for practice in applying problem-solving skills. They are divided by topic, and some are keyed to exercises (see the ends of the exercises). The problems are arranged in matching pairs; the odd-numbered problem of each pair is listed first, and its answer is given in the back of the book.

## Formula Weights and Mole Calculations

**3.27** Find the formula weights of the following substances to three significant figures.

- formaldehyde,  $CH_2O$
- sulfur dioxide,  $SO_2$
- sodium carbonate,  $Na_2CO_3$
- lead(II) phosphate,  $Pb_3(PO_4)_2$

**3.28** Find the formula weights of the following substances to three significant figures.

- sulfuric acid,  $H_2SO_4$
- phosphorus pentachloride,  $PCl_5$
- ammonium chloride,  $NH_4Cl$
- calcium hydroxide,  $Ca(OH)_2$

**3.29** Calculate the formula weight of the following molecules to three significant figures.

**3.30** Calculate the formula weight of the following molecules to three significant figures.

**3.31** Ammonium nitrate,  $NH_4NO_3$ , is used as a nitrogen fertilizer and in explosives. What is the molar mass of  $NH_4NO_3$ ?

**3.32** Phosphoric acid,  $H_3PO_4$ , is used to make phosphate fertilizers and detergents and is also used in carbonated beverages. What is the molar mass of  $H_3PO_4$ ?

**3.33** Calculate the mass (in grams) of each of the following species.

- Ar atom
- Te atom
- $PBr_3$  molecule
- $Fe(OH)_3$  formula unit

**3.34** Calculate the mass (in grams) of each of the following species.

- Br atom
- Te atom
- $PBr_3$  molecule
- $Fe(OH)_2$  formula unit

**3.35** Diethyl ether,  $(C_2H_5)_2O$ , commonly known as ether, is used as an anesthetic. What is the mass in grams of a molecule of diethyl ether?

**3.36** Glycerol,  $C_3H_8O_3$ , is used as a moistening agent for candy and is the starting material for nitroglycerin. Calculate the mass of a glycerol molecule in grams.

**3.37** Calculate the mass in grams of the following.

- 0.15 mol Na
- 0.594 mol S
- 2.78 mol  $CH_2Cl_2$
- 38 mol  $(NH_4)_2S$

**3.38** Calculate the mass in grams of the following.

- 0.331 mol Fe
- 2.1 mol F
- 0.034 mol  $CO_2$
- 1.89 mol  $K_2CrO_4$

**3.39** Boric acid,  $H_3BO_3$ , is a mild antiseptic and is often used as an eyewash. A sample contains 0.543 mol  $H_3BO_3$ . What is the mass of boric acid in the sample?

**3.40** Carbon disulfide,  $CS_2$ , is a colorless, highly flammable liquid used in the manufacture of rayon and cellophane. A sample contains 0.0116 mol  $CS_2$ . Calculate the mass of carbon disulfide in the sample.

**3.41** Obtain the moles of substance in the following.

- 7.17 g C
- 4.02 g  $Cl_2$
- 78 g  $C_4H_{10}$
- 73.5 g  $Al_2(CO_3)_3$

**3.42** Obtain the moles of substance in the following.

- 2.57 g As
- 7.83 g  $S_8$
- 33.8 g  $N_2H_4$
- 227 g  $Al_2(SO_4)_3$

**3.43** Calcium sulfate,  $CaSO_4$ , is a white, crystalline powder. Gypsum is a mineral, or natural substance, that is a hydrate of calcium sulfate. A 1.000-g sample of gypsum contains 0.791 g  $CaSO_4$ . How many moles of  $CaSO_4$  are there in this sample? Assuming that the rest of the sample is water, how many moles of  $H_2O$  are there in the sample? Show that the result is consistent with the formula  $CaSO_4 \cdot 2H_2O$ .

**3.44** A 1.547-g sample of blue copper(II) sulfate pentahydrate,  $CuSO_4 \cdot 5H_2O$ , is heated carefully to drive off the water. The white crystals of  $CuSO_4$  that are left behind have a mass

of 0.989 g. How many moles of  $\text{H}_2\text{O}$  were in the original sample? Show that the relative molar amounts of  $\text{CuSO}_4$  and  $\text{H}_2\text{O}$  agree with the formula of the hydrate.

**3.45** Calculate the following.

- a number of atoms in 8.21 g Li
- b number of atoms in 32.0 g  $\text{Br}_2$
- c number of molecules in 45 g  $\text{NH}_3$
- d number of formula units in 201 g  $\text{PbCrO}_4$
- e number of  $\text{SO}_4^{2-}$  ions in 14.3 g  $\text{Cr}_2(\text{SO}_4)_3$

**3.46** Calculate the following.

- a number of atoms in 25.7 g Al
- b number of atoms in 5.66 g  $\text{I}_2$
- c number of molecules in 14.9 g  $\text{N}_2\text{O}_5$
- d number of formula units in 2.99 g  $\text{NaClO}_4$
- e number of  $\text{Ca}^{2+}$  ions in 4.71 g  $\text{Ca}_3(\text{PO}_4)_2$

**3.47** Carbon tetrachloride is a colorless liquid used in the manufacture of fluorocarbons and as an industrial solvent. How many molecules are there in 7.58 mg of carbon tetrachloride?

**3.48** Chlorine trifluoride is a colorless, reactive gas used in nuclear fuel reprocessing. How many molecules are there in a 8.55-mg sample of chlorine trifluoride?

### Mass Percentage

**3.49** A 1.680-g sample of coal contains 1.584 g C. Calculate the mass percentage of C in the coal.

**3.50** A 6.01-g aqueous solution of isopropyl alcohol contains 3.67 g of isopropyl alcohol. What is the mass percentage of isopropyl alcohol in the solution?

**3.51** Phosphorus oxychloride is the starting compound for preparing substances used as flame retardants for plastics. An 8.53-mg sample of phosphorus oxychloride contains 1.72 mg of phosphorus. What is the mass percentage of phosphorus in the compound?

**3.52** Ethyl mercaptan is an odorous substance added to natural gas to make leaks easily detectable. A sample of ethyl mercaptan weighing 3.52 mg contains 1.64 mg of sulfur. What is the mass percentage of sulfur in the substance?

**3.53** A fertilizer is advertised as containing 14.0% nitrogen (by mass). How much nitrogen is there in 4.15 kg of fertilizer?

**3.54** Seawater contains 0.0065% (by mass) of bromine. How many grams of bromine are there in 2.50 L of seawater? The density of seawater is  $1.025 \text{ g/cm}^3$ .

**3.55** A sample of an alloy of aluminum contains 0.0898 mol Al and 0.0381 mol Mg. What are the mass percentages of Al and Mg in the alloy?

**3.56** A sample of gas mixture from a neon sign contains 0.0856 mol Ne and 0.0254 mol Kr. What are the mass percentages of Ne and Kr in the gas mixture?

### Chemical Formulas

**3.57** Calculate the percentage composition for each of the following compounds (three significant figures).

- a NO
- b  $\text{SO}_3$
- c  $\text{NaH}_2\text{PO}_3$
- d  $\text{Pb}(\text{NO}_3)_2$

**3.58** Calculate the percentage composition for each of the following compounds (three significant figures).

- a  $\text{NO}_2$
- b  $\text{H}_2\text{N}_2$
- c  $\text{KClO}_4$
- d  $\text{Mg}(\text{NO}_3)_2$

**3.59** Calculate the mass percentage of each element in toluene, represented by the following molecular model.

**3.60** Calculate the mass percentage of each element in 2-propanol, represented by the following molecular model.

**3.61** Which contains more carbon, 6.01 g of glucose,  $\text{C}_6\text{H}_{12}\text{O}_6$ , or 5.85 g of ethanol,  $\text{C}_2\text{H}_6\text{O}$ ?

**3.62** Which contains more sulfur, 40.8 g of calcium sulfate,  $\text{CaSO}_4$ , or 38.8 g of sodium sulfite,  $\text{Na}_2\text{SO}_3$ ?

**3.63** Ethylene glycol is used as an automobile antifreeze and in the manufacture of polyester fibers. The name glycol stems from the sweet taste of this poisonous compound. Combustion of 6.38 mg of ethylene glycol gives 9.06 mg  $\text{CO}_2$  and 5.58 mg  $\text{H}_2\text{O}$ . The compound contains only C, H, and O. What are the mass percentages of the elements in ethylene glycol?

**3.64** Phenol, commonly known as carbolic acid, was used by Joseph Lister as an antiseptic for surgery in 1865. Its principal use today is in the manufacture of phenolic resins and plastics. Combustion of 5.23 mg of phenol yields 14.67 mg  $\text{CO}_2$  and 3.01 mg  $\text{H}_2\text{O}$ . Phenol contains only C, H, and O. What is the percentage of each element in this substance?

## 101e

## Calculations with Chemical Formulas and Equations

**3.65** An oxide of osmium (symbol Os) is a pale yellow solid. If 2.89 g of the compound contains 2.16 g of osmium, what is its empirical formula?

**3.66** An oxide of tungsten (symbol W) is a bright yellow solid. If 5.34 g of the compound contains 4.23 g of tungsten, what is its empirical formula?

**3.67** Potassium bromate is a colorless, crystalline substance whose composition is 23.4% K, 47.8% Br, and 28.8% O, by mass. What is its empirical formula?

**3.68** Hydroquinone, used as a photographic developer, is 65.4% C, 5.5% H, and 29.1% O, by mass. What is the empirical formula of hydroquinone?

**3.69** Acrylic acid, used in the manufacture of acrylic plastics, has the composition 50.0% C, 5.6% H, and 44.4% O. What is its empirical formula?

**3.70** Malonic acid is used in the manufacture of barbiturates (sleeping pills). The composition of the acid is 34.6% C, 3.9% H, and 61.5% O. What is malonic acid's empirical formula?

**3.71** Two compounds have the same composition: 92.25% C and 7.75% H.

**a** Obtain the empirical formula corresponding to this composition.

**b** One of the compounds has a molecular weight of 52.03 amu; the other, of 78.05 amu. Obtain the molecular formulas of both compounds.

**3.72** Two compounds have the same composition: 85.62% C and 14.38% H.

**a** Obtain the empirical formula corresponding to this composition.

**b** One of the compounds has a molecular weight of 28.03 amu; the other, of 56.06 amu. Obtain the molecular formulas of both compounds.

**3.73** Putrescine, a substance produced by decaying animals, has the empirical formula  $C_2H_6N$ . Several determinations of molecular weight give values in the range of 87 to 90 amu. Find the molecular formula of putrescine.

**3.74** Compounds of boron with hydrogen are called boranes. One of these boranes has the empirical formula  $BH_3$  and a molecular weight of 28 amu. What is its molecular formula?

**3.75** Oxalic acid is a toxic substance used by laundries to remove rust stains. Its composition is 26.7% C, 2.2% H, and 71.1% O (by mass), and its molecular weight is 90 amu. What is its molecular formula?

**3.76** Adipic acid is used in the manufacture of nylon. The composition of the acid is 49.3% C, 6.9% H, and 43.8% O (by mass), and the molecular weight is 146 amu. What is the molecular formula?

### Stoichiometry: Quantitative Relations in Reactions

**3.77** Ethylene,  $C_2H_4$ , burns in oxygen to give carbon dioxide,  $CO_2$ , and water. Write the equation for the reaction, giving molecular, molar, and mass interpretations below the equation.

**3.78** Hydrogen sulfide gas,  $H_2S$ , burns in oxygen to give sulfur dioxide,  $SO_2$ , and water. Write the equation for the reaction, giving molecular, molar, and mass interpretations below the equation.

**3.79** Butane,  $C_4H_{10}$ , burns with the oxygen in air to give carbon dioxide and water.

What is the amount (in moles) of carbon dioxide produced from 0.41 mol  $C_4H_{10}$ ?

**3.80** Ethanol,  $C_2H_5OH$ , burns with the oxygen in air to give carbon dioxide and water.

What is the amount (in moles) of water produced from 0.77 mol  $C_2H_5OH$ ?

**3.81** Iron in the form of fine wire burns in oxygen to form iron(III) oxide.

How many moles of  $O_2$  are needed to produce 7.38 mol  $Fe_2O_3$ ?

**3.82** Nickel(II) chloride reacts with sodium phosphate to precipitate nickel(II) phosphate.

How many moles of nickel(II) chloride are needed to produce 0.715 mol nickel(II) phosphate?

**3.83** Nitric acid,  $HNO_3$ , is manufactured by the Ostwald process, in which nitrogen dioxide,  $NO_2$ , reacts with water.

How many grams of nitrogen dioxide are required in this reaction to produce 8.60 g  $HNO_3$ ?

**3.84** White phosphorus,  $P_4$ , is prepared by fusing calcium phosphate,  $Ca_3(PO_4)_2$ , with carbon, C, and sand,  $SiO_2$ , in an electric furnace.

How many grams of calcium phosphate are required to give 30.0 g of phosphorus?

**3.85** Tungsten metal, W, is used to make incandescent bulb filaments. The metal is produced from the yellow tungsten(VI) oxide,  $WO_3$ , by reaction with hydrogen.

How many grams of tungsten can be obtained from 4.81 kg of hydrogen with excess tungsten(VI) oxide?

**3.86** Acrylonitrile,  $C_3H_3N$ , is the starting material for the production of a kind of synthetic fiber (acrylics). It can be made from propylene,  $C_3H_6$ , by reaction with nitric oxide, NO.

How many grams of acrylonitrile are obtained from 452 kg of propylene and excess NO?

**3.87** The following reaction, depicted using molecular models, is used to make carbon tetrachloride,  $\text{CCl}_4$ , a solvent and starting material for the manufacture of fluorocarbon refrigerants and aerosol propellants.

Calculate the number of grams of carbon disulfide,  $\text{CS}_2$ , needed for a laboratory-scale reaction with 62.7 g of chlorine,  $\text{Cl}_2$ .

**3.88** Using the following reaction (depicted using molecular models), large quantities of ammonia are burned in the presence of a platinum catalyst to give nitric oxide, as the first step in the preparation of nitric acid.

Suppose a vessel contains 5.5 g of  $\text{NH}_3$ . How many grams of  $\text{O}_2$  are needed for a complete reaction?

**3.89** When dinitrogen pentoxide,  $\text{N}_2\text{O}_5$ , a white solid, is heated, it decomposes to nitrogen dioxide and oxygen.

If a sample of  $\text{N}_2\text{O}_5$  produces 1.381 g  $\text{O}_2$ , how many grams of  $\text{NO}_2$  are formed?

**3.90** Copper metal reacts with nitric acid. Assume that the reaction is

If 5.58 g  $\text{Cu}(\text{NO}_3)_2$  is eventually obtained, how many grams of nitrogen monoxide,  $\text{NO}$ , would have formed?

### Limiting Reactant; Theoretical and Percentage Yields

**3.91** Potassium superoxide,  $\text{KO}_2$ , is used in rebreathing gas masks to generate oxygen.

If a reaction vessel contains 0.25 mol  $\text{KO}_2$  and 0.15 mol  $\text{H}_2\text{O}$ , what is the limiting reactant? How many moles of oxygen can be produced?

**3.92** Solutions of sodium hypochlorite,  $\text{NaClO}$ , are sold as a bleach (such as Clorox). They are prepared by the reaction of chlorine with sodium hydroxide.

If you have 1.44 mol of  $\text{NaOH}$  in solution and 1.47 mol of  $\text{Cl}_2$  gas available to react, which is the limiting reactant? How many moles of  $\text{NaClO}(aq)$  could be obtained?

**3.93** Methanol,  $\text{CH}_3\text{OH}$ , is prepared industrially from the gas-phase catalytic balanced reaction that has been depicted here using molecular models.

In a laboratory test, a reaction vessel was filled with 41.1 g  $\text{CO}$  and 10.2 g  $\text{H}_2$ . How many grams of methanol would be produced in a complete reaction? Which reactant remains unconsumed at the end of the reaction? How many grams of it remain?

**3.94** Carbon disulfide,  $\text{CS}_2$ , burns in oxygen. Complete combustion gives the balanced reaction that has been depicted here using molecular models.

Calculate the grams of sulfur dioxide,  $\text{SO}_2$ , produced when a mixture of 35.0 g of carbon disulfide and 35.0 g of oxygen reacts. Which reactant remains unconsumed at the end of the combustion? How many grams remain?

**3.95** Titanium, which is used to make airplane engines and frames, can be obtained from titanium(IV) chloride, which in turn is obtained from titanium(IV) oxide by the following process:

A vessel contains 4.15 g  $\text{TiO}_2$ , 5.67 g  $\text{C}$ , and 6.78 g  $\text{Cl}_2$ . Suppose the reaction goes to completion as written. How many grams of titanium(IV) chloride can be produced?

**3.96** Hydrogen cyanide,  $\text{HCN}$ , is prepared from ammonia, air, and natural gas ( $\text{CH}_4$ ) by the following process:

Hydrogen cyanide is used to prepare sodium cyanide, which is used in part to obtain gold from gold-containing rock. If a reaction vessel contains 11.5 g  $\text{NH}_3$ , 12.0 g  $\text{O}_2$ , and 10.5 g  $\text{CH}_4$ , what is the maximum mass in grams of hydrogen cyanide that could be made, assuming the reaction goes to completion as written?

**3.97** Aspirin (acetylsalicylic acid) is prepared by heating salicylic acid,  $\text{C}_7\text{H}_6\text{O}_3$ , with acetic anhydride,  $\text{C}_4\text{H}_6\text{O}_3$ . The other product is acetic acid,  $\text{C}_2\text{H}_4\text{O}_2$ .

What is the theoretical yield (in grams) of aspirin,  $\text{C}_9\text{H}_8\text{O}_4$ , when 2.00 g of salicylic acid is heated with 4.00 g of acetic anhydride? If the actual yield of aspirin is 1.86 g, what is the percentage yield?

**3.98** Methyl salicylate (oil of wintergreen) is prepared by heating salicylic acid,  $\text{C}_7\text{H}_6\text{O}_3$ , with methanol,  $\text{CH}_3\text{OH}$ .

In an experiment, 2.50 g of salicylic acid is reacted with 10.31 g of methanol. The yield of methyl salicylate,  $\text{C}_8\text{H}_8\text{O}_3$ , is 1.27 g. What is the percentage yield?

## General Problems

**Key:** These problems provide more practice but are not divided by topic or keyed to exercises. Each section ends with essay questions, each of which is color coded to refer to the *Instrumental Methods* (light blue) chapter essay on which it is based. Odd-numbered problems and the even-numbered problems that follow are similar; answers to all odd-numbered problems except the essay questions are given in the back of the book.

**3.99** Caffeine, the stimulant in coffee and tea, has the molecular formula  $C_8H_{10}N_4O_2$ . Calculate the mass percentage of each element in the substance. Give the answers to three significant figures.

**3.100** Morphine, a narcotic substance obtained from opium, has the molecular formula  $C_{17}H_{19}NO_3$ . What is the mass percentage of each element in morphine (to three significant figures)?

**3.101** A moth repellent, *para*-dichlorobenzene, has the composition 49.1% C, 2.7% H, and 48.2% Cl. Its molecular weight is 147 amu. What is its molecular formula?

**3.102** Sorbic acid is added to food as a mold inhibitor. Its composition is 64.3% C, 7.2% H, and 28.5% O, and its molecular weight is 112 amu. What is its molecular formula?

**3.103** Thiophene is a liquid compound of the elements C, H, and S. A sample of thiophene weighing 7.96 mg was burned in oxygen, giving 16.65 mg  $CO_2$ . Another sample was subjected to a series of reactions that transformed all of the sulfur in the compound to barium sulfate. If 4.31 mg of thiophene gave 11.96 mg of barium sulfate, what is the empirical formula of thiophene? Its molecular weight is 84 amu. What is its molecular formula?

**3.104** Aniline, a starting compound for urethane plastic foams, consists of C, H, and N. Combustion of such compounds yields  $CO_2$ ,  $H_2O$ , and  $N_2$  as products. If the combustion of 9.71 mg of aniline yields 6.63 mg  $H_2O$  and 1.46 mg  $N_2$ , what is its empirical formula? The molecular weight of aniline is 93 amu. What is its molecular formula?

**3.105** A sample of limestone (containing calcium carbonate,  $CaCO_3$ ) weighing 438 mg is treated with oxalic acid,  $H_2C_2O_4$ , to give calcium oxalate,  $CaC_2O_4$ .

The mass of the calcium oxalate produced is 469 mg. What is the mass percentage of calcium carbonate in this limestone?

**3.106** A titanium ore contains rutile ( $TiO_2$ ) plus some iron oxide and silica. When it is heated with carbon in the presence of chlorine, titanium tetrachloride,  $TiCl_4$ , is formed.

Titanium tetrachloride, a liquid, can be distilled from the mixture. If 35.4 g of titanium tetrachloride is recovered from 18.1 g of crude ore, what is the mass percentage of  $TiO_2$  in the ore (assuming all  $TiO_2$  reacts)?

**3.107** Ethylene oxide,  $C_2H_4O$ , is made by the oxidation of ethylene,  $C_2H_4$ .

Ethylene oxide is used to make ethylene glycol for automobile antifreeze. In a pilot study, 10.6 g of ethylene gave 9.91 g of ethylene oxide. What is the percentage yield of ethylene oxide?

**3.108** Nitrobenzene,  $C_6H_5NO_2$ , an important raw material for the dye industry, is prepared from benzene,  $C_6H_6$ , and nitric acid,  $HNO_3$ .

When 21.6 g of benzene and an excess of  $HNO_3$  are used, what is the theoretical yield of nitrobenzene? If 30.0 g of nitrobenzene is recovered, what is the percentage yield?

**3.109** Zinc metal can be obtained from zinc oxide,  $ZnO$ , by reaction at high temperature with carbon monoxide,  $CO$ .

The carbon monoxide is obtained from carbon.

What is the maximum amount of zinc that can be obtained from 75.0 g of zinc oxide and 50.0 g of carbon?

**3.110** Hydrogen cyanide,  $HCN$ , can be made by a two-step process. First, ammonia is reacted with  $O_2$  to give nitric oxide,  $NO$ .

Then nitric oxide is reacted with methane,  $CH_4$ .

When 24.2 g of ammonia and 25.1 g of methane are used, how many grams of hydrogen cyanide can be produced?

**3.111** Calcium carbide,  $CaC_2$ , used to produce acetylene,  $C_2H_2$ , is prepared by heating calcium oxide,  $CaO$ , and carbon,  $C$ , to high temperature.

If a mixture contains 8.49 kg of each reactant, how many grams of calcium carbide can be prepared?

**3.112** A mixture consisting of 11.9 g of calcium fluoride,  $CaF_2$ , and 12.1 g of sulfuric acid,  $H_2SO_4$ , is heated to drive off hydrogen fluoride,  $HF$ .

What is the maximum number of grams of hydrogen fluoride that can be obtained?

**3.113** Alloys, or metallic mixtures, of mercury with another metal are called amalgams. Sodium in sodium amalgam reacts with water. (Mercury does not.)

If a 15.23-g sample of sodium amalgam evolves 0.108 g of hydrogen, what is the percentage of sodium in the amalgam?

**3.114** A sample of sandstone consists of silica,  $\text{SiO}_2$ , and calcite,  $\text{CaCO}_3$ . When the sandstone is heated, calcium carbonate,  $\text{CaCO}_3$ , decomposes into calcium oxide,  $\text{CaO}$ , and carbon dioxide.

What is the percentage of silica in the sandstone if 18.7 mg of the rock yields 3.95 mg of carbon dioxide?

■ **3.115** What type of information can you obtain from a compound using a mass spectrometer?

■ **3.116** Why is the mass spectrum of a molecule much more complicated than that of an atom?

## Strategy Problems

**Key:** As noted earlier, all of the practice and general problems are matched pairs. This section is a selection of problems that are not in matched-pair format. These challenging problems require that you employ many of the concepts and strategies that were developed in the chapter. In some cases, you will have to integrate several concepts and operational skills in order to solve the problem successfully.

**3.117** Exactly 4.0 g of hydrogen gas combines with 32 g of oxygen gas according to the following reaction.

- a How many hydrogen molecules are required to completely react with 48 oxygen molecules?
- b If you conducted the reaction, and it produced 5.0 mol  $\text{H}_2\text{O}$ , how many moles of both  $\text{O}_2$  and  $\text{H}_2$  did you start with?
- c If you started with 37.5 g  $\text{O}_2$ , how many grams of  $\text{H}_2$  did you start with to have a complete reaction?
- d How many grams of  $\text{O}_2$  and  $\text{H}_2$  were reacted to produce 30.0 g  $\text{H}_2\text{O}$ ?

**3.118** Aluminum metal reacts with iron(III) oxide to produce aluminum oxide and iron metal.

- a How many moles of  $\text{Fe}_2\text{O}_3$  are required to completely react with 44 g Al?
- b How many moles of Fe are produced by the reaction of 3.14 mol  $\text{Fe}_2\text{O}_3$  and 99.1 g Al?
- c How many atoms of Al are required to produce 7.0 g Fe?

**3.119** Consider the equation

- a If 25 g  $\text{H}_2\text{SO}_4$  is reacted with 7.7 g KOH, how many grams of  $\text{K}_2\text{SO}_4$  are produced?
- b For part a of this problem, identify the limiting reactant and calculate the mass of excess reactant that remains after the reaction is completed.
- c Calculate the theoretical yield of the reaction. How many grams of material would you expect to obtain if the reaction has a 67.1% yield?

**3.120** You perform a combustion analysis on a 255 mg sample of a substance that contains only C, H, and O, and you find that 561 mg  $\text{CO}_2$  is produced, along with 306 mg  $\text{H}_2\text{O}$ .

- a If the substance contains only C, H, and O, what is the empirical formula?
- b If the molar mass of the compound is 180 g/mol, what is the molecular formula of the compound?

**3.121** When ammonia and oxygen are reacted, they produce nitric oxide and water. When 8.5 g of ammonia is allowed to react with an excess of  $\text{O}_2$ , the reaction produces 12.0 g of nitrogen monoxide. What is the percentage yield of the reaction?

**3.122** A 3.0-L sample of paint that has a density of 4.65 g/mL is found to contain 33.1 g  $\text{Pb}_3\text{N}_2(s)$ . How many grams of lead were in the paint sample?

**3.123** A 12.1-g sample of  $\text{Na}_2\text{SO}_3$  is mixed with a 14.6-g sample of  $\text{MgSO}_4$ . What is the total mass of oxygen present in the mixture?

**3.124** Potassium superoxide,  $\text{KO}_2$ , is employed in a self-contained breathing apparatus used by emergency personnel as a source of oxygen. The reaction is

If a self-contained breathing apparatus is charged with 750 g  $\text{KO}_2$  and then is used to produce 188 g of oxygen, was all of the  $\text{KO}_2$  consumed in this reaction? If the  $\text{KO}_2$  wasn't all consumed, how much is left over and what mass of additional  $\text{O}_2$  could be produced?

**3.125** Calcium carbonate is a common ingredient in stomach antacids. If an antacid tablet has 68.4 mg of calcium carbonate, how many moles of calcium carbonate are there in 175 tablets?

**3.126** While cleaning out your closet, you find a jar labeled "2.21 moles lead nitrite." Since Stock convention was not used, you do not know the oxidation number of the lead. You weigh the contents, and find a mass of  $6.61 \times 10^5$  mg. What is the percentage composition of nitrite?

**3.127** Sulfuric acid can be produced by the following sequence of reactions.

You find a source of sulfur that is 65.0% sulfur by mass. How many grams of this starting material would be required to produce 87.0 g of sulfuric acid?

**3.128** Copper reacts with nitric acid according to the following reaction.

If 2.40 g of Cu is added to a container with 2.00 mL of concentrated nitric acid (70% by mass  $\text{HNO}_3$ ; density =  $1.42 \text{ g/cm}^3$ ), what mass of nitrogen monoxide gas will be produced?

**3.129** A sample of methane gas,  $\text{CH}_4(g)$ , is reacted with oxygen gas to produce carbon dioxide and water. If 20.0 L of methane (density =  $1.82 \text{ kg/m}^3$ ) and 30.0 L of oxygen gas (density =  $1.31 \text{ kg/m}^3$ ) are placed into a container and allowed to react, how many kg of carbon dioxide will be produced by the reaction?

**3.130** A sample containing only boron and fluorine was decomposed yielding 4.75 mg of boron and 17.5 mL of fluorine gas (density = 1.43 g/L). What is the empirical formula of the sample compound?

**3.131** Sodium azide,  $\text{NaN}_3$ , undergoes the reaction  $\text{NaN}_3(s) \longrightarrow 2\text{Na}(s) + 3\text{N}_2(g)$ . Because this reaction is very fast and produces nitrogen gas,  $\text{NaN}_3$  is used to inflate airplane escape chutes. Sodium azide can be produced through two reaction steps.

Starting with 1.0 kg of Na, 6.0 kg of  $\text{NH}_3$ , and 1.0 kg of  $\text{N}_2\text{O}$ , what is the maximum mass (kg) of sodium azide that can be produced?

**3.132** Dinotrogen monoxide, commonly known as laughing gas, can be obtained by cautiously warming ammonium nitrate according to the equation

If the reaction has a 75% yield, what mass of ammonium nitrate must be used to produce 685 mg of  $\text{N}_2\text{O}$ ?

## Capstone Problems

**Key:** The problems under this heading combine skills, strategies, and concepts learned in previous chapters with those introduced in the current one.

**3.133** A 0.500-g mixture of  $\text{Cu}_2\text{O}$  and  $\text{CuO}$  contains 0.425 g Cu. What is the mass of  $\text{CuO}$  in the mixture?

**3.134** A mixture of  $\text{Fe}_2\text{O}_3$  and  $\text{FeO}$  was found to contain 72.00% Fe by mass. What is the mass of  $\text{Fe}_2\text{O}_3$  in 0.750 g of this mixture?

**3.135** Hemoglobin is the oxygen-carrying molecule of red blood cells, consisting of a protein and a nonprotein substance. The nonprotein substance is called heme. A sample of heme weighing 35.2 mg contains 3.19 mg of iron. If a heme molecule contains one atom of iron, what is the molecular weight of heme?

**3.136** Penicillin V was treated chemically to convert sulfur to barium sulfate,  $\text{BaSO}_4$ . An 8.19-mg sample of penicillin V gave 5.46 mg  $\text{BaSO}_4$ . What is the percentage of sulfur in penicillin V? If there is one sulfur atom in the molecule, what is the molecular weight?

**3.137** A 3.41-g sample of a metallic element, M, reacts completely with 0.0158 mol of a gas,  $\text{X}_2$ , to form 4.52 g MX. What are the identities of M and X?

**3.138** 1.92 g  $\text{M}^{2+}$  ion reacts with 0.158 mol  $\text{X}^-$  ion to produce a compound,  $\text{MX}_2$ , which is 86.8% X by mass. What are the identities of  $\text{M}^{2+}$  and  $\text{X}^-$ ?

**3.139** An alloy of iron (54.7%), nickel (45.0%), and manganese (0.3%) has a density of 8.17 g/cm<sup>3</sup>. How many iron atoms are there in a block of alloy measuring 10.0 cm × 20.0 cm × 15.0 cm?

**3.140** An alloy of iron (71.0%), cobalt (12.0%), and molybdenum (17.0%) has a density of 8.20 g/cm<sup>3</sup>. How many cobalt atoms are there in a cylinder with a radius of 2.50 cm and a length of 10.0 cm?

**3.141** A power plant is driven by the combustion of a complex fossil fuel having the formula  $\text{C}_{11}\text{H}_7\text{S}$ . Assume the air supply is composed of only  $\text{N}_2$  and  $\text{O}_2$  with a molar ratio of 3.76:1.00, and the  $\text{N}_2$  remains unreacted. In addition to the water produced, the fuel's C is completely combusted to  $\text{CO}_2$  and its sulfur content is converted to  $\text{SO}_2$ . In order to evaluate gases emitted at the exhaust stacks for environmental regulation purposes, the nitrogen supplied with the air must also be included in the balanced reactions.

- Including the  $\text{N}_2$  supplied in the air, write a balanced combustion equation for the complex fuel assuming 100% stoichiometric combustion (i.e., when there is no excess oxygen in the products and the only C-containing product is  $\text{CO}_2$ ). Except in the case of  $\text{N}_2$ , use only integer coefficients.
- Including  $\text{N}_2$  supplied in the air, write a balanced combustion equation for the complex fuel assuming 120% stoichiometric combustion (i.e., when excess oxygen is present in the products and the only C-containing product is  $\text{CO}_2$ ). Except in the case of  $\text{N}_2$ , use only integer coefficients.
- Calculate the minimum mass (in kg) of air required to completely combust 1700 kg of  $\text{C}_{11}\text{H}_7\text{S}$ .
- Calculate the air/fuel mass ratio, assuming 100% stoichiometric combustion.
- Calculate the air/fuel mass ratio, assuming 120% stoichiometric combustion.

## 4

## Chemical Reactions

The addition of an acid to a basic solution containing aqueous sodium benzoate. The white precipitate formed during this acid-base reaction is benzoic acid. Sodium benzoate is an important substance used as a food preservative.

Andrew Lambert Photography/Science Source

## CONTENTS AND CONCEPTS

**Ions in Aqueous Solution**

Explore how molecular and ionic substances behave when they dissolve in water to form *solutions*.

**Quantitative Analysis**

Using chemical reactions in aqueous solution, determine the amount of substance or species present in materials

**4.9** Gravimetric Analysis

**4.10** Volumetric Analysis

**C**hemical reactions are the heart of chemistry. Some reactions, such as those accompanying a forest fire or the explosion of dynamite, are quite dramatic. Others are much less obvious, although all chemical reactions must involve detectable change. A chemical reaction involves a change from reactant substances to product substances, and the product substances will have physical and chemical properties different from those of the reactants.

Figure 4.1 shows an experimenter adding a colorless solution of potassium iodide, KI, to a colorless solution of lead(II) nitrate,  $\text{Pb}(\text{NO}_3)_2$ . What you see is the formation of a cloud of bright yellow crystals where the two solutions have come into contact, clear evidence of a chemical reaction. The bright yellow crystals are lead(II) iodide,  $\text{PbI}_2$ , one of the reaction products. We call a solid that forms during a chemical reaction in solution a *precipitate*; the reaction is a precipitation reaction.

In this chapter, we will discuss the major types of chemical reactions, including precipitation reactions. Some of the most important reactions we will describe involve ions in aqueous (water) solution. Therefore, we will first look at these ions and see how we represent by chemical equations the reactions involving ions in aqueous solution.

Some questions we will answer are: What is the evidence for ions in solution? How do we write chemical equations for reactions involving ions? How can we classify and describe the many reactions we observe so that we can begin to understand them? What is the quantitative description of solutions and reactions in solution?

## ► Ions in Aqueous Solution

You probably have heard that you should not operate electrical equipment while standing in water. And you may have read a murder mystery in which the victim was electrocuted when an electrical appliance “accidentally” fell into his or her bath water. Actually, if the water were truly pure, the person would be safe from electrocution, because pure water is a nonconductor of electricity. Bath water, or water as it flows from the faucet, however, is a *solution* of water with small amounts of dissolved substances in it, and these dissolved substances make the solution an electrical conductor. This allows an electric current to flow from an electrical appliance to the human body. Let us look at the nature of such solutions.

### 4.1 Ionic Theory of Solutions and Solubility Rules

Chemists began studying the electrical behavior of substances in the early nineteenth century, and they knew that you could make pure water electrically conducting by dissolving certain substances in it. In 1884, the young Swedish chemist Svante Arrhenius proposed the *ionic theory of solutions* to account for this conductivity. He said that certain substances produce freely moving ions when they dissolve in water, and these ions conduct an electric current in an aqueous solution. ►

Suppose you dissolve sodium chloride,  $\text{NaCl}$ , in water. From our discussion in Section 2.6, you may remember that sodium chloride is an ionic solid consisting of sodium ions,  $\text{Na}^+$ , and chloride ions,  $\text{Cl}^-$ , held in a regular, fixed array. When you dissolve solid sodium chloride in water, the  $\text{Na}^+$  and  $\text{Cl}^-$  ions go into solution as freely moving ions. Now suppose you dip electric wires that are connected to the poles of a battery into a solution of sodium chloride. The wire that connects to the positive pole of the battery attracts the negatively charged chloride ions in solution, because of their opposite charges. Similarly, the wire connected to the negative pole of the battery attracts the positively charged sodium ions in solution (Figure 4.2). Thus, the ions in the solution begin to move, and these moving charges

© Cengage Learning

**Figure 4.1** ▲

**Reaction of potassium iodide solution and lead(II) nitrate solution** The reactant solutions are colorless, but one of the products, lead(II) iodide, forms as a yellow precipitate.

Arrhenius submitted his ionic theory as part of his doctoral dissertation to the faculty at Uppsala, Sweden, in 1884. It was not well received and he barely passed. In 1903, however, he was awarded the Nobel Prize in chemistry for this theory.

**Figure 4.2** ▲

**Motion of ions in solution** Ions are in fixed positions in a crystal. During the solution process, however, ions leave the crystal and become freely moving. Note that  $\text{Na}^+$  ions (small gray spheres) are attracted to the negative wire, whereas  $\text{Cl}^-$  ions (large green spheres) are attracted to the positive wire.

form the electric current in the solution. (In a wire, it is moving electrons that constitute the electric current.)

Now consider pure water. Water consists of molecules, each of which is electrically neutral. Since each molecule carries no net electric charge, it carries no overall electric charge when it moves. Thus, pure water is a nonconductor of electricity.

In summary, although water is itself nonconducting, it has the ability to dissolve various substances, some of which go into solution as freely moving ions. An aqueous solution of ions is electrically conducting.

### Electrolytes and Nonelectrolytes

We can divide the substances that dissolve in water into two broad classes, electrolytes and nonelectrolytes. An **electrolyte** is a substance that dissolves in water to give an electrically conducting solution. Sodium chloride, table salt, is an example of an electrolyte. When most ionic substances dissolve in water, ions that were in fixed sites in the crystalline solid go into the surrounding aqueous solution, where they are free to move about. The resulting solution is conducting because the moving ions form an electric current. Thus, in general, *ionic solids that dissolve in water are electrolytes*.

Not all electrolytes are ionic substances. Certain molecular substances dissolve in water to form ions. The resulting solution is electrically conducting, and so we say that the molecular substance is an electrolyte. An example is hydrogen chloride gas,  $\text{HCl}(g)$ , which is a molecular substance. Hydrogen chloride gas dissolves in water, giving  $\text{HCl}(aq)$ , which in turn produces hydrogen ions,  $\text{H}^+$ , and chloride ions,  $\text{Cl}^-$ , in aqueous solution. (The solution of  $\text{H}^+$  and  $\text{Cl}^-$  ions is called hydrochloric acid.)

We will look more closely at molecular electrolytes, such as  $\text{HCl}$ , at the end of this section.

A **nonelectrolyte** is a substance that dissolves in water to give a nonconducting or very poorly conducting solution. A common example is sucrose,  $\text{C}_{12}\text{H}_{22}\text{O}_{11}$ , which is ordinary table sugar. Another example is methanol,  $\text{CH}_3\text{OH}$ , a compound used in car window washer solution. Both of these are molecular substances. The solution process occurs because molecules of the substance mix with molecules of water. Molecules are electrically neutral and cannot carry an electric current, so the solution is electrically nonconducting.

### Observing the Electrical Conductivity of a Solution

Figure 4.3 shows a simple apparatus that allows you to observe the ability of a solution to conduct an electric current. The apparatus has two electrodes; here they are flat metal plates, dipping into the solution in a beaker. One electrode connects directly to a battery through a wire. The other electrode connects by a wire to a light bulb that connects with another wire to the other side of the battery. For an electric current to flow from the battery, there must be a complete circuit, which allows the current to flow from the positive pole of the battery through the circuit to the negative pole of the battery. To have a complete circuit, the solution in the beaker must conduct electricity, as the wires do. If the solution is conducting, the circuit is complete and the bulb lights. If the solution is nonconducting, the circuit is incomplete and the bulb does not light.

The beaker shown on the left side of Figure 4.3 contains pure water. Because the bulb is not lit, we conclude that pure water is a nonconductor (or very poor conductor) of electricity, which is what we expect from our earlier discussion. The beaker shown on the right side of Figure 4.3 contains a solution of sodium chloride in water. In this case, the bulb burns brightly, showing that the solution is a very good conductor of electricity, due to the movement of ions in the solution.

How brightly the bulb lights tells you whether the solution is a very good conductor (contains a “strong” electrolyte) or only a moderately good conductor

Figure 4.3 ◀

Testing the electrical conductivity of a solution

Pure water does not conduct; therefore, the bulb does not light.

A solution of sodium chloride in which moving ions are present allows the current to pass through it, and the bulb lights.

(contains a “weak” electrolyte). The solution of sodium chloride burns brightly, so we conclude that sodium chloride is a strong electrolyte. Let us look more closely at such strong and weak electrolytes.

### Strong and Weak Electrolytes

When electrolytes dissolve in water they produce ions, but to varying extents. A **strong electrolyte** is *an electrolyte that exists in solution almost entirely as ions*. Most ionic solids that dissolve in water do so by going into the solution almost completely as ions, so they are strong electrolytes. An example is sodium chloride. We can represent the dissolution of sodium chloride in water by the following equation:

A **weak electrolyte** is *an electrolyte that dissolves in water to give a relatively small percentage of ions*. These are generally molecular substances. Ammonia,  $\text{NH}_3$ , is an example. Pure ammonia is a gas that readily dissolves in water and goes into solution as ammonia molecules,  $\text{NH}_3(aq)$ . When you buy “ammonia” in the grocery store, you are buying an aqueous solution of ammonia. Ammonia molecules react with water to form ammonium ions,  $\text{NH}_4^+$ , and hydroxide ions,  $\text{OH}^-$ .

However, these ions,  $\text{NH}_4^+ + \text{OH}^-$ , react with each other to give back ammonia molecules and water molecules.

Both reactions, the original one and its reverse, occur constantly and simultaneously. We denote this situation by writing a single equation with a double arrow:

As a result of this forward and reverse reaction, just a small percentage of the  $\text{NH}_3$  molecules (about 3%) have reacted at any given moment to form ions. Thus, ammonia is a weak electrolyte. The electrical conductivities of a strong and a weak electrolyte are contrasted in Figure 4.4.

Most soluble molecular substances are either nonelectrolytes or weak electrolytes. An exception is hydrogen chloride gas,  $\text{HCl}(g)$ , which dissolves in water to produce hydrogen ions and chloride ions. We represent its reaction with water by an equation with a single arrow:

Figure 4.4 ►

Comparing strong and weak electrolytes

© Cengage Learning

The apparatus is similar to that in Figure 4.3, but this time strong and weak electrolytes are compared. The solution on the left is of HCl (a strong electrolyte) and that on the right is of NH<sub>3</sub> (a weak electrolyte). Note how much more brightly the bulb on the left burns compared with that on the right.

Since hydrogen chloride dissolves to give almost entirely ions, hydrogen chloride (or hydrochloric acid) is a strong electrolyte.

### Solubility Rules

It is clear from the preceding discussion that substances vary widely in their *solubility*, or ability to dissolve, in water. Some compounds, such as sodium chloride and ethyl alcohol (CH<sub>3</sub>CH<sub>2</sub>OH), dissolve readily and are said to be *soluble*. Others, such as calcium carbonate (which occurs naturally as limestone and marble) and benzene (C<sub>6</sub>H<sub>6</sub>), have quite limited solubilities and are thus said to be *insoluble*.

Soluble ionic compounds form solutions that contain many ions and therefore are strong electrolytes. To predict the solubility of ionic compounds, chemists have developed solubility rules. Table 4.1 lists eight solubility rules for ionic compounds. These rules apply to most of the common ionic compounds that we will discuss in this course. Example 4.1 illustrates how to use the rules.

### ✓ CONCEPT CHECK 4.1

Which of the following would you expect to be strong electrolytes when placed in water?

Which of the statements below support the answers you chose above? (Pick as many as apply.)

- a** Ionic compounds always produce a significant number of ions in aqueous solution.
- b** A molecular compound can be either a weak electrolyte or a nonelectrolyte.
- c** Soluble ionic compounds are strong electrolytes.
- d** Water conducts electricity so that whenever water is present, we would expect a strong electrolyte.
- e** Some molecular substances completely ionize in aqueous solution.

Let us summarize the main points in this section. Compounds that dissolve in water are soluble; those that dissolve little, or not at all, are insoluble. Soluble substances are either electrolytes or nonelectrolytes. Nonelectrolytes form nonconducting

Rule	Applies to	Statement	Exceptions
1	$\text{Li}^+$ , $\text{Na}^+$ , $\text{K}^+$ , $\text{NH}_4^+$	Group 1A and ammonium compounds are soluble.	—
2	$\text{C}_2\text{H}_3\text{O}_2^-$ , $\text{NO}_3^-$	Acetates and nitrates are soluble.	—
3	$\text{Cl}^-$ , $\text{Br}^-$ , $\text{I}^-$	Most chlorides, bromides, and iodides are soluble.	$\text{AgCl}$ , $\text{Hg}_2\text{Cl}_2$ , $\text{PbCl}_2$ , $\text{AgBr}$ , $\text{HgBr}_2$ , $\text{Hg}_2\text{Br}_2$ , $\text{PbBr}_2$ , $\text{AgI}$ , $\text{HgI}_2$ , $\text{Hg}_2\text{I}_2$ , $\text{PbI}_2$
4	$\text{SO}_4^{2-}$	Most sulfates are soluble.	$\text{CaSO}_4$ , $\text{SrSO}_4$ , $\text{BaSO}_4$ , $\text{Ag}_2\text{SO}_4$ , $\text{Hg}_2\text{SO}_4$ , $\text{PbSO}_4$
5	$\text{CO}_3^{2-}$	Most carbonates are insoluble.	Group 1A carbonates, $(\text{NH}_4)_2\text{CO}_3$
6	$\text{PO}_4^{3-}$	Most phosphates are insoluble.	Group 1A phosphates, $(\text{NH}_4)_3\text{PO}_4$
7	$\text{S}^{2-}$	Most sulfides are insoluble.	Group 1A sulfides, $(\text{NH}_4)_2\text{S}$
8	$\text{OH}^-$	Most hydroxides are insoluble.	Group 1A hydroxides, $\text{Ca}(\text{OH})_2$ , $\text{Sr}(\text{OH})_2$ , $\text{Ba}(\text{OH})_2$

**Example 4.1** Using the Solubility Rules**Gaining Mastery Toolbox****Critical Concept 4.1**

The solubility rules are used to predict if an ionic compound will dissolve in water. Soluble ionic compounds are strong electrolytes; therefore, they exist as ions in solution. Insoluble ionic compounds do not appreciably dissolve in water.

**Solution Essentials:**

- Solubility Rules
- Ionic Compound
- Ions

Determine whether the following compounds are soluble or insoluble in water.

- $\text{Hg}_2\text{Cl}_2$
- KI
- lead(II) nitrate

**Problem Strategy** You should refer to Table 4.1 for the solubility rules of ionic compounds to see which compounds are soluble in water. The soluble ionic compounds are those that readily dissolve in water. The insoluble compounds hardly dissolve at all.

**Solution**

- According to Rule 3 in Table 4.1, most compounds that contain chloride,  $\text{Cl}^-$ , are soluble. However,  $\text{Hg}_2\text{Cl}_2$  is listed as one of the exceptions to this rule, so it does not dissolve in water. Therefore,  **$\text{Hg}_2\text{Cl}_2$  is not soluble in water.**
- According to both Rule 1, Group 1A compounds are soluble, and Rule 3, most iodides are soluble, KI is expected to be soluble. Therefore, **KI is soluble in water.**
- According to Rule 2, compounds containing nitrates,  $\text{NO}_3^-$ , are soluble. Since there are no exceptions to this rule, **lead(II) nitrate,  $\text{Pb}(\text{NO}_3)_2$ , is soluble in water.**

**Answer Check** Most incorrect determinations of solubility occur when the exceptions are overlooked, so always be sure to check the exceptions column of Table 4.1.

**Exercise 4.1** Determine whether the following compounds are soluble or insoluble in water.

- NaBr
- $\text{Ba}(\text{OH})_2$
- calcium carbonate

See Problems 4.29 and 4.30.

aqueous solutions because they dissolve completely as molecules. Electrolytes form electrically conducting solutions in water because they dissolve to give ions in solution. Electrolytes can be strong or weak. Almost all soluble ionic substances are strong electrolytes. Soluble molecular substances usually are nonelectrolytes or weak electrolytes; the latter solution consists primarily of molecules, but has a small percentage of ions. Ammonia,  $\text{NH}_3$ , is an example of a molecular substance that is a weak electrolyte. A few molecular substances (such as HCl) dissolve almost entirely as ions in the solution and are therefore strong electrolytes. The solubility rules can be used to predict the solubility of ionic compounds in water.

**CONCEPT CHECK 4.2**

$\text{LiI}(s)$  and  $\text{CH}_3\text{OH}(l)$  are introduced into separate beakers containing water. Using the drawings shown here, label each beaker with the appropriate compound and indicate whether you would expect each substance to be a strong electrolyte, a weak electrolyte, or a nonelectrolyte.

## 4.2 Molecular and Ionic Equations

We use chemical equations to help us describe chemical reactions. For a reaction involving ions, we have a choice of chemical equations, depending on the kind of information we want to convey. We can represent such a reaction by a *molecular equation*, a *complete ionic equation*, or a *net ionic equation*.

To illustrate these different kinds of equations, consider the preparation of precipitated calcium carbonate,  $\text{CaCO}_3$ . This white, fine, powdery compound is used as a paper filler to brighten and retain ink, as an antacid (as in the trade-named Tums), and as a mild abrasive in toothpastes. One way to prepare this compound is to react calcium hydroxide,  $\text{Ca}(\text{OH})_2$ , with sodium carbonate,  $\text{Na}_2\text{CO}_3$ . Let us look at the different ways to write the equation for this reaction.

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. WCH 02-200-203

### Molecular Equations

You could write the equation for this reaction as follows:

We call this a **molecular equation**, which is a *chemical equation in which the reactants and products are written as if they were molecular substances, even though they may actually exist in solution as ions*. The molecular equation is useful because it is explicit about what the reactant solutions are and what products you obtain. The equation says that you add aqueous solutions of calcium hydroxide and sodium carbonate to the reaction vessel. As a result of the reaction, the insoluble, white calcium carbonate solid forms in the solution; that is, calcium carbonate precipitates. After you remove the precipitate, you are left with a solution of sodium hydroxide. The molecular equation closely describes what you actually do in the laboratory or in an industrial process.

## Complete Ionic Equations

Although a molecular equation is useful in describing the actual reactant and product substances, it does not tell you what is happening at the level of ions. That is, it does not give you an ionic-theory interpretation of the reaction. Because this kind of information is useful, you often need to rewrite the molecular equation as an ionic equation.

Again, consider the reaction of calcium hydroxide,  $\text{Ca}(\text{OH})_2$ , and sodium carbonate,  $\text{Na}_2\text{CO}_3$ . Both are soluble ionic substances and therefore strong electrolytes; when they dissolve in water, they go into solution as ions. Each formula unit of  $\text{Ca}(\text{OH})_2$  forms one  $\text{Ca}^{2+}$  ion and two  $\text{OH}^-$  ions in solution. If you want to emphasize that the solution contains freely moving ions, it would be better to write  $\text{Ca}^{2+}(\text{aq}) + 2\text{OH}^-(\text{aq})$  in place of  $\text{Ca}(\text{OH})_2(\text{aq})$ . Similarly, each formula unit of  $\text{Na}_2\text{CO}_3$  forms two  $\text{Na}^+$  ions and one  $\text{CO}_3^{2-}$  ion in solution, and you would emphasize this by writing  $2\text{Na}^+(\text{aq}) + \text{CO}_3^{2-}(\text{aq})$  in place of  $\text{Na}_2\text{CO}_3(\text{aq})$ . The reactant side of the equation becomes

Thus, the reaction mixture begins as a solution of four different kinds of ions.

Now let us look at the product side of the equation. One product is the precipitate  $\text{CaCO}_3(\text{s})$ . According to the solubility rules, this is an insoluble ionic compound, so it will exist in water as a solid. We leave the formula as  $\text{CaCO}_3(\text{s})$  to convey this information in the equation. On the other hand,  $\text{NaOH}$  is a soluble ionic substance and therefore a strong electrolyte; it dissolves in aqueous solution to give the freely moving ions, which we denote by writing  $\text{Na}^+(\text{aq}) + \text{OH}^-(\text{aq})$ . The complete equation is

The purpose of such a *complete ionic equation* is to represent each substance by its predominant form in the reaction mixture. For example, if the substance is a soluble ionic compound, it probably dissolves as individual ions (so it is a strong electrolyte). In a complete ionic equation, you represent the compound as separate ions. If the substance is a weak electrolyte, it is present in solution primarily as molecules, so you represent it by its molecular formula. If the substance is an insoluble ionic compound, you represent it by the formula of the compound, not by the formulas of the separate ions in solution.

Thus, a **complete ionic equation** is a chemical equation in which strong electrolytes (such as soluble ionic compounds) are written as separate ions in the solution. You represent other reactants and products by the formulas of the compounds, indicating any soluble substance by (aq) after its formula and any insoluble solid substance by (s) after its formula.

## Net Ionic Equations

In the complete ionic equation representing the reaction of calcium hydroxide and sodium carbonate, some ions ( $\text{OH}^-$  and  $\text{Na}^+$ ) appear on both sides of the equation. This means that nothing happens to these ions as the reaction occurs. They are called spectator ions. A **spectator ion** is an ion in an ionic equation that does not take part in the reaction. You can cancel such ions from both sides to express the essential reaction that occurs.

The resulting equation is

This is the **net ionic equation**, an ionic equation from which spectator ions have been canceled. It shows that the reaction that actually occurs at the ionic level is between calcium ions and carbonate ions to form solid calcium carbonate.

From the net ionic equation, you can see that mixing any solution of calcium ion with any solution of carbonate ion will give you this same reaction. For example, the strong electrolyte calcium nitrate,  $\text{Ca}(\text{NO}_3)_2$ , dissolves readily in water to provide a source of calcium ions. (According to the solubility rules, calcium nitrate is soluble, so it goes into solution as  $\text{Ca}^{2+}$  and  $\text{NO}_3^-$  ions.) Similarly, the strong electrolyte potassium carbonate,  $\text{K}_2\text{CO}_3$ , dissolves readily in water to provide a source of carbonate ions. (According to the solubility rules, potassium carbonate is soluble, so it goes into solution as  $\text{K}^+$  and  $\text{CO}_3^{2-}$  ions.) When you mix solutions of these two compounds, you obtain a solution of calcium ions and carbonate ions, which react to form the insoluble calcium carbonate. The other product is potassium nitrate, a soluble ionic compound, and therefore a strong electrolyte. The molecular equation representing the reaction is

You obtain the complete ionic equation from this molecular equation by rewriting each of the soluble ionic compounds as ions, but retaining the formula for the precipitate  $\text{CaCO}_3(\text{s})$ :

The net ionic equation is

Note that the net ionic equation is identical to the one obtained from the reaction of  $\text{Ca}(\text{OH})_2$  and  $\text{Na}_2\text{CO}_3$ . The essential reaction is the same whether you mix solutions of calcium hydroxide and sodium carbonate or solutions of calcium nitrate and potassium carbonate.

The value of the net ionic equation is its generality. For example, seawater contains  $\text{Ca}^{2+}$  and  $\text{CO}_3^{2-}$  ions from various sources. Whatever the sources of these ions, you expect them to react to form a precipitate of calcium carbonate. In seawater, this precipitate results in sediments of calcium carbonate, which eventually form limestone (Figure 4.5).

Robert Marien/Spirit/Corbis

**Figure 4.5** ▲

**Limestone formations** It is believed that most limestone formed as a precipitate of calcium carbonate (and other carbonates) from seawater. The photograph shows limestone formations at Bryce Point, Bryce Canyon National Park, Utah. More than 60 million years ago, this area was covered by seawater.

### Example 4.2 Writing Net Ionic Equations

#### Gaining Mastery Toolbox

##### Critical Concept 4.2

The net ionic equation depicts the reaction that is occurring. In the net ionic equation, soluble ionic compounds are represented as aqueous ions, whereas nonelectrolytes and weak electrolytes are written with their molecular formula (not as ions). You expect a reaction to occur when a nonelectrolyte, weak electrolyte, or insoluble solid (precipitate) is formed as a product. If no reaction occurs, then there will be no net ionic equation.

##### Solution Essentials:

- Net ionic equation
- Spectator ion
- Complete ionic equation
- Molecular equation
- Solubility rules
- Nonelectrolyte
- Weak electrolyte

Write a net ionic equation for each of the following molecular equations.

Perchloric acid,  $\text{HClO}_4$ , is a strong electrolyte, forming  $\text{H}^+$  and  $\text{ClO}_4^-$  ions in solution.  $\text{Ca}(\text{ClO}_4)_2$  is a soluble ionic compound.

Acetic acid,  $\text{HC}_2\text{H}_3\text{O}_2$ , is a molecular substance and a weak electrolyte.

**Problem Strategy** You will need to convert the molecular equation to the complete ionic equation, then cancel spectator ions to obtain the net ionic equation. For each ionic compound in the reaction, use the solubility rules to determine if the compound will be soluble (in the solution as ions) or insoluble (present as an undissolved solid). For the complete ionic equation, represent all of the strong electrolytes by their separate ions in solution, adding (aq) after the formula of each. Retain the formulas of the other compounds. An ionic compound should have (aq) after its formula if it is soluble or (s) if it is insoluble.

##### Solution

- a. According to the solubility rules presented in Table 4.1 and the problem statement,  $\text{Ca}(\text{OH})_2$  and  $\text{Ca}(\text{ClO}_4)_2$  are soluble ionic compounds, so they are strong electrolytes. The problem statement notes that  $\text{HClO}_4$  is also a strong electrolyte. You write each strong electrolyte in the form of separate ions. Water,  $\text{H}_2\text{O}$ , is a

(continued)

**Example 4.2** (continued)

nonelectrolyte (or very weak electrolyte), so you retain its molecular formula. The complete ionic equation is

After canceling spectator ions and dividing by 2, you get the following net ionic equation:

b. According to the solubility rules, NaOH and NaC<sub>2</sub>H<sub>3</sub>O<sub>2</sub> are soluble ionic compounds, so they are strong electrolytes. The problem statement notes that HC<sub>2</sub>H<sub>3</sub>O<sub>2</sub> is a weak electrolyte, which you write by its molecular formula. Water, H<sub>2</sub>O, is a nonelectrolyte, so you retain its molecular formula also. The complete ionic equation is

and the net ionic equation is

**Answer Check** If both of the reactants are strong electrolytes and a reaction occurs, your correct net ionic equation should not have any ions as products of the reaction. In this case, because the reaction is with a weak electrolyte, ions in the net ionic equation are possible.

**Exercise 4.2** Write complete ionic and net ionic equations for each of the following molecular equations.

Nitric acid, HNO<sub>3</sub>, is a strong electrolyte.

See Problems 4.33 and 4.34.

## ► Types of Chemical Reactions

Among the several million known substances, many millions of chemical reactions are possible. Beginning students are often bewildered by the possibilities. How can I know whether two substances will react when they are mixed? How can I predict the products? Although it is not possible to give completely general answers to these questions, it is possible to make sense of chemical reactions. Most of the reactions we will study belong to one of three types:

1. Precipitation reactions. In these reactions, you mix solutions of two ionic substances, and a solid ionic substance (a precipitate) forms.
2. Acid–base reactions. An acid substance reacts with a substance called a base. Such reactions involve the transfer of a proton between reactants.
3. Oxidation–reduction reactions. These involve the transfer of electrons between reactants.

We will look at each of these types of reactions. By the time you finish this chapter, you should feel much more comfortable with the descriptions of chemical reactions that you will encounter in this course.

### 4.3 Precipitation Reactions

In the previous section, we used a precipitation reaction to illustrate how to convert a molecular equation to an ionic equation. A precipitation reaction occurs in aqueous

**Figure 4.6** ▲

**Reaction of magnesium chloride and silver nitrate** Magnesium chloride solution is added to a beaker of silver nitrate solution. A white precipitate of silver chloride forms.

solution because one product is insoluble. A **precipitate** is an *insoluble solid compound formed during a chemical reaction in solution*. To predict whether a precipitate will form when you mix two solutions of ionic compounds, you need to know whether any of the potential products that might form are insoluble. This is another application of the solubility rules (Section 4.1).

### Predicting Precipitation Reactions

Now let us see how you would go about predicting whether a precipitation reaction will occur. Suppose you mix together solutions of magnesium chloride,  $\text{MgCl}_2$ , and silver nitrate,  $\text{AgNO}_3$ . You can write the potential reactants as follows:

How can you tell if a reaction will occur, and if it does, what products to expect?

When you write a precipitation reaction as a molecular equation, the reaction has the form of an exchange reaction. An **exchange** (or **metathesis**) **reaction** is a *reaction between compounds that, when written as a molecular equation, appears to involve the exchange of parts between the two reactants*. In a precipitation reaction, the anions exchange between the two cations (or vice versa).

Let us momentarily assume that a reaction does occur between magnesium chloride and silver nitrate. If you exchange the anions, you get silver chloride and magnesium nitrate. Once you figure out the formulas of these potential products, you can write the molecular equation. The formulas are  $\text{AgCl}$  and  $\text{Mg}(\text{NO}_3)_2$ . (If you do not recall how to write the formula of an ionic compound, given the ions, turn back to Example 2.3.) The balanced equation, assuming there *is* a reaction, is

Let us verify that  $\text{MgCl}_2$  and  $\text{AgNO}_3$  are soluble and then check the solubilities of the products. Rule 3 in Table 4.1 says that chlorides are soluble, with certain exceptions, which do not include magnesium chloride. Thus, we predict that magnesium chloride is soluble. Rule 2 indicates that nitrates are soluble, so  $\text{AgNO}_3$  is soluble as well. The potential products are silver chloride and magnesium nitrate. According to Rule 3, silver chloride is one of the exceptions to the general solubility of chlorides. Therefore, we predict that the silver chloride is insoluble. Magnesium nitrate is soluble according to Rule 2.

Now we can append the appropriate phase labels to the compounds in the preceding equation.

We predict that reaction occurs because silver chloride is insoluble, and precipitates from the reaction mixture. Figure 4.6 shows the formation of the white silver chloride from this reaction and depicts the net ionic equation using molecular models. If you separate the precipitate from the solution by pouring it through filter paper, the solution that passes through (the filtrate) contains magnesium nitrate, which you could obtain by evaporating the water. The molecular equation is a summary of the actual reactants and products in the reaction. ◀

To see the reaction that occurs on an ionic level, you need to rewrite the molecular equation as a net ionic equation. You first write the strong electrolytes (here soluble ionic compounds) in the form of ions, leaving the formula of the precipitate unchanged.

After canceling spectator ions and reducing the coefficients to the smallest whole numbers, you obtain the net ionic equation:

The reactants  $\text{MgCl}_2$  and  $\text{AgNO}_3$  must be added in correct amounts; otherwise, the excess reactant will remain along with the product  $\text{Mg}(\text{NO}_3)_2$ .

This equation represents the essential reaction that occurs:  $\text{Ag}^+$  ions and  $\text{Cl}^-$  ions in aqueous solution react to form solid silver chloride.

If silver chloride were soluble, a reaction would not have occurred. When you first mix solutions of  $\text{MgCl}_2(aq)$  and  $\text{AgNO}_3(aq)$ , you obtain a solution of four ions:  $\text{Mg}^{2+}(aq)$ ,  $\text{Cl}^-(aq)$ ,  $\text{Ag}^+(aq)$ , and  $\text{NO}_3^-(aq)$ . If no precipitate formed, you would end up simply with a solution of these four ions. However, because  $\text{Ag}^+$  and  $\text{Cl}^-$  react to give the precipitate  $\text{AgCl}$ , the effect is to remove these ions from the reaction mixture as an insoluble compound and leave behind a solution of  $\text{Mg}(\text{NO}_3)_2(aq)$ .

### Example 4.3 Deciding Whether a Precipitation Reaction Occurs

#### Gaining Mastery Toolbox

##### Critical Concept 4.3

Use the solubility rules to predict if a precipitate will form during the reaction. Whenever one of the products of an aqueous reaction between two soluble salts is an insoluble compound, then a precipitation reaction will occur. Otherwise, there will be no reaction, and we predict that the solution will consist only of dissolved ions.

##### Solution Essentials

- Exchange (metathesis) reaction
- Precipitate
- Net ionic equation
- Spectator ion
- Complete ionic equation
- Molecular equation
- Solubility rules

For each of the following, decide whether a precipitation reaction occurs. If it does, write the balanced molecular equation and then the net ionic equation. If no reaction occurs, write the compounds followed by an arrow and then *NR* (no reaction).

- Aqueous solutions of sodium chloride and iron(II) nitrate are mixed.
- Aqueous solutions of aluminum sulfate and sodium hydroxide are mixed.

**Problem Strategy** When aqueous solutions containing soluble salts are mixed, a precipitation reaction occurs if an insoluble compound (precipitate) forms. Start by writing the formulas of the compounds that are mixed. (If you have trouble with this, see Examples 2.3 and 2.4.) Then, assuming momentarily that the compounds do react, write the exchange reaction. Make sure that you write the correct formulas of the products. Using the solubility rules, append phase labels to each formula in the equation consulting the solubility rules. If one of the products forms an insoluble compound (precipitate), reaction occurs; otherwise, no reaction occurs.

#### Solution

- The formulas of the compounds are  $\text{NaCl}$  and  $\text{Fe}(\text{NO}_3)_2$ . Exchanging anions, you get sodium nitrate,  $\text{NaNO}_3$ , and iron(II) chloride,  $\text{FeCl}_2$ . The equation for the exchange reaction is

Referring to Table 4.1, note that  $\text{NaCl}$  and  $\text{NaNO}_3$  are soluble (Rule 1). Also, iron(II) nitrate is soluble (Rule 2), and iron(II) chloride is soluble. (Rule 3 says that chlorides are soluble with some exceptions, none of which include  $\text{FeCl}_2$ .) Since there is no precipitate, no reaction occurs. You obtain simply an aqueous solution of the four different ions ( $\text{Na}^+$ ,  $\text{Cl}^-$ ,  $\text{Fe}^{2+}$ , and  $\text{NO}_3^-$ ). For the answer, we write

- The formulas of the compounds are  $\text{Al}_2(\text{SO}_4)_3$  and  $\text{NaOH}$ . Exchanging anions, you get aluminum hydroxide,  $\text{Al}(\text{OH})_3$ , and sodium sulfate,  $\text{Na}_2\text{SO}_4$ . The equation for the exchange reaction is

From Table 4.1, you see that  $\text{Al}_2(\text{SO}_4)_3$  is soluble (Rule 4),  $\text{NaOH}$  and  $\text{Na}_2\text{SO}_4$  are soluble (Rule 1), and  $\text{Al}(\text{OH})_3$  is insoluble (Rule 8). Thus, aluminum hydroxide precipitates. The balanced molecular equation with phase labels is

To get the net ionic equation, you write the strong electrolytes (here, soluble ionic compounds) as ions in aqueous solution and cancel spectator ions.

The net ionic equation is

Thus, aluminum ion reacts with hydroxide ion to precipitate aluminum hydroxide.

(continued)

**Example 4.3** (continued)

**Answer Check** One of the most critical aspects of getting this type of problem right is making certain that you are using the correct chemical formulas for the reactants and products.

**Exercise 4.3** You mix aqueous solutions of sodium iodide and lead(II) acetate. If a reaction occurs, write the balanced molecular equation and the net ionic equation. If no reaction occurs, indicate this by writing the formulas of the compounds and an arrow followed by *NR*.

See Problems 4.37, 4.38, 4.39, and 4.40.

**CONCEPT CHECK 4.3**

Your lab partner tells you that she mixed two solutions that contain ions. You analyze the solution and find that it contains the ions and precipitate shown in the beaker.

- Write the molecular equation for the reaction.
- Write the complete ionic equation for the reaction.
- Write the net ionic equation for the reaction.

**4.4 Acid–Base Reactions**

Acids and bases are some of the most important electrolytes. You can recognize acids and bases by some simple properties. Acids have a sour taste. Solutions of bases, on the other hand, have a bitter taste and a soapy feel. (Of course, you should *never* taste laboratory chemicals.) Some examples of acids are acetic acid, present in vinegar; citric acid, a constituent of lemon juice; and hydrochloric acid, found in the digestive fluid of the stomach. An example of a base is aqueous ammonia, often used as a household cleaner. Table 4.2 lists further examples; see also Figure 4.7.

Another simple property of acids and bases is their ability to cause color changes in certain dyes. An **acid–base indicator** is a dye used to distinguish between acidic and basic solutions by means of the color changes it undergoes in these solutions. Such dyes are common in natural materials. The amber color of tea, for example, is lightened by the addition of lemon juice (citric acid). Red cabbage juice changes to green and

**Table 4.2** Common Acids and Bases

Name	Formula	Remarks
<b>Acids</b>		
Acetic acid	$\text{HC}_2\text{H}_3\text{O}_2$	Found in vinegar
Acetylsalicylic acid	$\text{HC}_9\text{H}_7\text{O}_4$	Aspirin
Ascorbic acid	$\text{H}_2\text{C}_6\text{H}_6\text{O}_6$	Vitamin C
Citric acid	$\text{H}_3\text{C}_6\text{H}_5\text{O}_7$	Found in lemon juice
Hydrochloric acid	$\text{HCl}$	Found in gastric juice (digestive fluid in stomach)
Sulfuric acid	$\text{H}_2\text{SO}_4$	Battery acid
<b>Bases</b>		
Ammonia	$\text{NH}_3$	Aqueous solution used as a household cleaner
Calcium hydroxide	$\text{Ca}(\text{OH})_2$	Slaked lime (used in mortar for building construction)
Magnesium hydroxide	$\text{Mg}(\text{OH})_2$	Milk of magnesia (antacid and laxative)
Sodium hydroxide	$\text{NaOH}$	Drain cleaners, oven cleaners

then yellow when a base is added (Figure 4.8). The green and yellow colors change back to red when an acid is added. Litmus is a common laboratory acid–base indicator. This dye, produced from certain species of lichens, turns red in acidic solution and blue in basic solution. Phenolphthalein (fee' nol thay' leen), another laboratory acid–base indicator, is colorless in acidic solution and pink in basic solution.

An important chemical characteristic of acids and bases is the way they react with one another. To understand these acid–base reactions, we need to have precise definitions of the terms *acid* and *base*.

### Definitions of Acid and Base

When Arrhenius developed his ionic theory of solutions, he also gave the classic definitions of acids and bases. According to Arrhenius, an **acid** is a substance that produces hydrogen ions,  $H^+$ , when it dissolves in water. An example is nitric acid,  $HNO_3$ , a molecular substance that dissolves in water to give  $H^+$  and  $NO_3^-$ .

An Arrhenius **base** is a substance that produces hydroxide ions,  $OH^-$ , when it dissolves in water. For example, sodium hydroxide is a base.

The molecular substance ammonia,  $NH_3$ , is also a base because it yields hydroxide ions when it reacts with water. ▶

Although the Arrhenius concept of acids and bases is useful, it is somewhat limited. For example, it tends to single out the  $OH^-$  ion as the source of base character, when other ions or molecules can play a similar role. In 1923, Johannes N. Brønsted and Thomas M. Lowry independently noted that many reactions involve nothing more than the transfer of a proton ( $H^+$ ) between reactants, and they realized that they could use this idea to expand the definitions of acids and bases to describe a large class of chemical reactions. In this view, acid–base reactions are *proton-transfer reactions*.

Preparation of red cabbage juice. The beaker (green solution) contains red cabbage juice and sodium bicarbonate (baking soda), which is a basic solution. The flask in the center contains red cabbage juice in an acidic solution.

Red cabbage juice has been added from a pipet to solutions in the beakers. These solutions vary in acidity from highly acidic on the left to highly basic on the right.

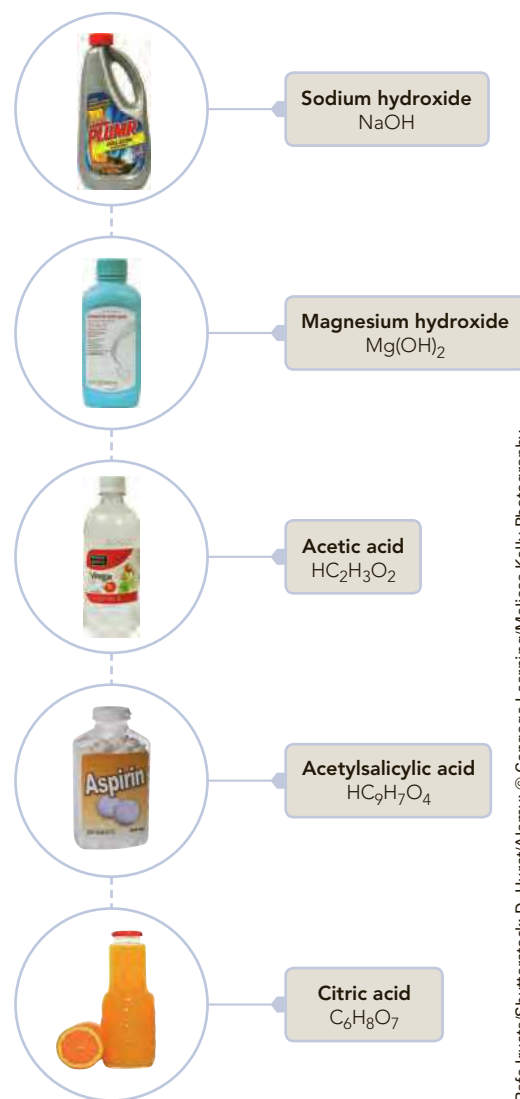

Figure 4.7 ▲

**Household acids and bases** Shown are a variety of household products that are either acids or bases.

Solutions of ammonia are sometimes called ammonium hydroxide and given the formula  $NH_4OH(aq)$ , based on analogy with  $NaOH$ . No  $NH_4OH$  molecule or compound has ever been found, however.

Figure 4.8 ◀

**Red cabbage juice as an acid–base indicator**

Consider the preceding reaction. It involves the transfer of a proton from the water molecule,  $\text{H}_2\text{O}$ , to the ammonia molecule,  $\text{NH}_3$ .

Once the proton,  $\text{H}^+$ , has left the  $\text{H}_2\text{O}$  molecule, it leaves behind an  $\text{OH}^-$  ion. When the  $\text{H}^+$  adds to  $\text{NH}_3$ , an  $\text{NH}_4^+$  ion results.  $\text{H}_2\text{O}$  is said to *donate* a proton to  $\text{NH}_3$ , and  $\text{NH}_3$  is said to *accept* a proton from  $\text{H}_2\text{O}$ .

Brønsted and Lowry defined an **acid** as *the species (molecule or ion) that donates a proton to another species in a proton-transfer reaction*. They defined a **base** as *the species (molecule or ion) that accepts a proton in a proton-transfer reaction*. In the reaction of ammonia with water, the  $\text{H}_2\text{O}$  molecule is the acid, because it donates a proton. The  $\text{NH}_3$  molecule is a base, because it accepts a proton.

The dissolution of nitric acid,  $\text{HNO}_3$ , in water is actually a proton-transfer reaction, although the following equation, which we used as an illustration of an Arrhenius acid, does not spell that out.

To see that this is a proton-transfer reaction, we need to clarify the structure of the hydrogen ion,  $\text{H}^+(aq)$ . This ion consists of a proton ( $\text{H}^+$ ) in association with water molecules, which is what *(aq)* means. This is not a weak association, however, because the proton (or hydrogen nucleus) would be expected to attract electrons strongly to itself. In fact, the  $\text{H}^+(aq)$  ion might be better thought of as a proton chemically bonded to a water molecule to give the  $\text{H}_3\text{O}^+$  ion, with other water molecules less strongly associated with this ion, which we represent by the phase-labeled formula  $\text{H}_3\text{O}^+(aq)$ . Written in this form, we usually call this the *hydronium ion*. It is important to understand that the hydrogen ion,  $\text{H}^+(aq)$ , and the hydronium ion,  $\text{H}_3\text{O}^+(aq)$ , represent precisely the same physical ion. For simplicity, we often write the formula for this ion as  $\text{H}^+(aq)$ , but when we want to be explicit about the proton-transfer aspect of a reaction, we write the formula as  $\text{H}_3\text{O}^+(aq)$ . ◀

Now let us rewrite the preceding equation by replacing  $\text{H}^+(aq)$  by  $\text{H}_3\text{O}^+(aq)$ . To maintain a balanced equation, we will also need to add  $\text{H}_2\text{O}(l)$  to the left side.

Note that the reaction involves simply a transfer of a proton ( $\text{H}^+$ ) from  $\text{HNO}_3$  to  $\text{H}_2\text{O}$ :

The  $\text{H}^+(aq)$  ion has variable structure in solution. In solids, there is evidence for  $[\text{H}(\text{H}_2\text{O})_n]^+$ , where  $n$  is 1, 2, 3, 4, or 6.

The  $\text{HNO}_3$  molecule is an acid (proton donor) and  $\text{H}_2\text{O}$  is a base (proton acceptor). Note that  $\text{H}_2\text{O}$  may function as an acid or a base, depending on the other reactant.

The Arrhenius definitions and those of Brønsted and Lowry are essentially equivalent for aqueous solutions, although their points of view are different. For instance, sodium hydroxide and ammonia are bases in the Arrhenius view because they increase the percentage of  $\text{OH}^-$  ion in the aqueous solution. They are bases in the Brønsted–Lowry view because they provide species ( $\text{OH}^-$  from the strong electrolyte sodium hydroxide and  $\text{NH}_3$  from ammonia) that can accept protons. ▶

### Strong and Weak Acids and Bases

Acids and bases are classified as strong or weak, depending on whether they are strong or weak electrolytes. A **strong acid** is *an acid that ionizes completely in water; it is a strong electrolyte*. Hydrochloric acid,  $\text{HCl}(aq)$ , and nitric acid,  $\text{HNO}_3(aq)$ , are examples of strong acids. Using the hydronium ion notation, we write the respective equations as follows:

Table 4.3 lists six common strong acids. Most of the other acids we will discuss are weak acids.

A **weak acid** is *an acid that only partly ionizes in water; it is a weak electrolyte*. Examples of weak acids are hydrocyanic acid,  $\text{HCN}(aq)$ , and hydrofluoric acid,  $\text{HF}(aq)$ . These molecules react with water to produce a small percentage of ions in solution.

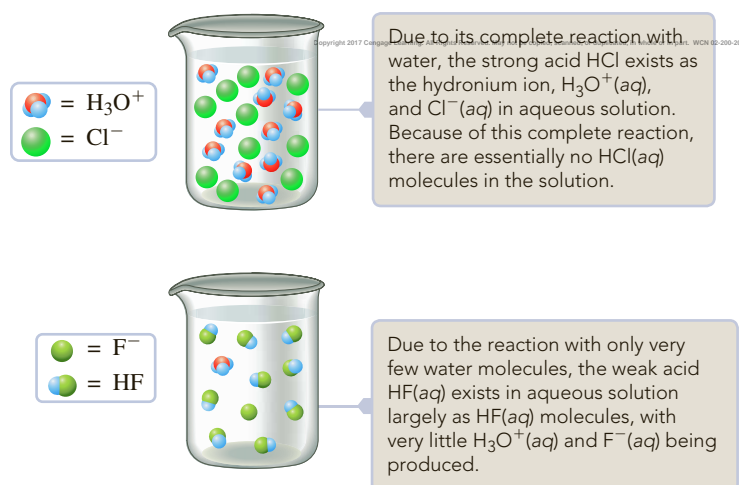

Figure 4.9 presents molecular views of the strong acid  $\text{HCl}(aq)$  and the weak acid  $\text{HF}(aq)$ . Note how both the strong and weak acid undergo the same reaction with water (proton donors); however, in the case of the weak acid such as  $\text{HF}$ , only a small portion of the acid molecules actually undergoes reaction, leaving the majority of the acid molecules unreacted. On the other hand, strong acids like  $\text{HCl}$  and  $\text{HNO}_3$  undergo complete reaction with water. The result is that weak acids can produce little  $\text{H}_3\text{O}^+$  in aqueous solution, whereas strong acids can produce large amounts. Hence, when chemists refer to a weak acid, they are often thinking about a substance that produces a limited amount of  $\text{H}_3\text{O}^+(aq)$ , whereas when chemists refer to a strong acid, they are thinking about a substance that can produce large amounts of  $\text{H}_3\text{O}^+(aq)$ .

We will discuss the Brønsted–Lowry concept of acids and bases more thoroughly in Chapter 15.

**Table 4.3** Common Strong Acids and Bases

Strong Acids	Strong Bases
$\text{HClO}_4$	$\text{LiOH}$
$\text{H}_2\text{SO}_4$	$\text{NaOH}$
$\text{HI}$	$\text{KOH}$
$\text{HBr}$	$\text{Ca}(\text{OH})_2$
$\text{HCl}$	$\text{Sr}(\text{OH})_2$
$\text{HNO}_3$	$\text{Ba}(\text{OH})_2$

**Figure 4.9** ◀

**Molecular views comparing the strong acid  $\text{HCl}$  and the weak acid  $\text{HF}$  in water ( $\text{H}_2\text{O}$  molecules are omitted for clarity)**

A **strong base** is a base that is present in aqueous solution entirely as ions, one of which is  $\text{OH}^-$ ; it is a strong electrolyte. The ionic compound sodium hydroxide,  $\text{NaOH}$ , is an example of a strong base. It dissolves in water as  $\text{Na}^+$  and  $\text{OH}^-$ .

The hydroxides of Groups 1A and 2A elements, except for beryllium hydroxide, are strong bases (see Table 4.3).

A **weak base** is a base that is only partly ionized in water; it is a weak electrolyte. Ammonia,  $\text{NH}_3$ , is an example.

You will find it important to be able to identify an acid or base as strong or weak. When you write an ionic equation, you represent strong acids and bases by the ions they form and weak acids and bases by the formulas of the compounds. ◀ The next example will give you some practice identifying acids and bases as strong or weak.

In many cases, when chemists are thinking about strong versus weak bases in aqueous solution, they consider a weak base to be a substance that can produce only limited amounts of  $\text{OH}^-(aq)$  and a strong base to be a substance that can produce large amounts of  $\text{OH}^-(aq)$ .

#### CONCEPT CHECK 4.4

Complete and balance the two chemical equations.

Which of the following statements is true regarding the solutions formed after the two chemical reactions have occurred?

- a The  $\text{HBr}$  is partially ionized in water.
- b The  $\text{HClO}_4$  is completely ionized in water.
- c In the solution of  $\text{HClO}_4$ , you would expect to find very few  $\text{HClO}_4(aq)$  molecules relative to  $\text{ClO}_4^-(aq)$  ions.
- d In the  $\text{HBr}$  solution there are significant quantities of  $\text{HBr}(aq)$  molecules.
- e None of the other statements (a–d) is true.

### Example 4.4 Classifying Acids and Bases as Strong or Weak

#### Gaining Mastery Toolbox

##### Critical Concept 4.4

Assume that if an acid or base is not listed in Table 4.3 (“Common Strong Acids and Bases”), it is a weak acid or a weak base. This assumption works very well for most acids and bases typically encountered in the laboratory.

##### Solution Essentials:

- Weak acid
- Weak base
- Strong acid
- Strong base

Identify each of the following compounds as a strong or weak acid or base:

- a.  $\text{LiOH}$       b.  $\text{HC}_2\text{H}_3\text{O}_2$       c.  $\text{HBr}$       d.  $\text{HNO}_2$

**Problem Strategy** Refer to Table 4.3 for the common strong acids and bases. You can assume that other acids and bases are weak.

#### Solution

- a. As noted in Table 4.3,  **$\text{LiOH}$  is a strong base.**
- b. Acetic acid,  $\text{HC}_2\text{H}_3\text{O}_2$ , is not one of the strong acids listed in Table 4.3; therefore, we assume  **$\text{HC}_2\text{H}_3\text{O}_2$  is a weak acid.**
- c. As noted in Table 4.3,  **$\text{HBr}$  is a strong acid.**
- d. Nitrous acid,  $\text{HNO}_2$ , is not one of the strong acids listed in Table 4.3; therefore, we assume  **$\text{HNO}_2$  is a weak acid.**

**Answer Check** Do not fall into the trap of assuming that if a compound has  $\text{OH}$  in the formula, it must be a base. For example, methyl alcohol,  $\text{CH}_3\text{OH}$ , has  $\text{OH}$  in the formula, but it is not a strong base. Likewise, do not assume that a compound is an acid just because it has  $\text{H}$ .

**Exercise 4.4** Label each of the following as a strong or weak acid or base:

- a.  $\text{H}_3\text{PO}_4$       b.  $\text{HClO}$       c.  $\text{HClO}_4$       d.  $\text{Sr}(\text{OH})_2$

See Problems 4.41 and 4.42.

## Neutralization Reactions

One of the chemical properties of acids and bases is that they neutralize one another. A **neutralization reaction** is a reaction of an acid and a base that results in an ionic compound and possibly water. When a base is added to an acid solution, the acid is said to be neutralized. The ionic compound that is a product of a neutralization reaction is called a **salt**. Most ionic compounds other than hydroxides and oxides are salts. Salts can be obtained from neutralization reactions such as

The salt formed in a neutralization reaction consists of cations obtained from the base and anions obtained from the acid. In the first example, the base is  $\text{Ca}(\text{OH})_2$ , which supplies  $\text{Ca}^{2+}$  cations; the acid is  $\text{HCl}$ , which supplies  $\text{Cl}^-$  anions. The salt contains  $\text{Ca}^{2+}$  and  $\text{Cl}^-$  ions ( $\text{CaCl}_2$ ).

We wrote these reactions as molecular equations. Written in this form, the equations make explicit the reactant compounds and the salts produced. However, to discuss the essential reactions that occur, you need to write the net ionic equations. You will see that the net ionic equation for each acid–base reaction involves the transfer of a proton.

The first reaction involves a strong acid,  $\text{HCl}(aq)$ , and a strong base,  $\text{Ca}(\text{OH})_2(aq)$ . Both  $\text{Ca}(\text{OH})_2$  and the product  $\text{CaCl}_2$ , being soluble ionic compounds, are strong electrolytes. Writing these strong electrolytes in the form of ions gives the following complete ionic equation:

Canceling spectator ions and dividing by 2 gives the net ionic equation:

Note the transfer of a proton from the hydrogen ion (or hydronium ion,  $\text{H}_3\text{O}^+$ ) to the hydroxide ion.

The second reaction involves  $\text{HCN}(aq)$ , a weak acid, and  $\text{KOH}(aq)$ , a strong base; the product is  $\text{KCN}$ , a strong electrolyte. The net ionic equation is

Note the proton transfer, characteristic of an acid–base reaction.

In each of these examples, hydroxide ions latch strongly onto protons to form water. Because water is a very stable substance, it effectively provides the driving force of the reaction.

Although water is one of the products in most neutralization reactions, the reaction of an acid with the base ammonia provides a prominent exception. Consider the reaction of sulfuric acid with ammonia:

The net ionic equation is

Note the proton transfer, a hallmark of an acid–base reaction. In this case,  $\text{NH}_3$  molecules latch onto protons and form relatively stable  $\text{NH}_4^+$  ions.

**Example 4.5 Writing an Equation for a Neutralization****Gaining Mastery Toolbox****Critical Concept 4.5**

One product of a neutralization reaction will be a salt. The salt is an ionic compound formed from the acid anions and the base cations. Water is often an additional product of neutralization reactions.

**Solution Essentials:**

- Neutralization reaction
- Salt
- Strong and weak acid
- Net ionic equation
- Spectator ion
- Strong and weak electrolyte

Write the molecular equation and then the net ionic equation for the neutralization of nitrous acid,  $\text{HNO}_2$ , by sodium hydroxide,  $\text{NaOH}$ , both in aqueous solution. Use an arrow with  $\text{H}^+$  over it to show the proton transfer.

**Problem Strategy** Because this is a neutralization reaction, you know that the reactants are an acid and a base and that there will be a salt and possibly water as a product. Therefore, start by writing the acid and base reactants and the salt product. Recall that the salt consists of cations from the base and anions from the acid. Note also that water is frequently a product; if it is, you will not be able to balance the equation without it. Once you have the balanced molecular equation, write the complete ionic equation. Do that by representing any strong electrolytes by the formulas of their ions. Finally, write the net ionic equation by canceling any spectator ions, and from it note the proton transfer.

**Solution** The salt consists of the cation from the base ( $\text{Na}^+$ ) and the anion from the acid ( $\text{NO}_2^-$ ); its formula is  $\text{NaNO}_2$ . You will need to add  $\text{H}_2\text{O}$  as a product to complete and balance the molecular equation:

Note that  $\text{NaOH}$  (a strong base) and  $\text{NaNO}_2$  (a soluble ionic substance) are strong electrolytes;  $\text{HNO}_2$  is a weak electrolyte (it is not one of the strong acids in Table 4.3). You write both  $\text{NaOH}$  and  $\text{NaNO}_2$  in the form of ions. The complete ionic equation is

The net ionic equation is

Note that a proton is transferred from  $\text{HNO}_2$  to the  $\text{OH}^-$  ion to yield the products:

**Answer Check** Remember that correct answers include phase labels and that ions must have correct charges.

**Exercise 4.5** Write the molecular equation and the net ionic equation for the neutralization of hydrocyanic acid,  $\text{HCN}$ , by lithium hydroxide,  $\text{LiOH}$ , both in aqueous solution.

See Problems 4.43, 4.44, 4.45, and 4.46.

**Exercise 4.6** Write molecular and net ionic equations for the successive neutralizations of each of the acidic hydrogens of sulfuric acid with potassium hydroxide. (That is, write equations for the reaction of sulfuric acid with  $\text{KOH}$  to give the acid salt and for the reaction of the acid salt with more  $\text{KOH}$  to give potassium sulfate.)

See Problems 4.47, 4.48, 4.49, and 4.50.

Acids such as  $\text{HCl}$  and  $\text{HNO}_3$  that have only one acidic hydrogen atom per acid molecule are called *monoprotic acids*. A **polyprotic acid** is an acid that yields two or more acidic hydrogens per molecule. Phosphoric acid is an example of a triprotic acid. By reacting this acid with different amounts of a base, you can obtain a series of salts:

Salts such as  $\text{NaH}_2\text{PO}_4$  and  $\text{Na}_2\text{HPO}_4$  that have acidic hydrogen atoms and can undergo neutralization with bases are called *acid salts*.

### Acid–Base Reactions with Gas Formation

Certain salts, notably carbonates, sulfites, and sulfides, react with acids to form a gaseous product. Consider the reaction of sodium carbonate with hydrochloric acid. The molecular equation for the reaction is

Here, a carbonate (sodium carbonate) reacts with an acid (hydrochloric acid) to produce a salt (sodium chloride), water, and carbon dioxide gas. A similar reaction is shown in Figure 4.10, in which baking soda (sodium hydrogen carbonate) reacts with the acetic acid in vinegar. Note the bubbles of carbon dioxide gas that evolve during the reaction. This reaction of a carbonate with an acid is the basis of a simple test for carbonate minerals. When you treat a carbonate mineral or rock, such as limestone, with hydrochloric acid, the material fizzes, as bubbles of odorless carbon dioxide form.

It is useful to consider the preceding reaction as an exchange, or metathesis, reaction. Recall that in an exchange reaction, you obtain the products from the reactants by exchanging the anions (or the cations) between the two reactants. In this case, we interchange the carbonate ion with the chloride ion and we obtain the following:

The last product shown in the equation is carbonic acid,  $\text{H}_2\text{CO}_3$ . (You obtain the formula of carbonic acid by noting that you need to associate two  $\text{H}^+$  ions with the carbonate ion,  $\text{CO}_3^{2-}$ , to obtain a neutral compound.) Carbonic acid is unstable and decomposes to water and carbon dioxide gas. The overall result is the equation we wrote earlier:

The net ionic equation for this reaction is

The carbonate ion reacts with hydrogen ion from the acid. If you write the hydrogen ion as  $\text{H}_3\text{O}^+$  (hydronium ion), you can see also that the reaction involves a proton transfer:

From the broader perspective of the Brønsted–Lowry view, this is an acid–base reaction.

Sulfites behave similarly to carbonates. When a sulfite, such as sodium sulfite ( $\text{Na}_2\text{SO}_3$ ), reacts with an acid, sulfur dioxide ( $\text{SO}_2$ ) is a product. Sulfides, such as sodium sulfide ( $\text{Na}_2\text{S}$ ), react with acids to produce hydrogen sulfide gas. The reaction can be viewed as a simple exchange reaction. The reactions are summarized in Table 4.4. ▶

**Table 4.4** Some Ionic Compounds That Evolve Gases When Treated with Acids

Ionic Compound	Gas	Example
Carbonate ( $\text{CO}_3^{2-}$ )	$\text{CO}_2$	$\text{Na}_2\text{CO}_3 + 2\text{HCl} \longrightarrow 2\text{NaCl} + \text{H}_2\text{O} + \text{CO}_2$
Sulfite ( $\text{SO}_3^{2-}$ )	$\text{SO}_2$	$\text{Na}_2\text{SO}_3 + 2\text{HCl} \longrightarrow 2\text{NaCl} + \text{H}_2\text{O} + \text{SO}_2$
Sulfide ( $\text{S}^{2-}$ )	$\text{H}_2\text{S}$	$\text{Na}_2\text{S} + \text{H}_2\text{SO}_4 \longrightarrow \text{Na}_2\text{SO}_4 + \text{H}_2\text{S}$

+

=

**Figure 4.10** ▲

**Reaction of a carbonate with an acid** Baking soda (sodium hydrogen carbonate) reacts with acetic acid in vinegar to evolve bubbles of carbon dioxide.

$\text{CO}_3^{2-}$ ,  $\text{S}^{2-}$ , and  $\text{SO}_3^{2-}$  are bases. Thus the net ionic equations involve a basic anion reacting with  $\text{H}^+$ , an acid.

**Example 4.6 Writing an Equation for a Reaction with Gas Formation****Gaining Mastery Toolbox****Critical Concept 4.6**

Ionic compounds that contain the carbonate, sulfite, or sulfide anions will produce a gas when reacted with an acid. In addition to the gas, these reactions will produce a salt.

**Solution Essentials:**

- Acid
- Salt
- Exchange reaction
- Solubility rules
- Carbonate, sulfite, and sulfide anions

Write the molecular equation and the net ionic equation for the reaction of zinc sulfide with hydrochloric acid.

**Problem Strategy** Start by writing the reactants, using the solubility rules to determine the phase labels. Next think about the ways in which this reaction can occur; first try to write it as an exchange reaction. Examine the products to see whether an insoluble compound forms and/or there is gas formation; either indicates a reaction.

**Solution** First write the reactants, noting from Table 4.1 that most sulfides (except those of the Group 1A metals and  $(\text{NH}_4)_2\text{S}$ ) are insoluble.

If you look at this as an exchange reaction, the products are  $\text{ZnCl}_2$  and  $\text{H}_2\text{S}$ . Since chlorides are soluble (with some exceptions, not including  $\text{ZnCl}_2$ ), we write the following balanced equation:

The complete ionic equation is

and the net ionic equation is

**Answer Check** When you are trying to solve problems of this type, if starting with an exchange reaction doesn't yield the desired results, use the examples in Table 4.4 as a guide.

**Exercise 4.7** Write the molecular equation and the net ionic equation for the reaction of calcium carbonate with nitric acid.

See Problems 4.51, 4.52, 4.53, and 4.54.

 **CONCEPT CHECK 4.5**

At times, we want to generalize the formula of certain important chemical substances; acids and bases fall into this category. Given the following reactions, try to identify the acids, bases, and some examples of what the general symbols (M and  $\text{A}^-$ ) represent.

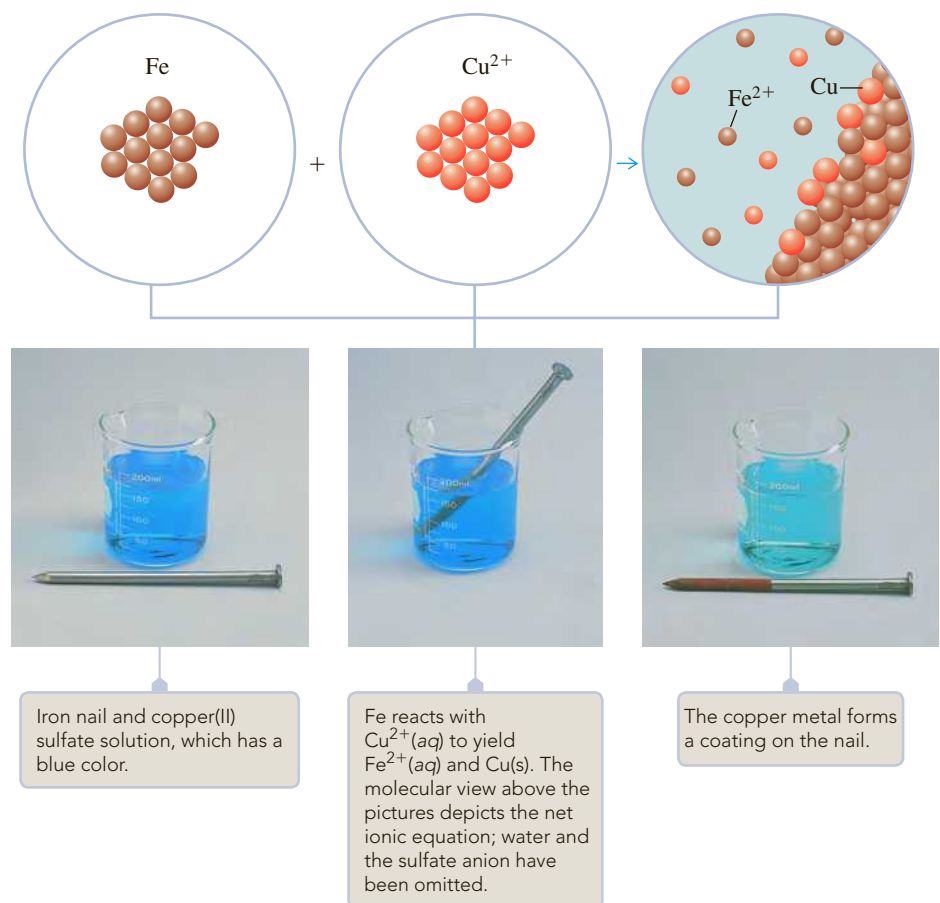

- $\text{MOH}(s) \longrightarrow \text{M}^+(aq) + \text{OH}^-(aq)$
- $\text{HA}(aq) + \text{H}_2\text{O}(l) \rightleftharpoons \text{H}_3\text{O}^+(aq) + \text{A}^-(aq)$
- $\text{H}_2\text{A}(aq) + \text{H}_2\text{O}(l) \rightleftharpoons \text{H}_3\text{O}^+(aq) + \text{HA}^-(aq)$
- For Parts a through c, provide real examples for M and A.

**4.5 Oxidation–Reduction Reactions**

In the two preceding sections, we described precipitation reactions (reactions producing a precipitate) and acid–base reactions (reactions involving proton transfer). Here we discuss the third major class of reactions, oxidation–reduction reactions, which are reactions involving a transfer of electrons from one species to another.

As a simple example of an oxidation–reduction reaction, let us look at what happens when you dip an iron nail into a blue solution of copper(II) sulfate (Figure 4.11). What you see is that the iron nail becomes coated with a reddish-brown tinge of metallic copper. The molecular equation for this reaction is

**Figure 4.11** ◀  
Reaction of iron with  $\text{Cu}^{2+}(\text{aq})$

The net ionic equation is

The electron-transfer aspect of the reaction is apparent from this equation. Note that each iron atom in the metal loses two electrons to form an iron(II) ion, and each copper(II) ion gains two electrons to form a copper atom in the metal. The net effect is that two electrons are transferred from each iron atom in the metal to each copper(II) ion.

The concept of *oxidation numbers* was developed as a simple way of keeping track of electrons in a reaction. Using oxidation numbers, you can determine whether electrons have been transferred from one atom to another. If electrons have been transferred, an oxidation–reduction reaction has occurred.

### Oxidation Numbers

We define the **oxidation number** (or **oxidation state**) of an atom in a substance as *the actual charge of the atom if it exists as a monatomic ion, or a hypothetical charge assigned to the atom in the substance by simple rules*. An oxidation–reduction reaction is one in which one or more atoms change oxidation number, implying that there has been a transfer of electrons.

Consider the combustion of calcium metal in oxygen gas (Figure 4.12).

This is an oxidation–reduction reaction. To see this, you assign oxidation numbers to the atoms in the equation and then note that the atoms change oxidation number during the reaction.

**Figure 4.12** ▲  
The burning of calcium metal in oxygen The burning calcium emits a red-orange flame.

Since the oxidation number of an atom in an element is always zero, Ca and O in  $O_2$  have oxidation numbers of zero. Another rule follows from the definition of oxidation number: The oxidation number of an atom that exists in a substance as a monatomic ion equals the charge on that ion. So the oxidation number of Ca in CaO is +2 (the charge on  $Ca^{2+}$ ), and the oxidation number of O in CaO is  $-2$  (the charge on  $O^{2-}$ ). To emphasize these oxidation numbers in an equation, we will write them above the atomic symbols in the formulas.

From this, you see that the Ca and O atoms change in oxidation number during the reaction. In effect, each calcium atom in the metal loses two electrons to form  $Ca^{2+}$  ions, and each oxygen atom in  $O_2$  gains two electrons to form  $O^{2-}$  ions. The net result is a transfer of electrons from calcium to oxygen, so this reaction is an oxidation–reduction reaction. In other words, an **oxidation–reduction reaction** (or **redox reaction**) is a reaction in which electrons are transferred between species or in which atoms change oxidation number.

Note that calcium has gained in oxidation number from 0 to +2. (Each calcium atom loses two electrons.) We say that calcium has been *oxidized*. Oxygen, on the other hand, has decreased in oxidation number from 0 to  $-2$ . (Each oxygen atom gains two electrons.) We say that oxygen has been *reduced*. An oxidation–reduction reaction always involves both oxidation (the loss of electrons) and reduction (the gain of electrons).

Formerly, the term *oxidation* meant “reaction with oxygen.” The current definition greatly enlarges the meaning of this term. Consider the reaction of calcium metal with chlorine gas (Figure 4.13); the reaction looks similar to the burning of calcium in oxygen. The chemical equation is

In this reaction, the calcium atom is oxidized, because it increases in oxidation number (from 0 to +2, as in the previous equation). Chlorine is reduced; it decreases in oxidation number from 0 to  $-1$ . This is clearly an oxidation–reduction reaction that does not involve oxygen.

### Oxidation-Number Rules

So far, we have used two rules for obtaining oxidation numbers: (1) the oxidation number of an atom in an element is zero, and (2) the oxidation number of an atom in a monatomic ion equals the charge on the ion. These and several other rules for assigning oxidation numbers are given in Table 4.5.

© Cengage Learning

**Figure 4.13** ▲

**The burning of calcium metal in chlorine** The reaction appears similar to the burning of calcium in oxygen.

**Table 4.5** Rules for Assigning Oxidation Numbers

Rule	Applies to	Statement
1	Elements	The oxidation number of an atom in an element is zero.
2	Monatomic ions	The oxidation number of an atom in a monatomic ion equals the charge on the ion.
3	Oxygen	The oxidation number of oxygen is $-2$ in most of its compounds. (An exception is O in $H_2O_2$ and other peroxides, where the oxidation number is $-1$ .)
4	Hydrogen	The oxidation number of hydrogen is $+1$ in most of its compounds. (The oxidation number of hydrogen is $-1$ in binary compounds with a metal, such as $CaH_2$ .)
5	Halogens	The oxidation number of fluorine is $-1$ in all of its compounds. Each of the other halogens (Cl, Br, I) has an oxidation number of $-1$ in binary compounds, except when the other element is another halogen above it in the periodic table or the other element is oxygen.
6	Compounds and ions	The sum of the oxidation numbers of the atoms in a compound is zero. The sum of the oxidation numbers of the atoms in a polyatomic ion equals the charge on the ion.

In molecular substances, we use these rules to give the *approximate* charges on the atoms. Consider the molecule  $\text{SO}_2$ . Oxygen atoms tend to attract electrons, pulling them from other atoms (sulfur in the case of  $\text{SO}_2$ ). As a result, an oxygen atom in  $\text{SO}_2$  takes on a negative charge relative to the sulfur atom. The magnitude of the charge on an oxygen atom in a molecule is not a full  $-2$  charge as in the  $\text{O}^{2-}$  ion. However, it is convenient to assign an oxidation number of  $-2$  to oxygen in  $\text{SO}_2$  (and in most other compounds of oxygen) to help us express the approximate charge distribution in the molecule. Rule 3 in Table 4.5 says that an oxygen atom has an oxidation number of  $-2$  in most of its compounds.

Rules 4 and 5 are similar in that they tell you what to expect for the oxidation number of certain elements in their compounds. Rule 4, for instance, says that hydrogen has an oxidation number of  $+1$  in most of its compounds.

Rule 6 states that the sum of the oxidation numbers of the atoms in a compound is zero. This rule follows from the interpretation of oxidation numbers as (hypothetical) charges on the atoms. Because any compound is electrically neutral, the sum of the charges on its atoms must be zero. This rule is easily extended to ions: the sum of the oxidation numbers (hypothetical charges) of the atoms in a polyatomic ion equals the charge on the ion.

You can use Rule 6 to obtain the oxidation number of one atom in a compound or ion, if you know the oxidation numbers of the other atoms in the compound or ion. Consider the  $\text{SO}_2$  molecule. According to Rule 6,

$$(\text{Oxidation number of S}) + 2 \times (\text{oxidation number of O}) = 0$$

or

$$(\text{Oxidation number of S}) + 2 \times (-2) = 0.$$

Therefore,

$$\text{Oxidation number of S (in SO}_2) = -2 \times (-2) = +4$$

The next example illustrates how to use the rules in Table 4.5 to assign oxidation numbers.

### Example 4.7 Assigning Oxidation Numbers

#### Gaining Mastery Toolbox

##### Critical Concept 4.7

The sum of all the oxidation numbers in a compound or polyatomic ion is equal to the overall charge on the compound or ion. This concept is very helpful in assigning the oxidation number of elements that are not covered by the rules (Table 4.5).

##### Solution Essentials:

- Oxidation number
- Rules for assigning oxidation numbers (Table 4.5)

Use the rules from Table 4.5 to obtain the oxidation number of the chlorine atom in each of the following: a.  $\text{HClO}_4$  (perchloric acid), b.  $\text{ClO}_3^-$  (chlorate ion).

**Problem Strategy** We need to apply the rules in Table 4.5. Rule 6 is the best place to start. Therefore, in each case, write the expression for the sum of the oxidation numbers, equating this to zero for a compound or to the charge for an ion. Now, use Rules 2 to 5 to substitute oxidation numbers for particular atoms, such as  $-2$  for oxygen and  $+1$  for hydrogen, and solve for the unknown oxidation number (Cl in this example).

#### Solution

a. For perchloric acid, Rule 6 gives the equation

$$(\text{Oxidation number of H}) + (\text{oxidation number of Cl}) + 4 \times (\text{oxidation number of O}) = 0$$

Using Rules 3 and 4, you obtain

$$(+1) + (\text{oxidation number of Cl}) + 4 \times (-2) = 0$$

Therefore,

$$\text{Oxidation number of Cl (in HClO}_4) = -(+1) - 4 \times (-2) = +7$$

b. For the chlorate ion, Rule 6 gives the equation

$$(\text{Oxidation number of Cl}) + 3 \times (\text{oxidation number of O}) = -1$$

(continued)

**Example 4.7** (continued)

Using Rule 3, you obtain

$$(\text{Oxidation number of Cl}) + 3 \times (-2) = -1$$

Therefore,

$$\text{Oxidation number of Cl (in ClO}_3^-) = -1 - 3 \times (-2) = +5$$

**Answer Check** Because most compounds do not have elements with very large positive or very large negative oxidation numbers, you should always be on the alert for a *possible* assignment mistake when you find oxidation states greater than +6 or less than -4. (From this example you see that a +7 oxidation state is possible; however, it occurs in only a limited number of cases.)

**Exercise 4.8** Obtain the oxidation numbers of the atoms in each of the following: a. potassium dichromate,  $\text{K}_2\text{Cr}_2\text{O}_7$ , b. permanganate ion,  $\text{MnO}_4^-$ .

See Problems 4.55, 4.56, 4.57, and 4.58.

**Describing Oxidation–Reduction Reactions**

We use special terminology to describe oxidation–reduction reactions. To illustrate this, we will look again at the reaction of iron with copper(II) sulfate. The net ionic equation is

We can write this reaction in terms of two half-reactions. A **half-reaction** is *one of two parts of an oxidation–reduction reaction, one part of which involves a loss of electrons (or increase of oxidation number) and the other a gain of electrons (or decrease of oxidation number)*. The half-reactions for the preceding equation are

**Oxidation** is the half-reaction in which there is a loss of electrons by a species (or an increase of oxidation number of an atom). **Reduction** is the half-reaction in which there is a gain of electrons by a species (or a decrease in the oxidation number of an atom). Thus, the equation  $\text{Fe}(\text{s}) \longrightarrow \text{Fe}^{2+}(\text{aq}) + 2\text{e}^-$  represents the oxidation half-reaction, and the equation  $\text{Cu}^{2+}(\text{aq}) + 2\text{e}^- \longrightarrow \text{Cu}(\text{s})$  represents the reduction half-reaction.

Recall that a species that is *oxidized* loses electrons (or contains an atom that increases in oxidation number) and a species that is *reduced* gains electrons (or contains an atom that decreases in oxidation number). An **oxidizing agent** is a species that oxidizes another species; it is itself reduced. Similarly, a **reducing agent** is a species that reduces another species; it is itself oxidized. In our example reaction, the copper(II) ion is the oxidizing agent, whereas iron metal is the reducing agent.

The relationships among these terms are shown in the following diagram for the reaction of iron with copper(II) ion.

### Some Common Oxidation–Reduction Reactions

Many oxidation–reduction reactions can be described as one of the following:

1. Combination reaction
2. Decomposition reaction
3. Displacement reaction
4. Combustion reaction

We will describe examples of each of these in this section.

**Combination Reactions** A **combination reaction** is a reaction in which two substances combine to form a third substance. Note that not all combination reactions are oxidation–reduction reactions. However, the simplest cases are those in which two elements react to form a compound; these are clearly oxidation–reduction reactions. In Chapter 2, we discussed the reaction of sodium metal and chlorine gas, which is a redox reaction (Figure 4.14).

Antimony and chlorine also combine in a fiery reaction.

Some combination reactions involve compounds as reactants and are not oxidation–reduction reactions. For example,

(If you check the oxidation numbers, you will see that this is not an oxidation–reduction reaction.)

**Decomposition Reactions** A **decomposition reaction** is a reaction in which a single compound reacts to give two or more substances. Often these reactions occur when the temperature is raised. In Chapter 1, we described the decomposition of

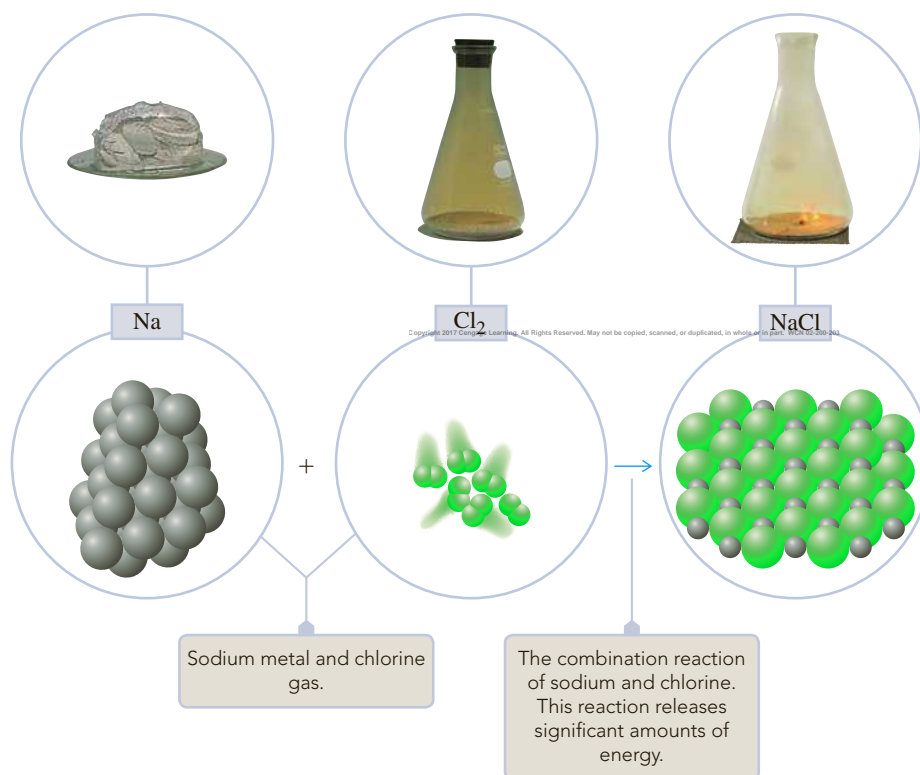

Figure 4.14 ◀  
Combination reaction

© Cengage Learning

**Figure 4.15** ▲

**Decomposition reaction** The decomposition reaction of mercury(II) oxide into its elements, mercury and oxygen.

mercury(II) oxide into its elements when the compound is heated (Figure 4.15). This is an oxidation–reduction reaction.

Another example is the preparation of oxygen by heating potassium chlorate with manganese(IV) oxide as a catalyst.

In this reaction, a compound decomposes into another compound and an element; it also is an oxidation–reduction reaction.

Not all decomposition reactions are of the oxidation–reduction type. For example, calcium carbonate at high temperatures decomposes into calcium oxide and carbon dioxide.

Is there a change in oxidation numbers? If not, this confirms that this is not an oxidation–reduction reaction.

**Displacement Reactions** A **displacement reaction** (also called a **single-replacement reaction**) is a reaction in which an element reacts with a compound, displacing another element from it. Since these reactions involve an element and one of its compounds, these must be oxidation–reduction reactions. An example is the reaction that occurs when you dip a copper metal strip into a solution of silver nitrate.

From the molecular equation, it appears that copper displaces silver in silver nitrate, producing crystals of silver metal and a greenish-blue solution of copper(II) nitrate. The net ionic equation, however, shows that the reaction involves the transfer of electrons from copper metal to silver ion:

When you dip a zinc metal strip into an acid solution, bubbles of hydrogen form on the metal and escape from the solution (Figure 4.16).

Zinc displaces hydrogen in the acid, producing zinc chloride solution and hydrogen gas. The net ionic equation is

© Cengage Learning/Melissa Kelly/Photography

**Figure 4.16** ▲

**Displacement reaction** Displacement reaction of zinc metal and hydrochloric acid. Hydrogen gas formed in the reaction bubbles from the submerged metal surface.

Whether a reaction occurs between a given element and a monatomic ion depends on the relative ease with which the two species gain or lose electrons. Table 4.6 shows the activity series of the elements, a listing of the elements in decreasing order of their ease of losing electrons during reactions in aqueous solution. The metals listed at the top are the strongest reducing agents (they lose electrons easily); those at the bottom, the weakest. A free element reacts with the monatomic ion of another element if the free element is above the other element in the activity series. The highlighted elements react slowly with liquid water, but readily with steam, to give  $\text{H}_2$ .

Consider this reaction:

You would expect this reaction to proceed as written, because potassium metal (K) is well above hydrogen in the activity series. In fact, potassium metal reacts violently with water, which contains only a very small percentage of  $\text{H}^+$  ions. Imagine the reaction of potassium metal with a strong acid like HCl!

**Combustion Reactions** A **combustion reaction** is a reaction in which a substance reacts with oxygen, usually with the rapid release of heat to produce a flame. The products include one or more oxides. Oxygen changes oxidation number from 0 to  $-2$ , so combustions are oxidation–reduction reactions.

Organic compounds usually burn in oxygen or air to yield carbon dioxide. If the compound contains hydrogen (as most do), water is also a product. For instance, butane ( $C_4H_{10}$ ) burns in air as follows:

Many metals burn in air as well. Although chunks of iron do not burn readily in air, iron wool, which consists of fine strands of iron, does (Figure 4.17). The increased surface area of the metal in iron wool allows oxygen from air to react quickly with it.

## 4.6 Balancing Simple Oxidation–Reduction Equations

Oxidation–reduction reactions can often be quite difficult to balance. ► Some are so complex in fact that chemists have written computer programs to accomplish the task. In this section, we will develop a method for balancing simple oxidation–reduction reactions that can later be generalized for far more complex reactions. One of the advantages of using this technique for even simple reactions is that you focus on what makes oxidation–reduction reactions different from other reaction types. See Chapter 19 for a comprehensive treatment of this topic.

At first glance, the equation representing the reaction of zinc metal with silver(I) ions in solution might appear to be balanced.

However, because a balanced chemical equation must have a charge balance as well as a mass balance, this equation is not balanced: it has a total charge of  $+1$  for the reactants and  $+2$  for the products. Let us apply the half-reaction method for balancing this equation.

### Half-Reaction Method Applied to Simple Oxidation–Reduction Equations

The *half-reaction method* consists of first separating the equation into two half-reactions, one for oxidation, the other for reduction. You balance each half-reaction, then combine them to obtain a balanced oxidation–reduction reaction. Here is an illustration of the process. First we identify the species being oxidized and reduced and assign the appropriate oxidation states.

Next, write the half-reactions in an unbalanced form.

Table 4.6 Activity Series of the Elements	
React vigorously with acidic solutions and water to give $H_2$	{ Li K Ba Ca Na
React with acids to give $H_2$	{ Mg Al Zn Cr Fe Cd Co Ni Sn Pb
Do not react with acids to give $H_2^*$	{ $H_2$ Cu Hg Ag Au

\*Cu, Hg, and Ag react with  $HNO_3$  but do not produce  $H_2$ . In these reactions, the metal is oxidized to the metal ion, and  $NO_3^-$  ion is reduced to  $NO_2$  or other nitrogen species.

**Figure 4.17** ▲

**The combustion of iron wool** Iron reacts with oxygen in the air to produce iron(III) oxide,  $Fe_2O_3$ . The reaction is similar to the rusting of iron but is much faster.

Balancing equations was discussed in Section 2.10.

Next, balance the charge in each equation by adding electrons to the more positive side to create balanced half-reactions. Following this procedure, the balanced half-reactions are:

Note that the number of electrons that Zn loses during the oxidation process (two) exceeds the number of electrons gained by  $\text{Ag}^{+}$  during the reduction (one). Since, according to the reduction half-reaction, each  $\text{Ag}^{+}$  is capable of gaining only one electron, we need to double the amount of  $\text{Ag}^{+}$  in order for it to accept all of the electrons produced by Zn during oxidation. To meet this goal and obtain the balanced oxidation–reduction reaction, we multiply each half-reaction by a factor (integer) so that when we add them together, the electrons cancel. We multiply the first equation by 1 (the number of electrons in the second half-reaction) and multiply the second equation by 2 (the number of electrons in the first half-reaction).

The electrons cancel, which finally yields the balanced oxidation–reduction equation:

Example 4.8 further illustrates this technique.

### Example 4.8 Balancing Simple Oxidation–Reduction Reactions by the Half-Reaction Method

#### Gaining Mastery Toolbox

##### Critical Concept 4.8

A balanced oxidation–reduction reaction has both mass balance and charge balance. Using the half-reaction method of balancing oxidation–reduction reactions assures that there is charge balance.

##### Solution Essentials:

- Half-reaction (oxidation and reduction)
- Oxidation
- Reduction
- Oxidation–reduction reaction
- Rules for assigning oxidation numbers (Table 4.5)

Consider a more difficult problem, the combination (oxidation–reduction) reaction of magnesium metal and nitrogen gas:

Apply the half-reaction method to balance this equation.

**Problem Strategy** Start by identifying the species undergoing oxidation and reduction and assigning oxidation numbers. Then write the two balanced half-reactions, keeping in mind that you add the electrons to the more positive side of the reaction. Next, multiply each of the half-reactions by a whole number that will cancel the electrons on each side of the equation. Finally, add the half-reactions together to yield the balanced equation.

**Solution** Identify the oxidation states of the elements:

In this problem, a molecular compound, nitrogen ( $\text{N}_2$ ), is undergoing reduction. When a species undergoing reduction or oxidation is a molecule, write the formula of the molecule (do not split it up) in the half-reaction. Also, make sure that both the mass and the charge are balanced. (Note the  $6\text{e}^{-}$  required to balance the charge due to the  $2\text{N}^{3-}$ .)

We now need to multiply each half-reaction by a factor that will cancel the electrons.

Therefore, the balanced combination (oxidation–reduction) reaction is

(continued)

**Example 4.8** (continued)

From inspecting the coefficients in this reaction, looking at the original equation, and knowing that  $\text{Mg}^{2+}$  and  $\text{N}^{3-}$  will combine to form an ionic compound ( $\text{Mg}_3\text{N}_2$ ), we can rewrite the equation in the following form:

**Answer Check** Do a final check for balance by counting the number of atoms of each element on both sides of the equation.

**Exercise 4.9** Use the half-reaction method to balance the equation  $\text{Ca}(s) + \text{Cl}_2(g) \longrightarrow \text{CaCl}_2(s)$ .

See Problems 4.65 and 4.66.

## ▶ Working with Solutions

The majority of the chemical reactions discussed in this chapter take place in solution. This is because the reaction between two solid reactants often proceeds very slowly or not at all. In a solid, the molecules or ions in a crystal tend to occupy approximately fixed positions, so the chance of two molecules or ions coming together to react is small. In liquid solutions, reactant molecules are free to move throughout the liquid; therefore, reaction is much faster. When you run reactions in liquid solutions, it is convenient to dispense the amounts of reactants by measuring out volumes of reactant solutions. In the next two sections, we will discuss calculations involved in making up solutions, and in Section 4.10 we will describe stoichiometric calculations involving such solutions.

### 4.7 Molar Concentration

When we dissolve a substance in a liquid, we call the substance the *solute* and the liquid the *solvent*. Consider ammonia solutions. Ammonia gas dissolves readily in water, and aqueous ammonia solutions are often used in the laboratory. In such solutions, ammonia gas is the solute and water is the solvent.

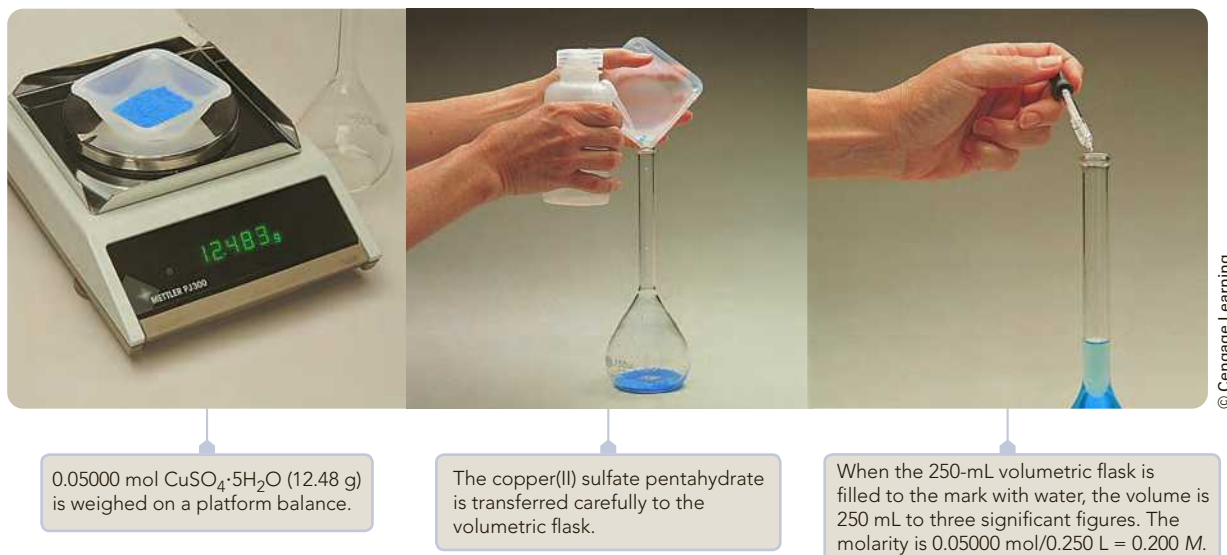

The general term *concentration* refers to the quantity of solute in a standard quantity of solution. Qualitatively, we say that a solution is *dilute* when the solute concentration is low and *concentrated* when the solute concentration is high. Usually these terms are used in a comparative sense and do not refer to a specific concentration. We say that one solution is more dilute, or less concentrated, than another. However, for commercially available solutions, the term *concentrated* refers to the maximum, or near maximum, concentration available. For example, concentrated aqueous ammonia contains about 28%  $\text{NH}_3$  by mass.

In this example, we expressed the concentration quantitatively by giving the mass percentage of solute—that is, the mass of solute in 100 g of solution. However, we need a unit of concentration that is convenient for dispensing reactants in solution, such as one that specifies moles of solute per solution volume.

**Molar concentration**, or **molarity (M)**, is defined as *the moles of solute dissolved in one liter (cubic decimeter) of solution*.

$$\text{Molarity (M)} = \frac{\text{moles of solute}}{\text{liters of solution}}$$

An aqueous solution that is 0.15 M  $\text{NH}_3$  (read this as “0.15 molar  $\text{NH}_3$ ”) contains 0.15 mol  $\text{NH}_3$  per liter of solution. If you want to prepare a solution that is, for example, 0.200 M  $\text{CuSO}_4$ , you place 0.200 mol  $\text{CuSO}_4$  in a 1.000-L volumetric flask, or a proportional amount in a flask of a different size (Figure 4.18). You add a small quantity of water to dissolve the  $\text{CuSO}_4$ . Then you fill the flask with additional water to the mark on the neck and mix the solution. The following example shows how to calculate the molarity of a solution given the mass of solute and the volume of solution.

0.05000 mol  $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$  (12.48 g) is weighed on a platform balance.

The copper(II) sulfate pentahydrate is transferred carefully to the volumetric flask.

When the 250-mL volumetric flask is filled to the mark with water, the volume is 250 mL to three significant figures. The molarity is  $0.05000 \text{ mol} / 0.250 \text{ L} = 0.200 \text{ M}$ .

**Figure 4.18** ▲

Preparing a 0.200 M  $\text{CuSO}_4$  solution

### Example 4.9 Calculating Molarity from Mass and Volume

#### Gaining Mastery Toolbox

##### Critical Concept 4.9

Molarity is a common way for chemists to express solution concentration. Molarity is a ratio of the moles of dissolved substance (solute) to the volume of solution in liters: mol/L. The concentration of a solution is always independent of the amount of solution. ▼

##### Solution Essentials:

- Molarity (molar concentration)
- Mole
- Molar mass
- Dimensional analysis
- Rules for significant figures and rounding

A sample of  $\text{NaNO}_3$  weighing 0.38 g is placed in a 50.0 mL volumetric flask. The flask is then filled with water to the mark on the neck, dissolving the solid. What is the molarity of the resulting solution?

**Problem Strategy** To calculate the molarity, you need the moles of solute. Therefore, you first convert grams  $\text{NaNO}_3$  to moles. The molarity equals the moles of solute divided by the liters of solution.

**Solution** You find that 0.38 g  $\text{NaNO}_3$  is  $4.47 \times 10^{-3}$  mol  $\text{NaNO}_3$ ; the last significant figure is underlined. The volume of solution is 50.0 mL, or  $50.0 \times 10^{-3}$  L, so the molarity is

$$\text{Molarity} = \frac{4.47 \times 10^{-3} \text{ mol NaNO}_3}{50.0 \times 10^{-3} \text{ L soln}} = 0.089 \text{ M NaNO}_3$$

**Answer Check** Although very dilute solutions are possible, there is a limit as to how concentrated solutions can be. Therefore, any answer that leads to solution concentrations that are in excess of 20 M should be suspect.

**Exercise 4.10** A sample of sodium chloride,  $\text{NaCl}$ , weighing 0.0678 g is placed in a 25.0-mL volumetric flask. Enough water is added to dissolve the  $\text{NaCl}$ , and then the flask is filled to the mark with water and carefully shaken to mix the contents. What is the molarity of the resulting solution?

See Problems 4.67, 4.68, 4.69, and 4.70.

This is the last instance where dimensional analysis and the rules for significant figures and rounding will be listed in the Solution Essentials. Any time that you perform a calculation and report an answer, you must consider the rules for rounding and significant figures. Dimensional analysis is a powerful tool that is applicable to most problem solving in which molar quantities are involved, as they are in this example.

The advantage of molarity as a concentration unit is that the amount of solute is related to the volume of solution. Rather than having to weigh out a specified mass of substance, you can instead measure out a definite volume of solution of the substance, which is usually easier. As the following example illustrates, molarity can be used as a factor for converting from moles of solute to liters of solution, and vice versa.

**Example 4.10 Using Molarity as a Conversion Factor****Gaining Mastery Toolbox****Critical Concept 4.10**

Molarity is a conversion factor. As a conversion factor it can be used to convert between moles of solute and the volume of solution or from volume of solution to moles of solute.

**Solution Essentials:**

- Molarity (molar concentration)
- Mole
- Molar mass
- Conversion factor

An experiment calls for the addition to a reaction vessel of 0.184 g of sodium hydroxide, NaOH, in aqueous solution. How many milliliters of 0.150 M NaOH should be added?

**Problem Strategy** Because molarity relates moles of solute to volume of solution, you first need to convert grams of NaOH to moles of NaOH. Then, you can convert moles NaOH to liters of solution, using the molarity as a conversion factor. Here, 0.150 M means that 1 L of solution contains 0.150 moles of solute, so the conversion factor is

$$\frac{1 \text{ L soln}}{0.150 \text{ mol NaOH}}$$

Converts  
mol NaOH to L soln

**Solution** Here is the calculation. (The molar mass of NaOH is 40.0 g/mol.)

$$0.184 \text{ g NaOH} \times \frac{1 \text{ mol NaOH}}{40.0 \text{ g NaOH}} \times \frac{1 \text{ L soln}}{0.150 \text{ mol NaOH}} = 3.07 \times 10^{-2} \text{ L soln (or 30.7 mL)}$$

You need to add **30.7 mL** of 0.150 M NaOH solution to the reaction vessel.

**Answer Check** Note that the mass of NaOH required for the experiment is relatively small. Because of this, you should not expect that a large volume of the 0.150 M NaOH solution will be required.

**Exercise 4.11** How many milliliters of 0.163 M NaCl are required to give 0.0958 g of sodium chloride?

See Problems 4.71, 4.72, 4.73, and 4.74.

**Exercise 4.12** How many moles of sodium chloride should be put in a 50.0-mL volumetric flask to give a 0.15 M NaCl solution when the flask is filled to the mark with water? How many grams of NaCl is this?

See Problems 4.75, 4.76, 4.77, and 4.78.

**4.8 Diluting Solutions**

Commercially available aqueous ammonia (28.0% NH<sub>3</sub>) is 14.8 M NH<sub>3</sub>. Suppose, however, that you want a solution that is 1.00 M NH<sub>3</sub>. You need to dilute the concentrated solution with a definite quantity of water. For this purpose, you must know the relationship between the molarity of the solution before dilution (the *initial molarity*) and that after dilution (the *final molarity*).

To obtain this relationship, first recall the equation defining molarity:

$$\text{Molarity} = \frac{\text{moles of solute}}{\text{liters of solution}}$$

You can rearrange this to give

$$\text{Moles of solute} = \text{molarity} \times \text{liters of solution}$$

The product of molarity and the volume (in liters) gives the moles of solute in the solution. Writing  $M_i$  for the initial molar concentration and  $V_i$  for the initial volume of solution, you get

$$\text{Moles of solute} = M_i \times V_i$$

Figure 4.19 ▲

Molecular view of the dilution process

© Cengage Learning

Figure 4.20 ▲

**Preparing a solution by diluting a concentrated one** A volume of concentrated ammonia, similar to the one in the beaker, has been added to the volumetric flask. Here water is being added from the plastic squeeze bottle to bring the volume up to the mark on the flask.

When the solution is diluted by adding more water, the concentration and volume change to  $M_f$  (the final molar concentration) and  $V_f$  (the final volume), and the moles of solute equals

$$\text{Moles of solute} = M_f \times V_f$$

Because the moles of solute has not changed during the dilution (Figure 4.19),

$$M_i \times V_i = M_f \times V_f$$

(Note: You can use any volume units, but both  $V_i$  and  $V_f$  must be in the same units.)

The next example illustrates how you can use this formula to find the volume of a concentrated solution needed to prepare a given volume of dilute solution.

### Example 4.11 Diluting a Solution

#### Gaining Mastery Toolbox

##### Critical Concept 4.11

The product of a solution's molar concentration and the volume of the solution gives the moles of solute in a solution. This relationship can be expressed mathematically as  $(M_{\text{solute}})(V_{\text{solute}}) = \text{mol}_{\text{solute}}$ . This relationship can be applied to derive the dilution equation  $(M_i \times V_i = M_f \times V_f)$ .

##### Solution Essentials:

- Dilution
- Dilution equation  $(M_i \times V_i = M_f \times V_f)$
- Molarity

You are given a solution of  $14.8 \text{ M NH}_3$ . How many milliliters of this solution do you require to give  $100.0 \text{ mL}$  of  $1.00 \text{ M NH}_3$  when diluted (Figure 4.20)?

**Problem Strategy** Because this problem is a dilution, you can use the dilution formula. In this case you want to know the initial volume ( $V_i$ ) of the solution that you are going to dilute; all of the other quantities needed for the formula are given in the problem.

**Solution** You know the final volume ( $100.0 \text{ mL}$ ), final concentration ( $1.00 \text{ M}$ ), and initial concentration ( $14.8 \text{ M}$ ). You write the dilution formula and rearrange it to give the initial volume.

$$M_i V_i = M_f V_f$$

$$V_i = \frac{M_f V_f}{M_i}$$

Now you substitute the known values into the right side of the equation.

$$V_i = \frac{1.00 \text{ M} \times 100.0 \text{ mL}}{14.8 \text{ M}} = 6.76 \text{ mL}$$

(continued)

**Example 4.11** (continued)

**Answer Check** When you perform a dilution, the volume of the more concentrated solution should always be less than the volume of the final solution, as it is in the photo. Related to this concept is the fact that the initial concentration of a solution is always greater than the final concentration after dilution. These two concepts will enable you to check the reasonableness of your calculated quantities whenever you use the dilution equation.

**Exercise 4.13** You have a solution that is  $1.5\text{ M H}_2\text{SO}_4$  (sulfuric acid). How many milliliters of this acid do you need to prepare  $100.0\text{ mL}$  of  $0.18\text{ M H}_2\text{SO}_4$ ?

See Problems 4.79 and 4.80.

**CONCEPT CHECK 4.6**

Consider the following beakers. Each contains a solution of the hypothetical atom X.

- Arrange the beakers in order of increasing concentration of X.
- Without adding or removing X, what specific things could you do to make the concentrations of X equal in each beaker? (*Hint*: Think about dilutions.)

## ▶ Quantitative Analysis

Analytical chemistry deals with the determination of composition of materials—that is, the analysis of materials. The materials that one might analyze include air, water, food, hair, body fluids, pharmaceutical preparations, and so forth. The analysis of materials is divided into qualitative and quantitative analysis. *Qualitative analysis* involves the identification of substances or species present in a material. For instance, you might determine that a sample of water contains lead(II) ion. **Quantitative analysis**, which we will discuss in the last sections of this chapter, involves *the determination of the amount of a substance or species present in a material*. In a quantitative analysis, you might determine that the amount of lead(II) ion in a sample of water is  $0.067\text{ mg/L}$ .

### 4.9 Gravimetric Analysis

**Gravimetric analysis** is a type of quantitative analysis in which the amount of a species in a material is determined by converting the species to a product that can be isolated completely and weighed. Precipitation reactions are frequently used in gravimetric analyses. In these reactions, you determine the amount of an ionic species by precipitating it from solution. The precipitate, or solid formed in the reaction, is then filtered from the solution, dried, and weighed. The advantages of a gravimetric

Figure 4.21 ▶

## Gravimetric analysis for barium ion

**a** A solution of potassium chromate (yellow) is poured down a stirring rod into a solution containing an unknown amount of barium ion,  $\text{Ba}^{2+}$ . The yellow precipitate that forms is barium chromate,  $\text{BaCrO}_4$ .

**b** The solution is filtered by pouring it into a crucible containing a porous glass partition. Afterward, the crucible is heated to dry the barium chromate. By weighing the crucible before and afterward, you can determine the mass of precipitate.

© Cengage Learning

analysis are its simplicity (at least in theory) and its accuracy. The chief disadvantage is that it requires meticulous, time-consuming work. Because of this, whenever possible, chemists use modern instrumental methods.

As an example of a gravimetric analysis, consider the problem of determining the amount of lead in a sample of drinking water. Lead, if it occurs in the water, probably exists as the lead(II) ion,  $\text{Pb}^{2+}$ . Lead(II) sulfate is a very insoluble compound of lead(II) ion. When sodium sulfate,  $\text{Na}_2\text{SO}_4$ , is added to a solution containing  $\text{Pb}^{2+}$ , lead(II) sulfate precipitates (that is,  $\text{PbSO}_4$  comes out of the solution as a fine, crystalline solid). If you assume that the lead is present in solution as lead(II) nitrate, you can write the following equation for the reaction:

You can separate the white precipitate of lead(II) sulfate from the solution by filtration. Then you dry and weigh the precipitate. Figure 4.21 shows the laboratory setup used in a similar analysis.

### Example 4.12 Determining the Amount of a Species by Gravimetric Analysis

#### Gaining Mastery Toolbox

##### Critical Concept 4.12

The precipitate will contain the species (element, ion, etc.) of interest. If you know the mass and chemical formula of the precipitate, you can determine the mass of each element in the precipitate as outlined in Example 3.7.

##### Solution Essentials:

- Mass percentage
- Molar mass
- Example 3.7

A 1.000-L sample of polluted water was analyzed for lead(II) ion,  $\text{Pb}^{2+}$ , by adding an excess of sodium sulfate to it. The mass of lead(II) sulfate that precipitated was 229.8 mg. What is the mass of lead in a liter of the water? Give the answer as milligrams of lead per liter of solution.

**Problem Strategy** Because an excess of sodium sulfate was added to the solution, you can expect that all of the lead is precipitated as lead(II) sulfate,  $\text{PbSO}_4$ . If you determine the percentage of lead in the  $\text{PbSO}_4$  precipitate, you can calculate the quantity of lead in the water sample.

**Solution** Following Example 3.7, you obtain the mass percentage of Pb in  $\text{PbSO}_4$  by dividing the molar mass of Pb by the molar mass of  $\text{PbSO}_4$ , then multiplying by 100%:

$$\% \text{ Pb} = \frac{207.2 \text{ g/mol}}{303.3 \text{ g/mol}} \times 100\% = 68.32\%$$

(continued)

**Example 4.12** (continued)

Therefore, the 1.000-L sample of water contains

$$\text{Amount Pb in sample} = 229.8 \text{ mg PbSO}_4 \times 0.6832 = 157.0 \text{ mg Pb}$$

The water sample contains **157.0 mg Pb per liter**.

**Answer Check** Check to make sure that the mass of the element of interest, 157.0 mg Pb in this case, is less than the total mass of the precipitate, 229.8 mg in this case. If you do not find this to be true, you have made an error.

**Exercise 4.14** You are given a sample of limestone, which is mostly  $\text{CaCO}_3$ , to determine the mass percentage of Ca in the rock. You dissolve the limestone in hydrochloric acid, which gives a solution of calcium chloride. Then you precipitate the calcium ion in solution by adding sodium oxalate,  $\text{Na}_2\text{C}_2\text{O}_4$ . The precipitate is calcium oxalate,  $\text{CaC}_2\text{O}_4$ . You find that a sample of limestone weighing 128.3 mg gives 140.2 mg of  $\text{CaC}_2\text{O}_4$ . What is the mass percentage of calcium in the limestone?

See Problems 4.83 and 4.84.

## 4.10 Volumetric Analysis

As you saw earlier, you can use molarity as a conversion factor, and in this way you can calculate the volume of solution that is equivalent to a given mass of solute (see Example 4.10). This means that you can replace mass measurements in solution reactions by volume measurements. In the next example, we look at the volumes of solutions involved in a given reaction.

### Example 4.13 Calculating the Volume of Reactant Solution Needed

#### Gaining Mastery Toolbox

##### Critical Concept 4.13

You need to start with a balanced chemical equation. From the balanced chemical equation, you can determine the molar relationship (conversion factor) between the reacting quantities. This conversion factor is critical for correctly solving this type of problem. Do *not* use the dilution equation ( $M_i \times V_i = M_f \times V_f$ ) to solve problems that involve chemical reactions in solution.

##### Solution Essentials:

- Molarity (molar concentration)
- Molar interpretation of a balanced chemical equation
- Stoichiometry

Consider the reaction of sulfuric acid,  $\text{H}_2\text{SO}_4$ , with sodium hydroxide, NaOH.

Suppose a beaker contains 35.0 mL of 0.175 M  $\text{H}_2\text{SO}_4$ . How many milliliters of 0.250 M NaOH must be added to react completely with the sulfuric acid?

**Problem Strategy** This is a stoichiometry problem that involves the reaction of sulfuric acid and sodium hydroxide. You have a known volume and concentration of  $\text{H}_2\text{SO}_4$  in the beaker, and you want to determine what volume of a known concentration of NaOH is required for complete reaction. If you can determine the number of moles of  $\text{H}_2\text{SO}_4$  that are contained in the beaker, you can then use the balanced chemical reaction to determine the number of moles of NaOH required to react completely with the  $\text{H}_2\text{SO}_4$ . Finally, you can use the concentration of the NaOH to determine the required volume of NaOH. Following this strategy, you convert from 35.0 mL (or  $35.0 \times 10^{-3}$  L)  $\text{H}_2\text{SO}_4$  solution to moles  $\text{H}_2\text{SO}_4$  (using the molarity of  $\text{H}_2\text{SO}_4$ ), then to moles NaOH (from the chemical equation). Finally, you convert this to volume of NaOH solution (using the molarity of NaOH).

The problem strategy is diagrammed as

(continued)

**Example 4.13** (continued)

**Solution** The calculation is as follows:

$$35.0 \times 10^{-3} \text{ L H}_2\text{SO}_4 \text{ soln} \times \frac{0.175 \text{ mol H}_2\text{SO}_4}{1 \text{ L H}_2\text{SO}_4 \text{ soln}} \times \frac{2 \text{ mol NaOH}}{1 \text{ mol H}_2\text{SO}_4} \times \frac{1 \text{ L NaOH soln}}{0.250 \text{ mol NaOH}} = 4.90 \times 10^{-2} \text{ L NaOH soln (or 49.0 mL NaOH soln)}$$

Thus, 35.0 mL of 0.175 M sulfuric acid solution reacts with exactly **49.0 mL** of 0.250 M sodium hydroxide solution.

**Answer Check** Whenever you perform a titration calculation, be sure that you have taken into account the stoichiometry of the reaction between the acid and base (use the balanced chemical equation). In this case, two moles of NaOH are required to neutralize each mole of acid. Furthermore, when performing titration calculations, do not be tempted to apply the dilution equation to solve the problem. If you were to take such an approach here, you would arrive at an incorrect result since the dilution equation fails to take into account the stoichiometry of the reaction.

**Exercise 4.15** Nickel sulfate, NiSO<sub>4</sub>, reacts with sodium phosphate, Na<sub>3</sub>PO<sub>4</sub>, to give a pale yellow-green precipitate of nickel phosphate, Ni<sub>3</sub>(PO<sub>4</sub>)<sub>2</sub>, and a solution of sodium sulfate, Na<sub>2</sub>SO<sub>4</sub>

How many milliliters of 0.375 M NiSO<sub>4</sub> will react with 45.7 mL of 0.265 M Na<sub>3</sub>PO<sub>4</sub>?

See Problems 4.89 and 4.90.

An important method for determining the amount of a particular substance is based on measuring the volume of reactant solution. Suppose substance *A* reacts in solution with substance *B*. If you know the volume and concentration of a solution of *B* that just reacts with substance *A* in a sample, you can determine the amount of *A*. **Titration** is a procedure for determining the amount of substance *A* by adding a carefully measured volume of a solution with known concentration of *B* until the reaction of *A* and *B* is just complete. **Volumetric analysis** is a method of analysis based on titration.

Figure 4.22 shows a flask containing hydrochloric acid with an unknown amount of HCl being titrated with sodium hydroxide solution, NaOH, of known molarity. The reaction is

To the HCl solution are added a few drops of phenolphthalein indicator. Phenolphthalein is colorless in the hydrochloric acid but turns pink at the completion of the reaction of NaOH with HCl. Sodium hydroxide with a concentration of 0.207 M is contained in a *buret*, a glass tube graduated to measure the volume of liquid delivered from the stopcock. The solution in the buret is added to the HCl in the flask until the phenolphthalein just changes from colorless to pink. At this point, the reaction is complete and the volume of NaOH that reacts with the HCl is read from the buret. This volume is then used to obtain the mass of HCl in the original solution.

An indicator is a substance that undergoes a color change when a reaction approaches completion. See Section 4.4.

**Example 4.14** Calculating the Quantity of Substance in a Titrated Solution**Gaining Mastery Toolbox****Critical Concept 4.14**

You need to start with a balanced chemical equation for the acid–base neutralization reaction. Just as in Example 4.13, a

A flask contains a solution with an unknown amount of HCl. This solution is titrated with 0.207 M NaOH. It takes 4.47 mL of the NaOH solution to complete the reaction. What is the mass of the HCl?

**Problem Strategy** First, in order to determine the stoichiometry of the reaction, you start by writing the balanced chemical equation.

**Example 4.14** (continued)

balanced chemical equation is essential for correctly solving the problem. In most instances the titration calculations will be based on acid–base neutralization reactions.

**Solution Essentials:**

- Molarity
- Acid–base neutralization reaction
- Molar interpretation of a balanced chemical equation
- Stoichiometry

If you use the numerical information from the problem to determine the moles of NaOH added to the solution, you then can use the stoichiometry of the reaction to determine the moles of HCl that reacted. Once you know the moles of HCl, you can use the molar mass of HCl to calculate the mass of HCl. Employing this strategy, you convert the volume of NaOH ( $4.47 \times 10^{-3}$  L NaOH solution) to moles NaOH (from the molarity of NaOH). Then you convert moles NaOH to moles HCl (from the chemical equation). Finally, you convert moles HCl to grams HCl.

The problem strategy is diagrammed as

**Solution** The calculation is as follows:

$$4.47 \times 10^{-3} \text{ L NaOH soln} \times \frac{0.207 \text{ mol NaOH}}{1 \text{ L NaOH soln}} \times \frac{1 \text{ mol HCl}}{1 \text{ mol NaOH}} \times \frac{36.5 \text{ g HCl}}{1 \text{ mol HCl}} = 0.0338 \text{ g HCl}$$

**Answer Check** Before you perform the titration calculations, always write down the balanced chemical equation.

**Exercise 4.16** A 5.00-g sample of vinegar is titrated with 0.108 *M* NaOH. If the vinegar requires 39.1 mL of the NaOH solution for complete reaction, what is the mass percentage of acetic acid, HC<sub>2</sub>H<sub>3</sub>O<sub>2</sub>, in the vinegar? The reaction is

See Problems 4.91 and 4.92.

**Figure 4.22** ◀

**Titration of an unknown amount of HCl with NaOH**

The flask contains HCl(aq) and a few drops of phenolphthalein indicator; the buret contains 0.207 *M* NaOH(aq) (the buret reading is 44.97 mL).

NaOH(aq) was added to the solution in the flask until a persistent faint pink color was reached, marking the endpoint of the titration (the buret reading is 49.44 mL). The amount of HCl can be determined from the volume of NaOH(aq) used (4.47 mL); see Example 4.14.

The addition of several drops of NaOH(aq) solution beyond the endpoint gives a deep pink color.

**CONCEPT CHECK 4.7**

Consider three flasks, each containing 0.10 mol of acid. You need to learn something about the acids in each of the flasks, so you perform titration using a NaOH solution. Here are the results of the experiment:

Flask A	10 mL of NaOH required for neutralization
Flask B	20 mL of NaOH required for neutralization
Flask C	30 mL of NaOH required for neutralization

- a** What have you learned about each of these acids from performing the experiment?
- b** Could you use the results of this experiment to determine the concentration of the NaOH? If not, what assumption about the molecular formulas of the acids would allow you to make the concentration determination?

**A Checklist for Review**
**Summary of Facts and Concepts**

Reactions often involve ions in aqueous solution. Many of the compounds in such reactions are *electrolytes*, which are substances that dissolve in water to give ions. Electrolytes that exist in solution almost entirely as ions are called *strong electrolytes*. Electrolytes that dissolve in water to give a relatively small percentage of ions are called *weak electrolytes*. The *solubility rules* can be used to predict the extent to which an ionic compound will dissolve in water. Most soluble ionic compounds are strong electrolytes.

We can represent a reaction involving ions in one of three different ways, depending on what information we want to convey. A *molecular equation* is one in which substances are written as if they were molecular, even though they are ionic. This equation closely describes what you actually do in the laboratory. However, this equation does not describe what is happening at the level of ions and molecules. For that purpose, we rewrite the molecular equation as a *complete ionic equation* by replacing the formulas for strong electrolytes by their ion formulas. If you cancel *spectator ions* from the complete ionic equation, you obtain the *net ionic equation*.

Most of the important reactions we consider in this course can be divided into three major classes: (1) precipitation reactions, (2) acid–base reactions, and (3) oxidation–reduction reactions. A *precipitation reaction* occurs in aqueous solution because one product is insoluble. You can decide whether two ionic compounds will result in a precipitation reaction, if you know from solubility rules that one of the potential products is insoluble.

*Acids* are substances that yield hydrogen ions in aqueous solution or donate protons. *Bases* are substances that yield hydroxide ions in aqueous solution or accept protons.

These *acid–base reactions* are proton-transfer reactions. In this chapter, we covered neutralization reactions (reactions of acids and bases to yield salts) and reactions of certain salts with acids to yield a gas.

*Oxidation–reduction reactions* are reactions involving a transfer of electrons from one species to another or a change in the oxidation number of atoms. The concept of *oxidation numbers* helps us describe this type of reaction. The atom that increases in oxidation number is said to undergo *oxidation*; the atom that decreases in oxidation number is said to undergo *reduction*. Oxidation and reduction must occur together in a reaction. Many oxidation–reduction reactions fall into the following categories: combination reactions, decomposition reactions, displacement reactions, and combustion reactions. Oxidation–reduction reactions can be balanced by the *half-reaction method*.

*Molar concentration*, or *molarity*, is the moles of solute in a liter of solution. Knowing the molarity allows you to calculate the amount of solute in any volume of solution. Because the moles of solute are constant during the *dilution of a solution*, you can determine to what volume to dilute a concentrated solution to give one of desired molarity.

*Quantitative analysis* involves the determination of the amount of a species in a material. In *gravimetric analysis*, you determine the amount of a species by converting it to a product you can weigh. In *volumetric analysis*, you determine the amount of a species by titration. *Titration* is a method of chemical analysis in which you measure the volume of solution of known molarity that reacts with a compound of unknown amount. You determine the amount of the compound from this volume of solution.

## Questions and Problems

### Self-Assessment and Review Questions

**Key:** These questions test your understanding of the ideas you worked with in the chapter. These problems vary in difficulty and often can be used for the basis of discussion.

**4.1** Explain why some electrolyte solutions are strongly conducting, whereas others are weakly conducting.

4.2 Define the terms *strong electrolyte* and *weak electrolyte*. Give an example of each.

4.3 Explain the terms *soluble* and *insoluble*. Use the solubility rules to write the formula of an insoluble ionic compound.

4.4 What are the advantages and disadvantages of using a molecular equation to represent an ionic reaction?

4.5 What is a *spectator ion*? Illustrate with a complete ionic reaction.

4.6 What is a net ionic equation? What is the value in using a net ionic equation? Give an example.

4.7 What are the major types of chemical reactions? Give a brief description and an example of each.

4.8 Describe in words how you would prepare pure crystalline AgCl and NaNO<sub>3</sub> from solid AgNO<sub>3</sub> and solid NaCl.

4.9 Give an example of a neutralization reaction. Label the acid, base, and salt.

4.10 Give an example of a polyprotic acid and write equations for the successive neutralizations of the acidic hydrogen atoms of the acid molecule to produce a series of salts.

4.11 Why must oxidation and reduction occur together in a reaction?

4.12 Give an example of a displacement reaction. What is the oxidizing agent? What is the reducing agent?

4.13 Why is the product of molar concentration and volume constant for a dilution problem?

4.14 Describe how the amount of sodium hydroxide in a mixture can be determined by titration with hydrochloric acid of known molarity.

4.15 What is the net ionic equation for the following molecular equation?

Hydrofluoric acid, HF, is a molecular substance and a weak electrolyte.

4.16 An aqueous sodium hydroxide solution mixed with an aqueous magnesium nitrate solution yields which of the following products?

a magnesium hydroxide(aq)

b magnesium dihydroxide(s)

c magnesium hydroxide(s)

d dimagnesium hydroxide(s)

e sodium nitrate(l)

4.17 Which of the following compounds would produce the highest concentration of Cl<sup>-</sup> ions when 0.10 mol of each is placed in separate beakers containing equal volumes of water?

a NaCl

b PbCl<sub>2</sub>

c HClO<sub>4</sub>

d MgCl<sub>2</sub>

e HCl

4.18 In an aqueous 0.10 M HNO<sub>2</sub> solution (HNO<sub>2</sub> is a weak electrolyte), which of the following would you expect to find in the highest concentration?

a H<sub>3</sub>O<sup>+</sup>

b NO<sub>2</sub><sup>-</sup>

c H<sup>+</sup>

d HNO<sub>2</sub>

e OH<sup>-</sup>

## Concept Explorations

**Key:** Concept explorations are comprehensive problems that provide a framework that will enable you to explore and learn many of the critical concepts and ideas in each chapter. If you master the concepts associated with these explorations, you will have a better understanding of many important chemistry ideas and will be more successful in solving all types of chemistry problems. These problems are well suited for group work and for use as in-class activities.

### 4.19 The Behavior of Substances in Water

#### Part 1:

- a Ammonia, NH<sub>3</sub>, is a weak electrolyte. It forms ions in solution by *reacting* with water molecules to form the ammonium ion and hydroxide ion. Write the balanced chemical reaction for this process, including state symbols.
- b From everyday experience you are probably aware that table sugar (sucrose), C<sub>12</sub>H<sub>22</sub>O<sub>11</sub>, is soluble in water. When sucrose dissolves in water, it doesn't form ions through any reaction with water. It just *dissolves* without forming ions, so it is a nonelectrolyte. Write the chemical equation for the dissolving of sucrose in water.
- c Both NH<sub>3</sub> and C<sub>12</sub>H<sub>22</sub>O<sub>11</sub> are soluble molecular compounds, yet they behave differently in aqueous solution. Briefly explain why one is a weak electrolyte and the other is a nonelectrolyte.

- d Hydrochloric acid, HCl, is a molecular compound that is a strong electrolyte. Write the chemical reaction of HCl with water.
- e Compare the ammonia reaction with that of hydrochloric acid. Why are both of these substances considered electrolytes?
- f Explain why HCl is a strong electrolyte and ammonia is a weak electrolyte.
- g Classify each of the following substances as either ionic or molecular.

- KCl
- NH<sub>3</sub>
- CO<sub>2</sub>
- MgBr<sub>2</sub>
- HCl
- Ca(OH)<sub>2</sub>
- PbS
- HC<sub>2</sub>H<sub>3</sub>O<sub>2</sub>

- h For those compounds above that you classified as ionic, use the solubility rules to determine which are soluble.
- i The majority of ionic substances are solids at room temperature. Describe what you would observe if you placed a soluble ionic compound and an insoluble ionic compound in separate beakers of water.
- j Write the chemical equation(s), including state symbols, for what happens when each soluble ionic compound that you identified above is placed in water. Are these

## 142b

## Chemical Reactions

substances reacting with water when they are added to water?

- k** How would you classify the soluble ionic compounds: strong electrolyte, weak electrolyte, or nonelectrolyte? Explain your answer.
- l** Sodium chloride, NaCl, is a strong electrolyte, as is hydroiodic acid, HI. Write the chemical equations for what happens when these substances are added to water.
- m** Are NaCl and HI strong electrolytes because they have similar behavior in aqueous solution? If not, describe, using words and equations, the different chemical process that takes place in each case.

**Part 2:** You have two hypothetical molecular compounds, AX and AY. AX is a strong electrolyte and AY is a weak electrolyte. The compounds undergo the following chemical reactions when added to water.

- a** Explain how the relative amounts of AX(aq) and AY(aq) would compare if you had a beaker of water with AX and a beaker of water with AY.
- b** How would the relative amounts of X<sup>-</sup>(aq) and Y<sup>-</sup>(aq) in the two beakers compare? Be sure to explain your answer.

#### 4.20 Working with Concentration (Molarity Concepts)

**Note:** You should be able to answer all of the following questions without using a calculator.

##### Part 1:

- a** Both NaCl and MgCl<sub>2</sub> are soluble ionic compounds. Write the balanced chemical equations for these two substances dissolving in water.
- b** Consider the pictures below. These pictures represent 1.0-L solutions of 1.0 M NaCl(aq) and 1.0 M MgCl<sub>2</sub>(aq). The representations of the ions in solution are the correct relative amounts. Water molecules have been omitted for clarity. Correctly label each of the beakers, provide a key to help identify the ions, and give a brief explanation of how you made your assignments.

Keeping in mind that the pictures represent the relative amounts of ions in the solution and that the numerical information about these solutions is presented above, answer the following questions c through f.

- c** How many moles of NaCl and MgCl<sub>2</sub> are in each beaker?
- d** How many moles of chloride ions are in each beaker? How did you arrive at this answer?
- e** What is the concentration of chloride ions in each beaker? Without using mathematical equations, briefly explain how you obtained your answer.
- f** Explain how it is that the concentrations of chloride ions in these beakers are different even though the concentrations of each substance (compound) are the same.

**Part 2:** Say you were to dump out half of the MgCl<sub>2</sub> solution from the beaker above.

- a** What would be the concentration of the MgCl<sub>2</sub>(aq) and of the chloride ions in the remaining solution?
- b** How many moles of the MgCl<sub>2</sub> and of the chloride ions would remain in the beaker?
- c** Explain why the concentration of MgCl<sub>2</sub>(aq) *would not* change, whereas the number of moles of MgCl<sub>2</sub> *would* change when solution was removed from the beaker. As part of your answer, you are encouraged to use pictures.

**Part 3:** Consider the beaker containing 1.0 L of the 1.0 M NaCl(aq) solution. You now add 1.0 L of water to this beaker.

- a** What is the concentration of this NaCl(aq) solution?
- b** How many moles of NaCl are present in the 2.0 L of NaCl(aq) solution?
- c** Explain why the concentration of NaCl(aq) *does* change with the addition of water, whereas the number of moles *does not* change. Here again, you are encouraged to use pictures to help answer the question.

## Conceptual Problems

**Key:** These problems are designed to check your understanding of the concepts associated with some of the main topics presented in each chapter. A strong conceptual understanding of chemistry is the foundation for both applying chemical knowledge and solving chemical problems. These problems vary in level of difficulty and often can be used as a basis for group discussion.

**4.21** You need to perform gravimetric analysis of a water sample in order to determine the amount of Ag<sup>+</sup> present.

- a** List three aqueous solutions that would be suitable for mixing with the sample to perform the analysis.

- b** Would adding KNO<sub>3</sub>(aq) allow you to perform the analysis?
- c** Assume you have performed the analysis and the silver solid that formed is moderately soluble. How might this affect your analysis results?

**4.22** In this problem you need to draw two pictures of solutions in beakers at different points in time. Time zero ( $t = 0$ ) will be the *hypothetical* instant at which the reactants dissolve in the solution (*if* they dissolve) *before* they react. Time after mixing ( $t > 0$ ) will be the time required to allow sufficient interaction of the materials. For now,

we assume that insoluble solids have no ions in solution and do not worry about representing the stoichiometric amounts of the dissolved ions. Here is an example: Solid NaCl and solid AgNO<sub>3</sub> are added to a beaker containing 250 mL of water.

Note that we are not showing the H<sub>2</sub>O, and we are representing only the ions and solids in solution. Using the same conditions as the example (adding the solids to H<sub>2</sub>O), draw pictures of the following:

- Solid lead(II) nitrate and solid ammonium chloride at  $t = 0$  and  $t > 0$
- FeS(s) and NaNO<sub>3</sub>(s) at  $t = 0$  and  $t > 0$
- Solid lithium iodide and solid sodium carbonate at  $t = 0$  and  $t > 0$

**4.23** You come across a beaker that contains water, aqueous ammonium acetate, and a precipitate of calcium phosphate.

- Write the balanced molecular equation for a reaction between two solutions containing ions that could produce this solution.
- Write the complete ionic equation for the reaction in part a.
- Write the net ionic equation for the reaction in part a.

**4.24** Three acid samples are prepared for titration by 0.01 M NaOH:

- Sample 1 is prepared by dissolving 0.01 mol of HCl in 50 mL of water.
- Sample 2 is prepared by dissolving 0.01 mol of HCl in 60 mL of water.
- Sample 3 is prepared by dissolving 0.01 mol of HCl in 70 mL of water.

- Without performing a formal calculation, compare the concentrations of the three acid samples (rank them from highest to lowest).
- When the titration is performed, which sample, if any, will require the largest volume of the 0.01 M NaOH for neutralization?

**4.25** Would you expect a precipitation reaction between an ionic compound that is an electrolyte and an ionic compound that is a nonelectrolyte? Justify your answer.

**4.26** Equal quantities of the hypothetical strong acid HX, weak acid HA, and weak base BZ are added to separate beakers of water, producing the solutions depicted in the drawings. In the drawings, the relative amounts of each substance present in the solution (neglecting the water) are shown. Identify the acid or base that was used to produce each of the solutions (HX, HA, or BZ).

**4.27** Try and answer the following questions without using a calculator.

- A solution is made by mixing 1.0 L of 0.5 M NaCl and 0.5 L of 1.0 M CaCl<sub>2</sub>. Which ion is at the highest concentration in the solution?
- Another solution is made by mixing 0.50 L of 1.0 M KBr and 0.50 L of 1.0 M K<sub>3</sub>PO<sub>4</sub>. What is the concentration of each ion in the solution?

**4.28** If one mole of the following compounds were each placed into separate beakers containing the same amount of water, rank the Cl<sup>-</sup>(aq) concentrations from highest to lowest (some may be equivalent): KCl, AlCl<sub>3</sub>, PbCl<sub>2</sub>, NaCl, HCl, NH<sub>3</sub>, KOH, and HCN.

## Practice Problems

**Key:** These problems are for practice in applying problem-solving skills. They are divided by topic, and some are keyed to exercises (see the ends of the exercises). The problems are arranged in matching pairs; the odd-numbered problem of each pair is listed first, and its answer is given in the back of the book.

### Solubility Rules

**4.29** Using solubility rules, predict the solubility in water of the following ionic compounds.

- |  |                            |
|--|----------------------------|
| <b>a</b> PbS                             | <b>b</b> AgNO <sub>3</sub> |
| <b>c</b> Na <sub>2</sub> CO <sub>3</sub> | <b>d</b> CaI <sub>2</sub>  |

**4.30** Using solubility rules, predict the solubility in water of the following ionic compounds.

- |                              |   |
|------------------------------|---|
| <b>a</b> Al(OH) <sub>3</sub> | <b>b</b> Ca <sub>3</sub> N <sub>2</sub> |
| <b>c</b> NH <sub>4</sub> Cl  | <b>d</b> KOH                            |

**4.31** Using solubility rules, decide whether the following ionic solids are soluble or insoluble in water. If they are soluble, write the chemical equation for dissolving in water and indicate what ions you would expect to be present in solution.

- |  |  |
|--|--|
| <b>a</b> AgBr  | <b>b</b> Li <sub>2</sub> SO <sub>4</sub> |
| <b>c</b> Ca <sub>3</sub> (PO <sub>4</sub> ) <sub>2</sub> | <b>d</b> Na <sub>2</sub> CO <sub>3</sub> |

**4.32** Using solubility rules, decide whether the following ionic solids are soluble or insoluble in water. If they are soluble, write the chemical equation for dissolving in water and indicate what ions you would expect to be present in solution.

- a**  $(\text{NH}_4)_2\text{SO}_4$       **b**  $\text{BaCO}_3$   
**c**  $\text{Pb}(\text{NO}_3)_2$       **d**  $\text{Ca}(\text{OH})_2$

### Ionic Equations

**4.33** Write net ionic equations for the following molecular equations. HBr is a strong electrolyte.

- a**  $\text{HBr}(aq) + \text{KOH}(aq) \longrightarrow \text{KBr}(aq) + \text{H}_2\text{O}(l)$   
**b**  $\text{AgNO}_3(aq) + \text{NaBr}(aq) \longrightarrow \text{AgBr}(s) + \text{NaNO}_3(aq)$   
**c**  $\text{K}_2\text{S}(aq) + 2\text{HBr}(aq) \longrightarrow 2\text{KBr}(aq) + \text{H}_2\text{S}(g)$   
**d**  $\text{NaOH}(aq) + \text{NH}_4\text{Br}(aq) \longrightarrow$   
 $\text{NaBr}(aq) + \text{NH}_3(g) + \text{H}_2\text{O}(l)$

**4.34** Write net ionic equations for the following molecular equations. HBr is a strong electrolyte.

- a**  $\text{HBr}(aq) + \text{NH}_3(aq) \longrightarrow \text{NH}_4\text{Br}(aq)$   
**b**  $2\text{HCl}(aq) + \text{Ba}(\text{OH})_2(aq) \longrightarrow 2\text{H}_2\text{O}(l) + \text{BaCl}_2(aq)$   
**c**  $\text{Pb}(\text{NO}_3)_2(aq) + 2\text{NaBr}(aq) \longrightarrow$   
 $\text{PbBr}_2(s) + 2\text{NaNO}_3(aq)$   
**d**  $\text{MgCO}_3(s) + \text{H}_2\text{SO}_4(aq) \longrightarrow$   
 $\text{MgSO}_4(aq) + \text{H}_2\text{O}(l) + \text{CO}_2(g)$

**4.35** Lead(II) nitrate solution and sodium sulfate solution are mixed. Crystals of lead(II) sulfate come out of solution, leaving a solution of sodium nitrate. Write the molecular equation and the net ionic equation for the reaction.

**4.36** Lithium carbonate solution reacts with aqueous hydrobromic acid to give a solution of lithium bromide, carbon dioxide gas, and water. Write the molecular equation and the net ionic equation for the reaction.

### Precipitation

**4.37** Write the molecular equation and the net ionic equation for each of the following aqueous reactions. If no reaction occurs, write *NR* after the arrow.

- a**  $\text{FeSO}_4 + \text{NaCl} \longrightarrow$   
**b**  $\text{Na}_2\text{CO}_3 + \text{MgBr}_2 \longrightarrow$   
**c**  $\text{MgSO}_4 + \text{NaOH} \longrightarrow$   
**d**  $\text{NiCl}_2 + \text{NaBr} \longrightarrow$

**4.38** Write the molecular equation and the net ionic equation for each of the following aqueous reactions. If no reaction occurs, write *NR* after the arrow.

- a**  $\text{AgNO}_3 + \text{NaI} \longrightarrow$   
**b**  $\text{Ba}(\text{NO}_3)_2 + \text{K}_2\text{SO}_4 \longrightarrow$   
**c**  $\text{NH}_4\text{NO}_3 + \text{K}_2\text{SO}_4 \longrightarrow$   
**d**  $\text{LiCl} + \text{Al}(\text{NO}_3)_3 \longrightarrow$

**4.39** For each of the following, write molecular and net ionic equations for any precipitation reaction that occurs. If no reaction occurs, indicate this.

- a** Solutions of barium nitrate and lithium sulfate are mixed.  
**b** Solutions of sodium bromide and calcium nitrate are mixed.  
**c** Solutions of aluminum sulfate and sodium hydroxide are mixed.  
**d** Solutions of calcium bromide and sodium phosphate are mixed.

**4.40** For each of the following, write molecular and net ionic equations for any precipitation reaction that occurs. If no reaction occurs, indicate this.

- a** Zinc chloride and sodium sulfide are dissolved in water.  
**b** Sodium sulfide and calcium chloride are dissolved in water.  
**c** Magnesium sulfate and potassium bromide are dissolved in water.  
**d** Magnesium sulfate and potassium carbonate are dissolved in water.

### Strong and Weak Acids and Bases

**4.41** Classify each of the following as a strong or weak acid or base.

- a** HF      **b** KOH      **c**  $\text{HClO}_4$       **d** HIO

**4.42** Classify each of the following as a strong or weak acid or base.

- a**  $\text{NH}_3$       **b** HCNO      **c**  $\text{Mg}(\text{OH})_2$       **d**  $\text{HClO}_3$

### Neutralization Reactions

**4.43** Complete and balance each of the following molecular equations (in aqueous solution); include phase labels. Then, for each, write the net ionic equation.

- a**  $\text{NaOH} + \text{HNO}_3 \longrightarrow$   
**b**  $\text{HCl} + \text{Ba}(\text{OH})_2 \longrightarrow$   
**c**  $\text{HC}_2\text{H}_3\text{O}_2 + \text{Ca}(\text{OH})_2 \longrightarrow$   
**d**  $\text{NH}_3 + \text{HNO}_3 \longrightarrow$

**4.44** Complete and balance each of the following molecular equations (in aqueous solution); include phase labels. Then, for each, write the net ionic equation.

- a**  $\text{Al}(\text{OH})_3 + \text{HCl} \longrightarrow$   
**b**  $\text{HClO} + \text{Sr}(\text{OH})_2 \longrightarrow$   
**c**  $\text{Ba}(\text{OH})_2 + \text{HC}_2\text{H}_3\text{O}_2 \longrightarrow$   
**d**  $\text{H}_2\text{SO}_4 + \text{KOH} \longrightarrow$

**4.45** For each of the following, write the molecular equation, including phase labels. Then write the net ionic equation. Note that the salts formed in these reactions are soluble.

- a** the neutralization of hydrobromic acid with calcium hydroxide solution  
**b** the reaction of solid aluminum hydroxide with nitric acid  
**c** the reaction of aqueous hydrogen cyanide with calcium hydroxide solution  
**d** the neutralization of lithium hydroxide solution by aqueous hydrogen cyanide

**4.46** For each of the following, write the molecular equation, including phase labels. Then write the net ionic equation. Note that the salts formed in these reactions are soluble.

- a** the neutralization of lithium hydroxide solution by aqueous chloric acid  
**b** the reaction of barium hydroxide solution and aqueous nitrous acid  
**c** the reaction of sodium hydroxide solution and aqueous nitrous acid  
**d** the neutralization of aqueous hydrogen cyanide by aqueous strontium hydroxide

4.47 Complete the right side of each of the following molecular equations. Then write the net ionic equations. Assume all salts formed are soluble. Acid salts are possible.

- a  $2\text{KOH}(aq) + \text{H}_3\text{PO}_4(aq) \longrightarrow$   
 b  $3\text{H}_2\text{SO}_4(aq) + 2\text{Al}(\text{OH})_3(s) \longrightarrow$   
 c  $2\text{HC}_2\text{H}_3\text{O}_2(aq) + \text{Ca}(\text{OH})_2(aq) \longrightarrow$   
 d  $\text{H}_2\text{SO}_3(aq) + \text{NaOH}(aq) \longrightarrow$

4.48 Complete the right side of each of the following molecular equations. Then write the net ionic equations. Assume all salts formed are soluble. Acid salts are possible.

- a  $\text{Ca}(\text{OH})_2(aq) + 2\text{H}_2\text{SO}_4(aq) \longrightarrow$   
 b  $2\text{H}_3\text{PO}_4(aq) + \text{Ca}(\text{OH})_2(aq) \longrightarrow$   
 c  $\text{NaOH}(aq) + \text{H}_2\text{SO}_4(aq) \longrightarrow$   
 d  $\text{Sr}(\text{OH})_2(aq) + 2\text{H}_2\text{CO}_3(aq) \longrightarrow$

4.49 Write molecular and net ionic equations for the successive neutralizations of each acidic hydrogen of sulfurous acid by aqueous calcium hydroxide.  $\text{CaSO}_3$  is insoluble; the acid salt is soluble.

4.50 Write molecular and net ionic equations for the successive neutralizations of each acidic hydrogen of phosphoric acid by calcium hydroxide solution.  $\text{Ca}_3(\text{PO}_4)_2$  is insoluble; assume that the acid salts are soluble.

### Reactions Evolving a Gas

4.51 The following reactions occur in aqueous solution. Complete and balance the molecular equations using phase labels. Then write the net ionic equations.

- a  $\text{CaS} + \text{HBr} \longrightarrow$   
 b  $\text{MgCO}_3 + \text{HNO}_3 \longrightarrow$   
 c  $\text{K}_2\text{SO}_3 + \text{H}_2\text{SO}_4 \longrightarrow$

4.52 The following reactions occur in aqueous solution. Complete and balance the molecular equations using phase labels. Then write the net ionic equations.

- a  $\text{BaCO}_3 + \text{HNO}_3 \longrightarrow$   
 b  $\text{K}_2\text{S} + \text{HCl} \longrightarrow$   
 c  $\text{CaSO}_3(s) + \text{HI} \longrightarrow$

4.53 Write the molecular equation and the net ionic equation for the reaction of solid iron(II) sulfide and hydrochloric acid. Add phase labels.

4.54 Write the molecular equation and the net ionic equation for the reaction of solid barium carbonate and hydrogen bromide in aqueous solution. Add phase labels.

### Oxidation Numbers

4.55 Obtain the oxidation number for the element noted in each of the following.

- a Sn in  $\text{SnO}_2$                       b Ta in  $\text{Ta}_2\text{O}_3$   
 c Br in  $\text{KBrO}_4$                     d Os in  $\text{K}_2\text{O}_5\text{O}_4$

4.56 Obtain the oxidation number for the element noted in each of the following.

- a Cr in  $\text{CrO}_3$                         b Hg in  $\text{Hg}_2\text{Cl}_2$   
 c Ga in  $\text{Ga}(\text{OH})_3$                 d P in  $\text{Na}_3\text{PO}_4$

4.57 Obtain the oxidation number for the element noted in each of the following.

- a N in  $\text{NH}_2^-$                         b I in  $\text{IO}_3^-$   
 c H in  $\text{H}_2$                             d Cl in  $\text{HClO}_4$

4.58 Obtain the oxidation number for the element noted in each of the following.

- a N in  $\text{N}_2$                             b Cr in  $\text{CrO}_4^{2-}$   
 c Zn in  $\text{Zn}(\text{OH})_4^{2-}$                 d As in  $\text{H}_2\text{AsO}_3^-$

4.59 Determine the oxidation numbers of all the elements in each of the following compounds. (*Hint*: Look at the ions present.)

- a  $\text{Mn}(\text{ClO}_2)_2$                         b  $\text{Fe}_2(\text{CrO}_4)_3$   
 c  $\text{HgCr}_2\text{O}_7$                             d  $\text{Co}_3(\text{PO}_4)_2$

4.60 Determine the oxidation numbers of all the elements in each of the following compounds. (*Hint*: Look at the ions present.)

- a  $\text{Hg}_2(\text{ClO}_4)_2$                         b  $\text{Cr}_2(\text{SO}_4)_3$   
 c  $\text{CoSeO}_4$                             d  $\text{Pb}(\text{OH})_2$

### Describing Oxidation–Reduction Reactions

4.61 In the following reactions, label the oxidizing agent and the reducing agent.

- a  $\text{P}_4(s) + 5\text{O}_2(g) \longrightarrow \text{P}_4\text{O}_{10}(s)$   
 b  $\text{Co}(s) + \text{Cl}_2(g) \longrightarrow \text{CoCl}_2(s)$

4.62 In the following reactions, label the oxidizing agent and the reducing agent.

- a  $\text{ZnO}(s) + \text{C}(s) \longrightarrow \text{Zn}(g) + \text{CO}(g)$   
 b  $8\text{Fe}(s) + \text{S}_8(s) \longrightarrow 8\text{FeS}(s)$

4.63 In the following reactions, label the oxidizing agent and the reducing agent.

- a  $2\text{Al}(s) + 3\text{F}_2(g) \longrightarrow 2\text{AlF}_3(s)$   
 b  $\text{Hg}^{2+}(aq) + \text{NO}_2^-(aq) + \text{H}_2\text{O}(l) \longrightarrow$   
 $\text{Hg}(s) + 2\text{H}^+(aq) + \text{NO}_3^-(aq)$

4.64 In the following reactions, label the oxidizing agent and the reducing agent.

- a  $\text{Fe}_2\text{O}_3(s) + 3\text{CO}(g) \longrightarrow 2\text{Fe}(s) + 3\text{CO}_2(g)$   
 b  $\text{PbS}(s) + 4\text{H}_2\text{O}_2(aq) \longrightarrow \text{PbSO}_4(s) + 4\text{H}_2\text{O}(l)$

### Balancing Oxidation–Reduction Reactions

4.65 Balance the following oxidation–reduction reactions by the half-reaction method.

- a  $\text{CuCl}_2(aq) + \text{Al}(s) \longrightarrow \text{AlCl}_3(aq) + \text{Cu}(s)$   
 b  $\text{Cr}^{3+}(aq) + \text{Zn}(s) \longrightarrow \text{Cr}(s) + \text{Zn}^{2+}(aq)$

4.66 Balance the following oxidation–reduction reactions by the half-reaction method.

- a  $\text{FeI}_3(aq) + \text{Mg}(s) \longrightarrow \text{Fe}(s) + \text{MgI}_2(aq)$   
 b  $\text{H}_2(g) + \text{Ag}^+(aq) \longrightarrow \text{Ag}(s) + \text{H}^+(aq)$

### Molarity

4.67 A sample of 0.0606 mol of iron(III) chloride,  $\text{FeCl}_3$ , was dissolved in water to give 35.4 mL of solution. What is the molarity of the solution?

4.68 A 50.0-mL volume of  $\text{AgNO}_3$  solution contains 0.0345 mol  $\text{AgNO}_3$  (silver nitrate). What is the molarity of the solution?

4.69 An aqueous solution is made from 0.798 g of potassium permanganate,  $\text{KMnO}_4$ . If the volume of solution is 50.0 mL, what is the molarity of  $\text{KMnO}_4$  in the solution?

**4.70** A sample of oxalic acid,  $\text{H}_2\text{C}_2\text{O}_4$ , weighing 1.200 g is placed in a 100.0-mL volumetric flask, which is then filled to the mark with water. What is the molarity of the solution?

**4.71** What volume of 0.120  $M$   $\text{CuSO}_4$  is required to give 0.150 mol of copper(II) sulfate,  $\text{CuSO}_4$ ?

**4.72** How many milliliters of 0.126  $M$   $\text{HClO}_4$  (perchloric acid) are required to give 0.150 mol  $\text{HClO}_4$ ?

**4.73** An experiment calls for 0.0353 g of potassium hydroxide,  $\text{KOH}$ . How many milliliters of 0.0176  $M$   $\text{KOH}$  are required?

**4.74** What is the volume (in milliliters) of 0.100  $M$   $\text{H}_2\text{SO}_4$  (sulfuric acid) containing 0.949 g  $\text{H}_2\text{SO}_4$ ?

**4.75** Heme, obtained from red blood cells, binds oxygen,  $\text{O}_2$ . How many moles of heme are there in 150 mL of 0.0019  $M$  heme solution?

**4.76** Insulin is a hormone that controls the use of glucose in the body. How many moles of insulin are required to make up 28 mL of 0.0048  $M$  insulin solution?

**4.77** How many grams of sodium dichromate,  $\text{Na}_2\text{Cr}_2\text{O}_7$ , should be added to a 100.0-mL volumetric flask to prepare 0.033  $M$   $\text{Na}_2\text{Cr}_2\text{O}_7$  when the flask is filled to the mark with water?

**4.78** Describe how you would prepare  $2.50 \times 10^2$  mL of 0.50  $M$   $\text{Na}_2\text{SO}_4$ . What mass (in grams) of sodium sulfate,  $\text{Na}_2\text{SO}_4$ , is needed?

**4.79** You wish to prepare 0.12  $M$   $\text{HNO}_3$  from a stock solution of nitric acid that is 15.8  $M$ . How many milliliters of the stock solution do you require to make up 1.00 L of 0.12  $M$   $\text{HNO}_3$ ?

**4.80** A chemist wants to prepare 0.75  $M$   $\text{HCl}$ . Commercial hydrochloric acid is 12.4  $M$ . How many milliliters of the commercial acid does the chemist require to make up 1.50 L of the dilute acid?

**4.81** A 8.50 g sample of  $\text{KCl}$  is dissolved in 66.0 mL of water. The resulting solution is then added to 72.0 mL of a 0.280  $M$   $\text{CaCl}_2(aq)$  solution. Assuming that the volumes are additive, calculate the concentrations of each ion present in the final solution.

**4.82** Calculate the concentrations of each ion present in a solution that results from mixing 50.0 mL of a 0.20  $M$   $\text{NaClO}_3(aq)$  solution with 25.0 mL of a 0.20  $M$   $\text{Na}_2\text{SO}_4(aq)$  solution. Assume that the volumes are additive.

### Gravimetric Analysis

**4.83** A chemist added an excess of sodium sulfate to a solution of a soluble barium compound to precipitate all of the barium ion as barium sulfate,  $\text{BaSO}_4$ . How many grams of barium ion are in a 458-mg sample of the barium compound if a solution of the sample gave 513 mg  $\text{BaSO}_4$  precipitate? What is the mass percentage of barium in the compound?

**4.84** A soluble iodide was dissolved in water. Then an excess of silver nitrate,  $\text{AgNO}_3$ , was added to precipitate all of the iodide ion as silver iodide,  $\text{AgI}$ . If 1.545 g of the soluble iodide gave 2.185 g of silver iodide, how many grams

of iodine are in the sample of soluble iodide? What is the mass percentage of iodine,  $\text{I}$ , in the compound?

**4.85** Copper has compounds with copper(I) ion or copper(II) ion. A compound of copper and chlorine was treated with a solution of silver nitrate,  $\text{AgNO}_3$ , to convert the chloride ion in the compound to a precipitate of  $\text{AgCl}$ . A 59.40-mg sample of the copper compound gave 86.00 mg  $\text{AgCl}$ .

- Calculate the percentage of chlorine in the copper compound.
- Decide whether the formula of the compound is  $\text{CuCl}$  or  $\text{CuCl}_2$ .

**4.86** Gold has compounds containing gold(I) ion or gold(III) ion. A compound of gold and chlorine was treated with a solution of silver nitrate,  $\text{AgNO}_3$ , to convert the chloride ion in the compound to a precipitate of  $\text{AgCl}$ . A 162.7-mg sample of the gold compound gave 100.3 mg  $\text{AgCl}$ .

- Calculate the percentage of the chlorine in the gold compound.
- Decide whether the formula of the compound is  $\text{AuCl}$  or  $\text{AuCl}_3$ .

**4.87** A compound of iron and chlorine is soluble in water. An excess of silver nitrate was added to precipitate the chloride ion as silver chloride. If a 134.8-mg sample of the compound gave 304.8 mg  $\text{AgCl}$ , what is the formula of the compound?

**4.88** A 1.345-g sample of a compound of barium and oxygen was dissolved in hydrochloric acid to give a solution of barium ion, which was then precipitated with an excess of potassium chromate to give 2.012 g of barium chromate,  $\text{BaCrO}_4$ . What is the formula of the compound?

### Volumetric Analysis

**4.89** What volume of 0.230  $M$   $\text{HNO}_3$  (nitric acid) reacts with 49.0 mL of 0.330  $M$   $\text{Na}_2\text{CO}_3$  (sodium carbonate) in the following reaction?

**4.90** A flask contains 49.8 mL of 0.150  $M$   $\text{Ca}(\text{OH})_2$  (calcium hydroxide). How many milliliters of 0.500  $M$   $\text{Na}_2\text{CO}_3$  (sodium carbonate) are required to react completely with the calcium hydroxide in the following reaction?

**4.91** How many milliliters of 0.250  $M$   $\text{H}_2\text{SO}_4$  (sulfuric acid) are required to react with 8.20 g of sodium hydrogen carbonate,  $\text{NaHCO}_3$ , according to the following equation?

**4.92** How many milliliters of 0.250  $M$   $\text{KMnO}_4$  are needed to react with 3.55 g of iron(II) sulfate,  $\text{FeSO}_4$ ? The reaction is as follows:

**4.93** A solution of hydrogen peroxide,  $\text{H}_2\text{O}_2$ , is titrated with a solution of potassium permanganate,  $\text{KMnO}_4$ . The reaction is

It requires 51.7 mL of 0.145  $M$   $\text{KMnO}_4$  to titrate 20.0 g of the solution of hydrogen peroxide. What is the mass percentage of  $\text{H}_2\text{O}_2$  in the solution?

**4.94** A 3.75-g sample of iron ore is transformed to a solution of iron(II) sulfate,  $\text{FeSO}_4$ , and this solution is titrated with 0.150  $M$   $\text{K}_2\text{Cr}_2\text{O}_7$  (potassium dichromate). If it requires 43.7 mL of potassium dichromate solution to titrate the iron(II) sulfate solution, what is the percentage of iron in the ore? The reaction is

## General Problems

**Key:** These problems provide more practice but are not divided by topic or keyed to exercises. Each section ends with essay questions. Odd-numbered problems and the even-numbered problems that follow are similar; answers to all odd-numbered problems except the essay questions are given in the back of the book.

**4.95** Magnesium metal reacts with hydrobromic acid to produce hydrogen gas and a solution of magnesium bromide. Write the molecular equation for this reaction. Then write the corresponding net ionic equation.

**4.96** Aluminum metal reacts with perchloric acid to produce hydrogen gas and a solution of aluminum perchlorate. Write the molecular equation for this reaction. Then write the corresponding net ionic equation.

**4.97** Nickel(II) sulfate solution reacts with sodium hydroxide solution to produce a precipitate of nickel(II) hydroxide and a solution of sodium sulfate. Write the molecular equation for this reaction. Then write the corresponding net ionic equation.

**4.98** Potassium sulfate solution reacts with barium bromide solution to produce a precipitate of barium sulfate and a solution of potassium bromide. Write the molecular equation for this reaction. Then write the corresponding net ionic equation.

**4.99** Decide whether a reaction occurs for each of the following. If it does not, write *NR* after the arrow. If it does, write the balanced molecular equation; then write the net ionic equation.

- a  $\text{LiOH} + \text{HCN} \longrightarrow$
- b  $\text{Li}_2\text{CO}_3 + \text{HNO}_3 \longrightarrow$
- c  $\text{LiCl} + \text{AgNO}_3 \longrightarrow$
- d  $\text{NaCl} + \text{MgSO}_4 \longrightarrow$

**4.100** Decide whether a reaction occurs for each of the following. If it does not, write *NR* after the arrow. If it does, write the balanced molecular equation; then write the net ionic equation.

- a  $\text{Al}(\text{OH})_3 + \text{HNO}_3 \longrightarrow$
- b  $\text{NaBr} + \text{HClO}_4 \longrightarrow$
- c  $\text{CaCl}_2 + \text{NaNO}_3 \longrightarrow$
- d  $\text{MgSO}_4 + \text{Ba}(\text{NO}_3)_2 \longrightarrow$

**4.101** Complete and balance each of the following molecular equations, including phase labels, if a reaction occurs.

Then write the net ionic equation. If no reaction occurs, write *NR* after the arrow.

- a  $\text{Sr}(\text{OH})_2 + \text{HC}_2\text{H}_3\text{O}_2 \longrightarrow$
- b  $\text{NH}_4\text{I} + \text{CsCl} \longrightarrow$
- c  $\text{NaNO}_3 + \text{CsCl} \longrightarrow$
- d  $\text{NH}_4\text{I} + \text{AgNO}_3 \longrightarrow$

**4.102** Complete and balance each of the following molecular equations, including phase labels, if a reaction occurs. Then write the net ionic equation. If no reaction occurs, write *NR* after the arrow.

- a  $\text{HClO}_4 + \text{BaCO}_3 \longrightarrow$
- b  $\text{H}_2\text{CO}_3 + \text{Sr}(\text{OH})_2 \longrightarrow$
- c  $\text{K}_3\text{PO}_4 + \text{MgCl}_2 \longrightarrow$
- d  $\text{FeSO}_4 + \text{MgCl}_2 \longrightarrow$

**4.103** Describe in words how you would do each of the following preparations. Then give the molecular equation for each preparation.

- a  $\text{CuCl}_2(s)$  from  $\text{CuSO}_4(s)$
- b  $\text{Ca}(\text{C}_2\text{H}_3\text{O}_2)_2(s)$  from  $\text{CaCO}_3(s)$
- c  $\text{NaNO}_3(s)$  from  $\text{Na}_2\text{SO}_3(s)$
- d  $\text{MgCl}_2(s)$  from  $\text{Mg}(\text{OH})_2(s)$

**4.104** Describe in words how you would do each of the following preparations. Then give the molecular equation for each preparation.

- a  $\text{MgCl}_2(s)$  from  $\text{MgCO}_3(s)$
- b  $\text{NaNO}_3(s)$  from  $\text{NaCl}(s)$
- c  $\text{Al}(\text{OH})_3(s)$  from  $\text{Al}(\text{NO}_3)_3(s)$
- d  $\text{HCl}(aq)$  from  $\text{H}_2\text{SO}_4(aq)$

**4.105** Classify each of the following reactions as a combination reaction, decomposition reaction, displacement reaction, or combustion reaction.

- a When they are heated, ammonium dichromate crystals,  $(\text{NH}_4)_2\text{Cr}_2\text{O}_7$ , decompose to give nitrogen, water vapor, and solid chromium(III) oxide,  $\text{Cr}_2\text{O}_3$ .
- b When aqueous ammonium nitrite,  $\text{NH}_4\text{NO}_2$ , is heated, it gives nitrogen and water vapor.
- c When gaseous ammonia,  $\text{NH}_3$ , reacts with hydrogen chloride gas,  $\text{HCl}$ , fine crystals of ammonium chloride,  $\text{NH}_4\text{Cl}$ , are formed.
- d Aluminum added to an aqueous solution of sulfuric acid,  $\text{H}_2\text{SO}_4$ , forms a solution of aluminum sulfate,  $\text{Al}_2(\text{SO}_4)_3$ . Hydrogen gas is released.

**4.106** Classify each of the following reactions as a combination reaction, decomposition reaction, displacement reaction, or combustion reaction.

- a** When solid calcium oxide,  $\text{CaO}$ , is exposed to gaseous sulfur trioxide,  $\text{SO}_3$ , solid calcium sulfate,  $\text{CaSO}_4$ , is formed.
- b** Calcium metal (solid) reacts with water to produce a solution of calcium hydroxide,  $\text{Ca(OH)}_2$ , and hydrogen gas.
- c** When solid sodium hydrogen sulfite,  $\text{NaHSO}_3$ , is heated, solid sodium sulfite,  $\text{Na}_2\text{SO}_3$ , sulfur dioxide gas,  $\text{SO}_2$ , and water vapor are formed.
- d** Magnesium reacts with bromine to give magnesium bromide,  $\text{MgBr}_2$ .

**4.107** Consider the reaction of all pairs of the following compounds in water solution:  $\text{Ba(OH)}_2$ ,  $\text{Pb(NO}_3)_2$ ,  $\text{H}_2\text{SO}_4$ ,  $\text{NaNO}_3$ ,  $\text{MgSO}_4$ .

- a** Which pair (or pairs) forms one insoluble compound and one soluble compound (not water)?
- b** Which pair (or pairs) forms two insoluble compounds?
- c** Which pair (or pairs) forms one insoluble compound and water?

**4.108** Consider the reaction of all pairs of the following compounds in water solution:  $\text{Sr(OH)}_2$ ,  $\text{AgNO}_3$ ,  $\text{H}_3\text{PO}_4$ ,  $\text{KNO}_3$ ,  $\text{CuSO}_4$ .

- a** Which pair (or pairs) forms one insoluble compound and one soluble compound (not water)?
- b** Which pair (or pairs) forms two insoluble compounds?
- c** Which pair (or pairs) forms one insoluble compound and water?

**4.109** An aqueous solution contains 5.00 g of calcium chloride,  $\text{CaCl}_2$ , per liter. What is the molarity of  $\text{CaCl}_2$ ? When calcium chloride dissolves in water, the calcium ions,  $\text{Ca}^{2+}$ , and chloride ions,  $\text{Cl}^-$ , in the crystal go into the solution. What is the molarity of each ion in the solution?

**4.110** An aqueous solution contains 3.75 g of iron(III) sulfate,  $\text{Fe}_2(\text{SO}_4)_3$ , per liter. What is the molarity of  $\text{Fe}_2(\text{SO}_4)_3$ ? When the compound dissolves in water, the  $\text{Fe}^{3+}$  ions and  $\text{SO}_4^{2-}$  ions in the crystal go into the solution. What is the molar concentration of each ion in the solution?

**4.111** A stock solution of potassium dichromate,  $\text{K}_2\text{Cr}_2\text{O}_7$ , is made by dissolving 84.5 g of the compound in 1.00 L of solution. How many milliliters of this solution are required to prepare 1.00 L of 0.150 M  $\text{K}_2\text{Cr}_2\text{O}_7$ ?

**4.112** A 71.2-g sample of oxalic acid,  $\text{H}_2\text{C}_2\text{O}_4$ , was dissolved in 1.00 L of solution. How would you prepare 2.50 L of 0.150 M  $\text{H}_2\text{C}_2\text{O}_4$  from this solution?

**4.113** A solution contains 6.00% (by mass)  $\text{NaBr}$  (sodium bromide). The density of the solution is  $1.046 \text{ g/cm}^3$ . What is the molarity of  $\text{NaBr}$ ?

**4.114** An aqueous solution contains 3.75%  $\text{NH}_3$  (ammonia) by mass. The density of the aqueous ammonia is 0.979 g/mL. What is the molarity of  $\text{NH}_3$  in the solution?

**4.115** A barium mineral was dissolved in hydrochloric acid to give a solution of barium ion. An excess of potassium sulfate was added to 50.0 mL of the solution, and 1.128 g of barium sulfate precipitate formed. Assume that the original solution was barium chloride. What was the molarity of  $\text{BaCl}_2$  in this solution?

**4.116** Bone was dissolved in hydrochloric acid, giving 50.0 mL of solution containing calcium chloride,  $\text{CaCl}_2$ . To precipitate the calcium ion from the resulting solution, an excess of potassium oxalate was added. The precipitate of calcium oxalate,  $\text{CaC}_2\text{O}_4$ , weighed 1.437 g. What was the molarity of  $\text{CaCl}_2$  in the solution?

**4.117** You have a sample of a rat poison whose active ingredient is thallium(I) sulfate. You analyze this sample for the mass percentage of active ingredient by adding potassium iodide to precipitate yellow thallium(I) iodide. If the sample of rat poison weighed 759.0 mg and you obtained 212.2 mg of the dry precipitate, what is the mass percentage of the thallium(I) sulfate in the rat poison?

**4.118** An antacid tablet has calcium carbonate as the active ingredient; other ingredients include a starch binder. You dissolve the tablet in hydrochloric acid and filter off insoluble material. You add potassium oxalate to the filtrate (containing calcium ion) to precipitate calcium oxalate. If a tablet weighing 0.750 g gave 0.629 g of calcium oxalate, what is the mass percentage of active ingredient in the tablet?

**4.119** A sample of  $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$  was heated to  $110^\circ\text{C}$ , where it lost water and gave another hydrate of copper(II) ion that contains 32.50% Cu. A 98.77-mg sample of this new hydrate gave 116.66 mg of barium sulfate precipitate when treated with a barium nitrate solution. What is the formula of the new hydrate?

**4.120** A sample of  $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$  was heated to  $100^\circ\text{C}$ , where it lost water and gave another hydrate of copper(II) ion that contained 29.76% Cu. An 85.42-mg sample of this new hydrate gave 93.33 mg of barium sulfate precipitate when treated with a barium nitrate solution. What is the formula of the new hydrate?

**4.121** A water-soluble compound of gold and chlorine is treated with silver nitrate to convert the chlorine completely to silver chloride,  $\text{AgCl}$ . In an experiment, 328 mg of the compound gave 464 mg of silver chloride. Calculate the percentage of Cl in the compound. What is its empirical formula?

**4.122** A solution of scandium chloride was treated with silver nitrate. The chlorine in the scandium compound was converted to silver chloride,  $\text{AgCl}$ . A 58.9-mg sample of scandium chloride gave 167.4 mg of silver chloride. What are the mass percentages of Sc and Cl in scandium chloride? What is its empirical formula?

**4.123** A 0.608-g sample of fertilizer contained nitrogen as ammonium sulfate,  $(\text{NH}_4)_2\text{SO}_4$ . It was analyzed for nitrogen by heating with sodium hydroxide.

The ammonia was collected in 46.3 mL of 0.213 M  $\text{HCl}$  (hydrochloric acid), with which it reacted.

This solution was titrated for excess hydrochloric acid with 44.3 mL of 0.128 M  $\text{NaOH}$ .

What is the percentage of nitrogen in the fertilizer?

**4.124** An antacid tablet contains sodium hydrogen carbonate,  $\text{NaHCO}_3$ , and inert ingredients. A 0.465-g sample of powdered tablet was mixed with 53.3 mL of 0.190 M HCl (hydrochloric acid). The mixture was allowed to stand until it reacted.

The excess hydrochloric acid was titrated with 54.6 mL of 0.128 M NaOH (sodium hydroxide).

What is the percentage of sodium hydrogen carbonate in the antacid?

## Strategy Problems

**Key:** As noted earlier, all of the practice and general problems are matched pairs. This section is a selection of problems that are not in matched-pair format. These challenging problems require that you employ many of the concepts and strategies that were developed in the chapter. In some cases, you will have to integrate several concepts and operational skills in order to solve the problem successfully.

**4.125** You order a glass of juice in a restaurant, only to discover that it is warm and too sweet. The sugar concentration of the juice is 3.47 M, but you would like it reduced to a concentration of 1.78 M. How many grams of ice should you add to 100 mL of juice, knowing that only a third of the ice will melt before you take the first sip? (The density of water is 1.00 g/mL.)

**4.126** If 45.1 mL of a solution containing 8.30 g of silver nitrate is added to 31.3 mL of 0.511 M sodium carbonate solution, calculate the molarity of silver ion in the resulting solution. (Assume volumes are additive.)

**4.127** If 38.2 mL of 0.248 M aluminum sulfate solution is diluted with deionized water to a total volume of 0.639 L, how many grams of aluminum ion are present in the diluted solution?

**4.128** An aluminum nitrate solution is labeled 0.256 M. If 31.6 mL of this solution is diluted to a total of 65.1 mL, calculate the molarity of nitrate ion in the resulting solution.

**4.129** Zinc acetate is sometimes prescribed by physicians for the treatment of Wilson's disease, which is a genetically caused condition wherein copper accumulates to toxic levels in the body. If you were to analyze a sample of zinc acetate and find that it contains  $3.33 \times 10^{23}$  acetate ions, how many grams of zinc acetate must be present in the sample?

**4.130** Arsenic acid,  $\text{H}_3\text{AsO}_4$ , is a poisonous acid that has been used in the treatment of wood to prevent insect damage. Arsenic acid has three acidic protons. Say you take a 25.00-mL sample of arsenic acid and prepare it for titration with NaOH by adding 25.00 mL of water. The complete neutralization of this solution requires the addition of 53.07 mL of 0.6441 M NaOH solution. Write the balanced chemical reaction for the titration, and calculate the molarity of the arsenic acid sample.

**4.131** When the following equation is balanced by the half-reaction method using the smallest set of whole-number stoichiometric coefficients possible, how many electrons are canceled when the two half-reactions are added together?

**4.132** Identify each of the following reactions as being a neutralization, precipitation, or oxidation–reduction reaction.

**4.133** A 414-mL sample of 0.196 M  $\text{MgBr}_2$  solution is prepared in a large flask. A 43.0-mL portion of the solution is then placed into an empty 100.0-mL beaker. What is the concentration of the solution in the beaker?

**4.134** Three 1.0-g samples of  $\text{PbCl}_2$ , KCl, and  $\text{CaCl}_2$  are placed in separate 500-mL beakers. In each case, enough 25°C water is added to bring the total volume of the mixture to 250 mL. Each of the mixtures is then stirred for five minutes. Which of the mixtures will have the highest concentration of chloride ( $\text{Cl}^-$ ) ion?

**4.135** A 25-mL sample of 0.50 M NaOH is combined with a 75-mL sample of 0.50 M NaOH. What is the concentration of the resulting NaOH solution?

**4.136** What is the molarity of pure water with a density of 1.00 g/mL?

**4.137** Nitric acid can be reacted with zinc according to the following chemical equation.

If 3.75 g of Zn is added to 175 mL of 0.500 M  $\text{HNO}_3$ , what mass of  $\text{NO}_2$  would be produced by the chemical reaction?

**4.138** How many grams of precipitate are formed if 175 mL of a 0.750 M aluminum sulfate solution and 375 mL of a 1.15 M sodium hydroxide solution are mixed together?

**4.139** You are asked to prepare 0.250 L of a solution that is 0.500 M in nitrate ion. Your only source of nitrate ion is a bottle of 1.00 M calcium nitrate. What volume (mL) of the calcium nitrate solution must you use?

**4.140** Potassium hydrogen phthalate (abbreviated as KHP) has the molecular formula  $\text{KHC}_8\text{H}_4\text{O}_4$  and a molar mass of 204.22 g/mol. KHP has one acidic hydrogen. A solid sample of KHP is dissolved in 50 mL of water and titrated to the equivalence point with 22.90 mL of a 0.5010 M NaOH solution. How many grams of KHP were used in the titration?

## Capstone Problems

**Key:** The problems under this heading combine skills, strategies, and concepts learned in previous chapters with those introduced in the current one.

**4.141** Lead(II) nitrate reacts with cesium sulfate in an aqueous precipitation reaction. What are the formulas of lead(II) nitrate and cesium sulfate? Write the molecular equation and net ionic equation for the reaction. What are the names of the products? Give the molecular equation for another reaction that produces the same precipitate.

**4.142** Silver nitrate reacts with strontium chloride in an aqueous precipitation reaction. What are the formulas of silver nitrate and strontium chloride? Write the molecular equation and net ionic equation for the reaction. What are the names of the products? Give the molecular equation for another reaction that produces the same precipitate.

**4.143** Elemental bromine is the source of bromine compounds. The element is produced from certain brine solutions that occur naturally. These brines are essentially solutions of calcium bromide that, when treated with chlorine gas, yield bromine in a displacement reaction. What are the molecular equation and net ionic equation for the reaction? A solution containing 40.0 g of calcium bromide requires 14.2 g of chlorine to react completely with it, and 22.2 g of calcium chloride is produced in addition to whatever bromine is obtained. How many grams of calcium bromide are required to produce 10.0 pounds of bromine?

**4.144** Barium carbonate is the source of barium compounds. It is produced in an aqueous precipitation reaction from barium sulfide and sodium carbonate. (Barium sulfide is a soluble compound obtained by heating the mineral barite, which is barium sulfate, with carbon.) What are the molecular equation and net ionic equation for the precipitation reaction? A solution containing 33.9 g of barium sulfide requires 21.2 g of sodium carbonate to react completely with it, and 15.6 g of sodium sulfide is produced in addition to whatever barium carbonate is obtained. How many grams of barium sulfide are required to produce 5.00 tons of barium carbonate? (One ton equals 2000 pounds.)

**4.145** Mercury(II) nitrate is treated with hydrogen sulfide,  $\text{H}_2\text{S}$ , forming a precipitate and a solution. Write the molecular equation and the net ionic equation for the reaction. An acid is formed; is it strong or weak? Name each of the products. If 81.15 g of mercury(II) nitrate and 8.52 g of hydrogen sulfide are mixed in 550.0 g of water to form 58.16 g of precipitate, what is the mass of the solution after the reaction?

**4.146** Mercury(II) nitrate is treated with hydrogen sulfide,  $\text{H}_2\text{S}$ , forming a precipitate and a solution. Write the molecular equation and the net ionic equation for the reaction. An acid is formed; is it strong or weak? Name each of the products. If 65.65 g of mercury(II) nitrate and 4.26 g of hydrogen sulfide are mixed in 395.0 g of water to form 54.16 g of precipitate, what is the mass of the solution after the reaction?

**4.147** Iron forms a sulfide with the approximate formula  $\text{Fe}_7\text{S}_8$ . Assume that the oxidation state of sulfur is  $-2$  and that iron atoms exist in both  $+2$  and  $+3$  oxidation states. What is the ratio of Fe(II) atoms to Fe(III) atoms in this compound?

**4.148** A transition metal X forms an oxide of formula  $\text{X}_2\text{O}_3$ . It is found that only 50% of X atoms in this compound are in the  $+3$  oxidation state. The only other stable oxidation states of X are  $+2$  and  $+5$ . What percentage of X atoms are in the  $+2$  oxidation state in this compound?

**4.149** What volume of a solution of ethanol,  $\text{C}_2\text{H}_6\text{O}$ , that is 94.0% ethanol by mass contains 0.200 mol  $\text{C}_2\text{H}_6\text{O}$ ? The density of the solution is 0.807 g/mL.

**4.150** What volume of a solution of ethylene glycol,  $\text{C}_2\text{H}_6\text{O}_2$ , that is 56.0% ethylene glycol by mass contains 0.350 mol  $\text{C}_2\text{H}_6\text{O}_2$ ? The density of the solution is 1.072 g/mL.

**4.151** A 10.0-mL sample of potassium iodide solution was analyzed by adding an excess of silver nitrate solution to produce silver iodide crystals, which were filtered from the solution.

If 2.183 g of silver iodide was obtained, what was the molarity of the original KI solution?

**4.152** A 25.0-mL sample of sodium sulfate solution was analyzed by adding an excess of barium chloride solution to produce barium sulfate crystals, which were filtered from the solution.

If 5.719 g of barium sulfate was obtained, what was the molarity of the original  $\text{Na}_2\text{SO}_4$  solution?

**4.153** A metal, M, was converted to the sulfate,  $\text{M}_2(\text{SO}_4)_3$ . Then a solution of the sulfate was treated with barium chloride to give barium sulfate crystals, which were filtered off.

If 1.200 g of the metal gave 6.026 g of barium sulfate, what is the atomic weight of the metal? What is the metal?

**4.154** A metal, M, was converted to the chloride  $\text{MCl}_2$ . Then a solution of the chloride was treated with silver nitrate to give silver chloride crystals, which were filtered from the solution.

If 2.434 g of the metal gave 7.964 g of silver chloride, what is the atomic weight of the metal? What is the metal?

**4.155** Phosphoric acid is prepared by dissolving phosphorus(V) oxide,  $\text{P}_4\text{O}_{10}$ , in water. What is the balanced

equation for this reaction? How many grams of  $\text{P}_4\text{O}_{10}$  are required to make 1.19 L of aqueous solution containing 5.50% phosphoric acid by mass? The density of the solution is 1.025 g/mL.

**4.156** Iron(III) chloride can be prepared by reacting iron metal with chlorine. What is the balanced equation for this reaction? How many grams of iron are required to make 3.00 L of aqueous solution containing 9.00% iron(III) chloride by mass? The density of the solution is 1.067 g/mL.

**4.157** An alloy of aluminum and magnesium was treated with sodium hydroxide solution, in which only aluminum reacts.

If a sample of alloy weighing 1.225 g gave 0.1093 g of hydrogen, what is the percentage of aluminum in the alloy?

**4.158** An alloy of iron and carbon was treated with sulfuric acid, in which only iron reacts.

If a sample of alloy weighing 2.358 g gave 0.1067 g of hydrogen, what is the percentage of iron in the alloy?

**4.159** Determine the volume of sulfuric acid solution needed to prepare 37.4 g of aluminum sulfate,  $\text{Al}_2(\text{SO}_4)_3$ , by the reaction

The sulfuric acid solution, whose density is 1.104 g/mL, contains 15.0%  $\text{H}_2\text{SO}_4$  by mass.

**4.160** Determine the volume of sodium hydroxide solution needed to prepare 26.2 g sodium phosphate,  $\text{Na}_3\text{PO}_4$ , by the reaction

The sodium hydroxide solution, whose density is 1.133 g/mL, contains 12.0% NaOH by mass.

**4.161** The active ingredients of an antacid tablet contained only magnesium hydroxide and aluminum hydroxide. Complete neutralization of a sample of the active ingredients required 48.5 mL of 0.187 M hydrochloric acid. The chloride salts from this neutralization were obtained by evaporation of the filtrate from the titration; they weighed 0.4200 g. What was the percentage by mass of magnesium hydroxide in the active ingredients of the antacid tablet?

**4.162** The active ingredients in an antacid tablet contained only calcium carbonate and magnesium carbonate. Complete reaction of a sample of the active ingredients required 39.20 mL of 0.08750 M hydrochloric acid. The chloride salts from the reaction were obtained by evaporation of the filtrate from this titration; they weighed 0.1900 g. What was the percentage by mass of the calcium carbonate in the active ingredients of the antacid tablet?

**4.163** When using  $\text{H}_2\text{SO}_4$  in aqueous reactions, many problems are presented or solved by assuming both of the hydrogen ions to be strongly ionized, as if they were both strong acid ionization processes. At the same time, the second  $\text{H}^+$  only weakly ionizes in aqueous solution.

1. Write molecular, complete ionic, and net ionic equations for the reaction between sulfuric acid and barium hydroxide (a strong base) using the following assumptions:

- a Both hydrogen ions of  $\text{H}_2\text{SO}_4$  are assumed to ionize 100% like strong acids.
- b Only the first hydrogen ion of  $\text{H}_2\text{SO}_4$  is 100% ionized, and the second is weakly ionized.

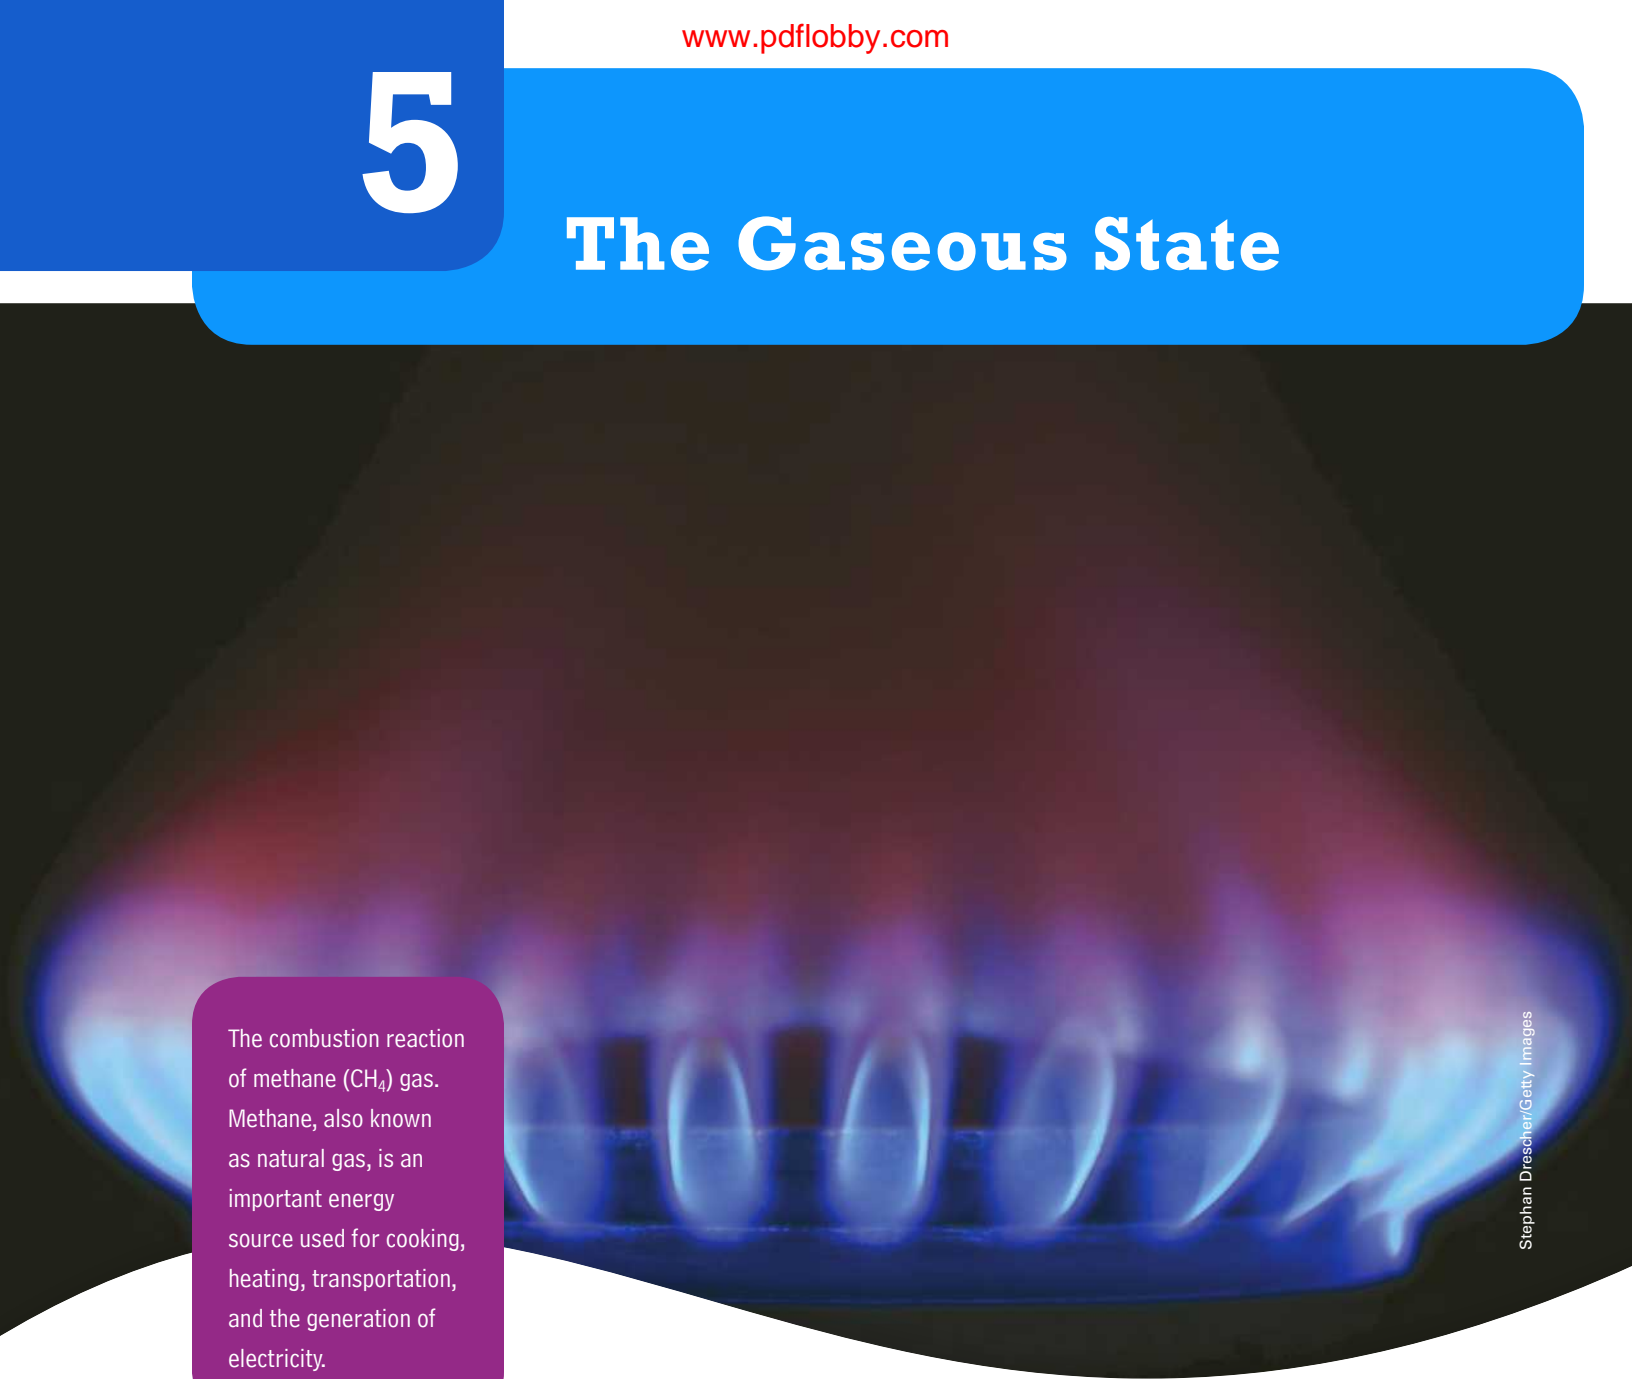

2. Write molecular, complete ionic, and net ionic equations for the reaction between sulfuric acid and sodium acetate, a weakly basic salt, using the following assumptions:

- c Both hydrogen ions of  $\text{H}_2\text{SO}_4$  are assumed to ionize 100% like strong acids.
- d Only the first hydrogen ion of  $\text{H}_2\text{SO}_4$  is 100% ionized, and the second is weakly ionized.

**Cylinders of gas** Gases such as oxygen and nitrogen can be transported as compressed gases in steel cylinders. Large volumes of gas at normal pressures can be compressed into a small volume. Note the pressure gauges.

**G**ases have several characteristics that distinguish them from liquids and solids. You can compress gases into smaller and smaller volumes. Anyone who has transported gases such as oxygen compressed in steel cylinders can appreciate this (Figure 5.1). Also, for gases, unlike for liquids and solids, you can relate pressure, volume, temperature, and molar amount of substance with fair accuracy by one simple equation, the ideal gas law. Suppose you wish to determine the amount of oxygen in a cylinder of compressed gas. You measure the pressure (with a gauge), the temperature, and the volume of gas (volume of the tank). Then, using the ideal gas law, you can calculate the amount of gas in the tank.

Kinetic-molecular theory describes a gas as composed of molecules in constant motion. This theory helps explain the simple relationship that exists among the pressure, volume, temperature, and amount of a gas. Kinetic theory has also enhanced our understanding of the flow of fluids, the transmission of sound, and the conduction of heat.

This chapter introduces the empirical gas laws, such as the ideal gas law, and the kinetic-molecular theory that explains these laws. After finishing the chapter, you will be able to answer questions such as, How many grams of oxygen are there in a 50.0-L gas cylinder at 21°C when the oxygen pressure is 15.7 atmospheres? (An atmosphere is a unit of pressure equal to that of the normal atmosphere.) You will also be able to calculate the average speed of an oxygen molecule in this tank (479 m/s, or 1071 mi/hr).

## ▶ Gas Laws

Most substances composed of small molecules are gases under normal conditions or else are easily vaporized liquids. Table 5.1 lists selected gaseous substances and some of their properties.

In the first part of this chapter, we will examine the quantitative relationships, or empirical laws, governing gases. We will first consider the concept of pressure.

### 5.1 Gas Pressure and Its Measurement

**Pressure** is defined as *the force exerted per unit area of surface*. A coin resting on a table exerts a force, and therefore a pressure, downward on the table as a consequence of gravity. The air above the table exerts an additional pressure on the table, because the air is also being pulled downward by gravity.

To obtain the SI unit of pressure and a feeling for its size, let us calculate the pressure on a table from a perfectly flat coin with a radius and mass equal to that of a new penny (9.3 mm in radius and 2.5 g). The force exerted by the coin from gravity equals the mass of the coin times the constant acceleration of gravity.

**Table 5.1** Properties of Selected Gases

Name	Formula	Color	Odor	Toxicity
Ammonia	NH <sub>3</sub>	Colorless	Penetrating	Toxic
Carbon dioxide	CO <sub>2</sub>	Colorless	Odorless	Nontoxic
Carbon monoxide	CO	Colorless	Odorless	Very toxic
Chlorine	Cl <sub>2</sub>	Pale green	Irritating	Very toxic
Hydrogen	H <sub>2</sub>	Colorless	Odorless	Nontoxic
Hydrogen sulfide	H <sub>2</sub> S	Colorless	Foul	Very toxic
Methane	CH <sub>4</sub>	Colorless	Odorless	Nontoxic
Nitrogen dioxide	NO <sub>2</sub>	Red-brown	Irritating	Very toxic

*Acceleration* is the change of speed per unit time, so the SI unit of acceleration is meters per second per second, abbreviated  $\text{m/s}^2$ . The constant acceleration of gravity is  $9.81 \text{ m/s}^2$ , and the force on the coin due to gravity is

$$\begin{aligned} \text{Force} &= \text{mass} \times \text{constant acceleration of gravity} \\ &= (2.5 \times 10^{-3} \text{ kg}) \times (9.81 \text{ m/s}^2) = 2.5 \times 10^{-2} \text{ kg}\cdot\text{m/s}^2 \end{aligned}$$

The cross-sectional area of the coin is  $\pi \times (\text{radius})^2 = 3.14 \times (9.3 \times 10^{-3} \text{ m})^2 = 2.7 \times 10^{-4} \text{ m}^2$ . Therefore,

$$\text{Pressure} = \frac{\text{force}}{\text{area}} = \frac{2.5 \times 10^{-2} \text{ kg}\cdot\text{m/s}^2}{2.7 \times 10^{-4} \text{ m}^2} = 93 \text{ kg}/(\text{m}\cdot\text{s}^2)$$

The SI unit of pressure,  $\text{kg}/(\text{m}\cdot\text{s}^2)$ , is given the name **pascal (Pa)**, after the French physicist Blaise Pascal (1623–1662), who studied fluid pressure. Note that the pressure exerted by a coin the size and mass of a penny is approximately 100 Pa. The pressure exerted by the atmosphere is about 1000 times larger, or about 100,000 Pa. Thus, the pascal is an extremely small unit.

Chemists have traditionally used two other units of pressure, based on the mercury barometer. A **barometer** is a device for measuring the pressure of the atmosphere. The mercury barometer consists of a glass tube about one meter long, filled with mercury and inverted in a dish of mercury (Figure 5.2). At sea level the mercury in the tube falls to a height of about 760 mm above the level in the dish. This height is a direct measure of the atmospheric pressure (Figure 5.3). ► Air pressure downward on the surface of the mercury in the dish is transmitted through the liquid and exerts a pressure upward at the base of the mercury column, supporting it. A mercury column placed in a sealed flask, as in Figure 5.4, measures the gas pressure in the flask. It acts as a **manometer**, a device that measures the pressure of a gas or liquid in a vessel.

The unit **millimeters of mercury (mmHg)**, also called the **torr** (after Evangelista Torricelli, who invented the mercury barometer in 1643), is a unit of pressure equal to that exerted by a column of mercury 1 mm high at  $0.00^\circ\text{C}$ . The **atmosphere (atm)** is a related unit of pressure equal to exactly 760 mmHg.

The general relationship between the pressure  $P$  and the height  $h$  of a liquid column in a barometer or manometer is

$$P = gdh$$

**Figure 5.3** ◀

**Atmospheric pressure from air mass.** The force of gravity on the mass of a column of air exerts a pressure at the earth's surface. This pressure varies slightly with weather, but is approximately 101 kPa (760 mmHg, or 1 atm).

**Figure 5.4** ▶

**A flask equipped with a closed-tube manometer.** The gas pressure in the flask is proportional to the difference in heights between the liquid levels in the manometer,  $\Delta h$ .

**Figure 5.2** ▲

**A mercury barometer.** The height  $h$  is proportional to the barometric pressure. For that reason, the pressure is often given as the height of the mercury column, in units of millimeters of mercury, mmHg.

Atmospheric, or barometric, pressure depends not only on altitude but also on weather conditions. The “highs” and “lows” of weather reports refer to high- and low-pressure air masses. A high is associated with fair weather; a low brings unsettled weather, or storms.

In 1982, the International Union of Pure and Applied Chemistry (IUPAC) recommended that standard pressure be defined as equal to 1 *bar*, a unit of pressure equal to  $1 \times 10^5$  Pa, slightly less than 1 atm. Despite this recommendation, 1 atm is still in common use by chemists as the standard pressure. Until the bar is more widely adopted by chemists as the standard unit of pressure, we will continue to use the atmosphere.

**Table 5.2** Important Units of Pressure

Unit	Relationship or Definition
Pascal (Pa)	$\text{kg}/(\text{m}\cdot\text{s}^2)$
Atmosphere (atm)	$1 \text{ atm} = 1.01325 \times 10^5 \text{ Pa} \approx 101 \text{ kPa}$
mmHg, or torr	$760 \text{ mmHg} = 1 \text{ atm}$
Bar	$1.01325 \text{ bar} = 1 \text{ atm}$

Here  $g$  is the constant acceleration of gravity ( $9.81 \text{ m/s}^2$ ) and  $d$  is the density of the liquid in the manometer. If  $g$ ,  $d$ , and  $h$  are in SI units, the pressure is given in pascals. Table 5.2 summarizes the relationships among the various units of pressure. ◀

**Example 5.1** Converting Units of Pressure**Gaining Mastery Toolbox****Critical Concept 5.1**

Many different units are used to express gas pressure. Of greatest importance to chemists are the units: pascal (Pa), atmosphere (atm), mmHg, or bar. There are conversion factors listed in Table 5.2 that allow conversion between these units.

**Solution Essentials:**

- Units of pressure (Table 5.2)
- Pressure conversion factors (Table 5.2)

The pressure of a gas in a flask is measured to be 797.7 mmHg using a mercury-filled manometer as in Figure 5.4. What is this pressure in pascals and atmospheres?

**Problem Strategy** This is a unit conversion problem. To convert to the appropriate units, use the conversion factors presented in Table 5.2 and the techniques presented in Chapter 1. Keep in mind that the conversion  $760 \text{ mmHg} = 1 \text{ atm}$  is exact.

**Solution** Conversion to pascals:

$$797.7 \text{ mmHg} \times \frac{1.01325 \times 10^5 \text{ Pa}}{760 \text{ mmHg}} = \mathbf{1.064 \times 10^5 \text{ Pa}}$$

Conversion to atmospheres:

$$797.7 \text{ mmHg} \times \frac{1 \text{ atm}}{760 \text{ mmHg}} = \mathbf{1.050 \text{ atm}}$$

**Answer Check** Pressure conversions between the units of atm and mmHg are very common, so it is helpful to remember the relationship  $1 \text{ atm} = 760 \text{ mmHg}$  in order to check your answers quickly.

**Exercise 5.1** A gas in a container had a measured pressure of 57 kPa. Calculate the pressure in units of atm and mmHg.

See Problems 5.37 and 5.38.

**CONCEPT CHECK 5.1**

Suppose that you set up two barometers like the one shown in Figure 5.2. In one of the barometers you use mercury, and in the other you use water. Which of the barometers would have a higher column of liquid, the one with Hg or H<sub>2</sub>O? Explain your answer.

**5.2 Empirical Gas Laws**

All gases under moderate conditions behave quite simply with respect to pressure, temperature, volume, and molar amount. By holding any two of these physical properties constant, it is possible to show a simple relationship between the other two. The discovery of these quantitative relationships, the empirical gas laws, occurred from the mid-seventeenth to the mid-nineteenth century.

**Boyle's Law: Relating Volume and Pressure**

One characteristic property of a gas is its *compressibility*—its ability to be squeezed into a smaller volume by the application of pressure. By comparison, liquids and solids are relatively incompressible. The compressibility of gases was first studied

**Figure 5.5** ▲

**Boyle's experiment** The volume of the gas at normal atmospheric pressure (760 mmHg) is 100 mL. When the pressure is doubled by adding 760 mm of mercury, the volume is halved (to 50 mL). Tripling the pressure decreases the volume to one-third of the original (to 33 mL).

quantitatively by Robert Boyle in 1661. When he poured mercury into the open end of a J-shaped tube, the volume of the enclosed gas decreased (Figure 5.5). Each addition of mercury increased the pressure on the gas, decreasing its volume. From such experiments, he formulated the law now known by his name. According to **Boyle's law**, the volume of a sample of gas at a given temperature varies inversely with the applied pressure. That is,  $V \propto 1/P$ , where  $V$  is the volume,  $P$  is the pressure, and  $\propto$  means "is proportional to." Thus, if the pressure is doubled, the volume is halved.

Boyle's law can also be expressed in the form of an equation. Putting pressure and volume on the same side of the equation, you can write

$$\text{Boyle's law:} \\ PV = \text{constant} \quad (\text{for a given amount of gas at fixed temperature})$$

That is, for a given amount of gas at a fixed temperature, the pressure times the volume equals a constant. Table 5.3 gives some pressure and volume data for 1.000 g  $O_2$  at  $0^\circ\text{C}$ . Figure 5.6 presents a molecular view of the pressure–volume relationship for two data points in Table 5.3. Note that the product of the pressure and volume for each data pair is nearly constant. By plotting the volume of the oxygen at different pressures (as shown in Figure 5.7), you obtain a graph showing the inverse relationship of  $P$  and  $V$ .

You can use Boyle's law to calculate the volume occupied by a gas when the pressure changes. Consider the 50.0-L gas cylinder of oxygen mentioned in the chapter opening. The pressure of gas in the cylinder is 15.7 atm at  $21^\circ\text{C}$ . What volume of oxygen can you get from the cylinder at  $21^\circ\text{C}$  if the atmospheric pressure is 1.00 atm? You can write  $P_i$  and  $V_i$  for the initial pressure (15.7 atm) and initial volume (50.0 L), and  $P_f$  and  $V_f$  for the final pressure (1.00 atm) and final volume (to be determined). Because the temperature does not change, the product of the pressure and volume remains constant. Thus, you can write

$$P_f V_f = P_i V_i$$

$P$ (atm)	$V$ (L)	$PV$
0.2500	2.801	0.7002
0.5000	1.400	0.7000
0.7500	0.9333	0.7000
1.000	0.6998	0.6998
2.000	0.3495	0.6990
3.000	0.2328	0.6984
4.000	0.1744	0.6976
5.000	0.1394	0.6970

**a** When a 1.000-g sample of  $O_2$  gas at  $0^\circ\text{C}$  is placed in a container at a pressure of 0.50 atm, it occupies a volume of 1.40 L.

**b** When the pressure on the  $O_2$  sample is doubled to 1.0 atm, the volume is reduced to 0.70 L, which is half the original volume.

**Figure 5.6** ▲

**Model of gas pressure–volume relationship at a constant temperature**

Figure 5.7 ►

## Gas pressure–volume relationship

**a** Plot of volume vs. pressure for a sample of oxygen. The volume (of 1.000 g  $O_2$  at  $0^\circ C$ ) decreases with increasing pressure. When the pressure is doubled (from 0.50 atm to 1.00 atm), the volume is halved (from 1.40 L to 0.70 L).

**b** Plot of  $1/V$  vs. pressure (at constant temperature) for the same sample. The straight line indicates that volume varies inversely with pressure.

Dividing both sides of the equation by  $P_f$  gives

$$V_f = V_i \times \frac{P_i}{P_f}$$

Substituting into this equation yields

$$V_f = 50.0 \text{ L} \times \frac{15.7 \text{ atm}}{1.00 \text{ atm}} = 785 \text{ L}$$

Note that the initial volume is multiplied by a ratio of pressures. You know the oxygen gas is changing to a lower pressure and will therefore expand, so this ratio will be greater than 1. The final volume, 785 L, is that occupied by all of the gas at 1.00 atm pressure. However, because the cylinder holds 50.0 L, only this volume of gas remains in the cylinder. The volume that escapes is  $(785 - 50.0) \text{ L} = 735 \text{ L}$ .

## Example 5.2 Using Boyle's Law

## Gaining Mastery Toolbox

## Critical Concept 5.2

At constant temperature there is an inverse relationship between the volume ( $V$ ) and pressure ( $P$ ) of a gas. Because it is an inverse relationship between  $V$  and  $P$ , if one of the two variables ( $V$  or  $P$ ) increases, the other variable must decrease by a proportional amount. For example, you can use this relationship to predict that the volume of a gas sample will decrease by a factor of 2 when the pressure on the gas is doubled.

## Solution Essentials:

- Boyle's law ( $PV = \text{constant}$ )
- Units of pressure (Table 5.2)

A volume of air occupying  $12.0 \text{ dm}^3$  at  $98.9 \text{ kPa}$  is compressed to a pressure of  $119.0 \text{ kPa}$ . The temperature remains constant. What is the new volume?

**Problem Strategy** Putting the data for the problem in tabular form, you see what data you have and what you must find. This will suggest the method of solution.

$$\left. \begin{array}{l} V_i = 12.0 \text{ dm}^3 \quad P_i = 98.9 \text{ kPa} \\ V_f = ? \quad P_f = 119.0 \text{ kPa} \end{array} \right\} \begin{array}{l} \text{Temperature and} \\ \text{moles remain} \\ \text{constant.} \end{array}$$

Because  $P$  and  $V$  vary but temperature and moles are constant, you use Boyle's law.

**Solution** Application of Boyle's law gives  $V_f = V_i \times \frac{P_i}{P_f} = 12.0 \text{ dm}^3 \times \frac{98.9 \text{ kPa}}{119.0 \text{ kPa}} = 9.97 \text{ dm}^3$

**Answer Check** In general, when the pressure on a gas increases, the gas is compressed and therefore occupies a smaller volume. When the pressure on a gas decreases, the gas expands—it will occupy a larger volume. Use these concepts to check your answers. In this example, since the pressure increases, the smaller final volume of the answer is what we would expect. (Note that you get the answer to this type of problem by multiplying the volume by a ratio of pressures. This ratio should be less than 1 if the volume decreases, but more than 1 if the volume increases.)

**Exercise 5.2** A volume of carbon dioxide gas,  $CO_2$ , equal to  $20.0 \text{ L}$  was collected at  $23^\circ C$  and  $1.00 \text{ atm}$  pressure. What would be the volume of carbon dioxide collected at  $23^\circ C$  and  $0.830 \text{ atm}$ ?

See Problems 5.39, 5.40, 5.41, and 5.42.

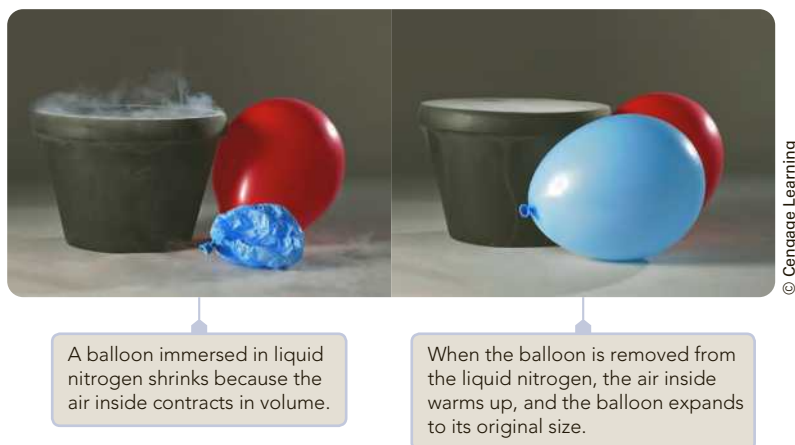

Figure 5.8 ◀

**Effect of temperature on volume of a gas**

Before leaving the subject of Boyle's law, we should note that the pressure–volume product for a gas is not precisely constant. You can see this from the  $PV$  data given in Table 5.3 for oxygen. In fact, all gases follow Boyle's law at low to moderate pressures but deviate from this law at high pressures. The extent of deviation depends on the gas. We will return to this point at the end of the chapter.

### Charles's Law: Relating Volume and Temperature

Temperature also affects gas volume. When you immerse an air-filled balloon in liquid nitrogen ( $-196^\circ\text{C}$ ), the balloon shrinks (Figure 5.8). After the balloon is removed from the liquid nitrogen, it returns to its original size. A gas contracts when cooled and expands when heated.

One of the first quantitative observations of gases at different temperatures was made by Jacques Alexandre Charles in 1787. Charles was a French physicist and a pioneer in hot-air and hydrogen-filled balloons. ▶ Later, John Dalton (in 1801) and Joseph Louis Gay-Lussac (in 1802) continued these kinds of experiments, which showed that a sample of gas at a fixed pressure increases in volume *linearly* with temperature. By linearly, we mean that if we plot the volume occupied by a given sample of gas at various temperatures, we get a straight line (Figure 5.9).

When you extend the straight lines in Figure 5.9 from the last experimental point toward lower temperatures—that is, when you *extrapolate* the straight lines backward—you find that they all intersect at a common point. This point occurs at a temperature of  $-273.15^\circ\text{C}$ , where the graph indicates a volume of zero. This seems to say that if the substances remain gaseous, the volumes occupied will be zero at  $-273.15^\circ\text{C}$ . This could not happen, however; all gases liquefy before they reach this temperature, and Charles's law does not apply to liquids. These extrapolations do show that we can express the volume variation of a gas with temperature more simply by choosing a different thermometer scale. Let us see how to do this.

The first ascent of a hot-air balloon carrying people was made on November 21, 1783. A few days later, Jacques Alexandre Charles made an ascent in a hydrogen-filled balloon. On landing, the balloon was attacked and torn to shreds by terrified peasants armed with pitchforks.

Figure 5.9 ◀

**Linear relationship of gas volume and temperature at constant pressure** The graph shows gas volume versus temperature for a given mass of gas at 1.00 atm pressure. This linear relationship is independent of amount or type of gas. Note that all lines extrapolate to  $-273^\circ\text{C}$  at zero volume.

The mathematical equation of a straight line,  $y = mx + b$ , is discussed in Appendix A.

The Kelvin temperature scale and a more formal equation for temperature conversion were discussed in Section 1.6.

- a A 1.0-g sample of  $O_2$  at 100 K and 1.0 atm of pressure occupies a volume of 0.26 L.

- b When the absolute temperature of the gas is doubled to 200 K, the volume of  $O_2$  doubles to 0.52 L.

**Figure 5.10** ▲  
Model of the temperature–volume relationship for a gas at a fixed volume

The fact that the volume occupied by a gas varies linearly with degrees Celsius can be expressed mathematically by the following equation:

$$V = bt + a$$

where  $t$  is the temperature in degrees Celsius and  $a$  and  $b$  are constants that determine the straight line. ◀ You can eliminate the constant  $a$  by observing that  $V = 0$  at  $t = -273.15$  for any gas. Substituting into the preceding equation, you get

$$0 = b(-273.15) + a \quad \text{or} \quad a = 273.15b$$

The equation for the volume can now be rewritten:

$$V = bt + 273.15b = b(t + 273.15)$$

Suppose you use a temperature scale equal to degrees Celsius plus 273.15, which you may recognize as the *Kelvin scale* (an absolute scale). ◀

$$K = ^\circ C + 273.15$$

If you write  $T$  for the temperature on the Kelvin scale, you obtain

$$V = bT$$

This is **Charles's law**, which we can state as follows: *the volume occupied by any sample of gas at a constant pressure is directly proportional to the absolute temperature.* Thus, doubling the absolute temperature of a gas doubles its volume (Figure 5.10).

Charles's law can be rearranged into a form that is very useful for computation.

Charles's law:

$$\frac{V}{T} = \text{constant} \quad (\text{for a given amount of gas at a fixed pressure})$$

This equation says that the volume divided by the absolute temperature, for a sample of gas at a fixed pressure, remains constant.

Consider a sample of gas at a fixed pressure, and suppose the temperature changes from its initial value  $T_i$  to a final value  $T_f$ . How does the volume change? Because the volume divided by absolute temperature is constant, you can write

$$\frac{V_f}{T_f} = \frac{V_i}{T_i}$$

Or, rearranging slightly,

$$V_f = V_i \times \frac{T_f}{T_i}$$

Note that to obtain the final volume, the initial volume is multiplied by a ratio of absolute temperatures. The next example illustrates a calculation involving a change in the temperature of a gas.

### Example 5.3 Using Charles's Law

#### Gaining Mastery Toolbox

##### Critical Concept 5.3

At constant pressure there is a direct proportional relationship between the volume ( $V$ ) and temperature ( $T$ ) of a gas. Because it is a direct proportional relationship between  $V$  and  $T$ , if one of the two variables ( $V$  or  $T$ ) increases, the other

Earlier we found that the total volume of oxygen that can be obtained from a particular tank at 1.00 atm and 21°C is 785 L (including the volume remaining in the tank). What would be this volume of oxygen if the temperature had been 28°C?

**Problem Strategy** You must first convert temperatures to the Kelvin scale. Then, list the data in tabular form so you can easily see what varies and what remains constant. You apply Charles's law when  $V$  and  $T$  vary and  $P$  is constant.

(continued)

**Example 5.3** (continued)

variable must increase by a proportional amount. For example, you can use this relationship to predict that the volume of a gas sample will triple when the Kelvin temperature is increased by a factor of 3.

**Solution Essentials:**

- Charles's law ( $V/T = \text{constant}$ )
- Units of pressure (Table 5.2)
- Kelvin temperature

**Solution**

$$T_i = (21 + 273) \text{ K} = 294 \text{ K}$$

$$T_f = (28 + 273) \text{ K} = 301 \text{ K}$$

Following is the data table:

$V_i = 785 \text{ L}$	$P_i = 1.00 \text{ atm}$	$T_i = 294 \text{ K}$
$V_f = ?$	$P_f = 1.00 \text{ atm}$	$T_f = 301 \text{ K}$

Note that  $T$  varies and  $P$  remains constant, so  $V$  must change. These are the conditions needed to apply Charles's law.

$$V_f = V_i \times \frac{T_f}{T_i} = 785 \text{ L} \times \frac{301 \text{ K}}{294 \text{ K}} = \mathbf{804 \text{ L}}$$

**Answer Check** In general, when the temperature increases, the volume of gas increases, and when the temperature decreases, the volume of gas decreases. Applying these concepts to check the answer, we verify that when the temperature was increased, the final volume is greater than the starting volume. (Note that you get the answer to this type of problem by multiplying the volume by a ratio of absolute temperatures. This ratio should be more than 1 if the volume increases but less than 1 if the volume decreases.)

**Exercise 5.3** If you expect a chemical reaction to produce 4.38 dm<sup>3</sup> of oxygen, O<sub>2</sub>, at 19°C and 101 kPa, what will be the volume at 25°C and 101 kPa? See Problems 5.45, 5.46, 5.47, and 5.48.

Although most gases follow Charles's law fairly well, they deviate from it at high pressures and low temperatures.

**Combined Gas Law: Relating Volume, Temperature, and Pressure**

Boyle's law ( $V \propto 1/P$ ) and Charles's law ( $V \propto T$ ) can be combined and expressed in a single statement: the volume occupied by a given amount of gas is proportional to the absolute temperature divided by the pressure ( $V \propto T/P$ ). You can write this as an equation.

$$V = \text{constant} \times \frac{T}{P} \quad \text{or} \quad \frac{PV}{T} = \text{constant} \quad (\text{for a given amount of gas})$$

Consider a problem in which you wish to calculate the final volume of a gas when the pressure and temperature are changed.  $PV/T$  is constant for a given amount of gas, so you can write

$$\frac{P_f V_f}{T_f} = \frac{P_i V_i}{T_i}$$

which rearranges to

$$V_f = V_i \times \frac{P_i}{P_f} \times \frac{T_f}{T_i}$$

Thus, the final volume is obtained by multiplying the initial volume by ratios of pressures and absolute temperatures.

**Example 5.4 Using the Combined Gas Law****Gaining Mastery Toolbox****Critical Concept 5.4**

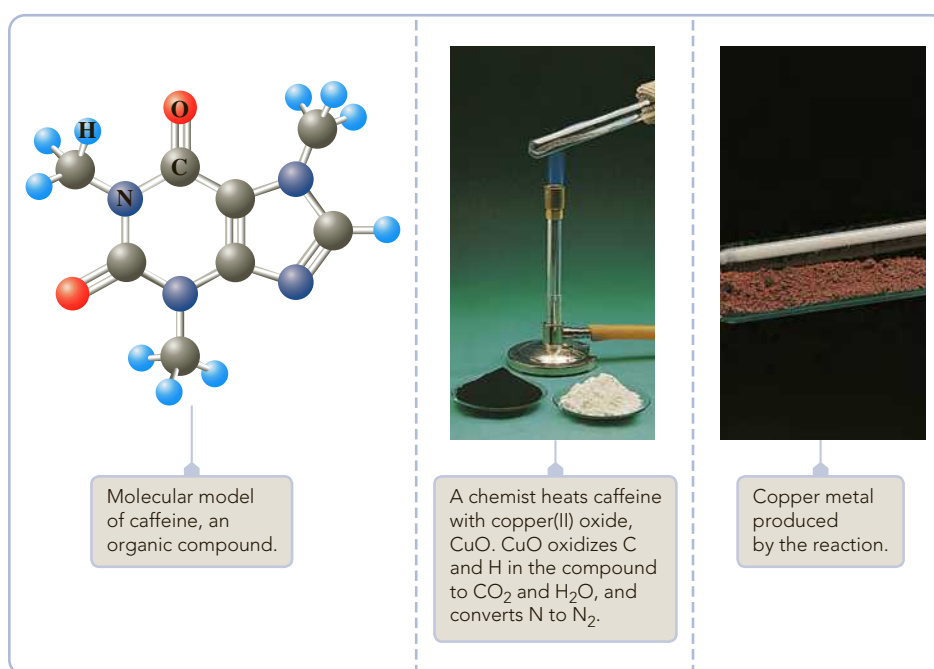

The relationships between the pressure ( $P$ ), volume ( $V$ ), and temperature ( $T$ ) of a gas can be combined into a single expression. This expression encompasses Boyle's and Charles's laws.

Modern determination of %N in an organic compound is an automated version of one developed by the French chemist Jean-Baptiste Dumas in 1830. The Dumas method uses hot copper(II) oxide to oxidize C and H in the compound to CO<sub>2</sub> and H<sub>2</sub>O (both are trapped chemically) and to convert N in the compound to N<sub>2</sub> gas (Figure 5.11). Using the Dumas method, 39.8 mg of caffeine gives 10.1 cm<sup>3</sup> of nitrogen gas at 23°C and 746 mmHg. What is the volume of nitrogen at 0°C and 760 mmHg?

(continued)

**Example 5.4** (continued)**Solution Essentials:**

- Combined gas law  $\frac{P_f V_f}{T_f} = \frac{P_i V_i}{T_i}$
- Units of pressure (Table 5.2)
- Kelvin temperature

**Figure 5.11** ▲**Oxidation of an organic compound with copper(II) oxide**

**Problem Strategy** As always, you will need to convert temperature to the Kelvin scale and put the data in tabular form to determine the law(s) that apply. In this case, since both pressure and temperature are changing, we should expect to use more than one law to arrive at an answer.

**Solution** You first express the temperatures in kelvins:

$$T_i = (23 + 273) \text{ K} = 296 \text{ K}$$

$$T_f = (0 + 273) \text{ K} = 273 \text{ K}$$

Now you put the data for the problem in tabular form:

$V_i = 10.1 \text{ cm}^3$	$P_i = 746 \text{ mmHg}$	$T_i = 296 \text{ K}$
$V_f = ?$	$P_f = 760 \text{ mmHg}$	$T_f = 273 \text{ K}$

From the data, you see that you need to use Boyle's and Charles's laws combined to find how  $V$  varies as  $P$  and  $T$  change. Note that the increase in pressure decreases the volume, making the pressure ratio less than 1. The decrease in temperature also decreases the volume, and the ratio of absolute temperatures is less than 1.

$$V_f = V_i \times \frac{P_i}{P_f} \times \frac{T_f}{T_i} = 10.1 \text{ cm}^3 \times \frac{746 \text{ mmHg}}{760 \text{ mmHg}} \times \frac{273 \text{ K}}{296 \text{ K}} = 9.14 \text{ cm}^3$$

**Answer Check** This gas sample is undergoing a temperature decrease and a pressure increase. These two changes will have opposite effects on the final gas volume. Considering the magnitude of the changes in temperature and pressure in this problem, we can conclude that the final volume of the gas should not be greatly different from its initial volume.

**Exercise 5.4** A balloon contains  $5.41 \text{ dm}^3$  of helium, He, at  $24^\circ\text{C}$  and  $101.5 \text{ kPa}$ . Suppose the gas in the balloon is heated to  $35^\circ\text{C}$ . If the helium pressure is now  $102.8 \text{ kPa}$ , what is the volume of the gas?

See Problems 5.51 and 5.52.

**CONCEPT CHECK 5.2**

To conduct some experiments, a 10.0-L flask equipped with a movable plunger, as illustrated here, is filled with enough H<sub>2</sub> gas to come to a pressure of 20 atm.

- a** In the first experiment, we decrease the temperature in the flask by 10°C and then increase the volume. Predict how the pressure in the flask changes during each of these events and, if possible, how the final pressure compares to your starting pressure.
- b** Once again we start with the pressure in the flask at 20 atm. The flask is then heated 10°C, followed by a volume decrease. Predict how the pressure in the flask changes during each of these events and, if possible, how the final pressure compares to your starting pressure.

**Avogadro's Law: Relating Volume and Amount**

In 1808 the French chemist Joseph Louis Gay-Lussac (1778–1850) concluded from experiments on gas reactions that the volumes of reactant gases at the same pressure and temperature are in ratios of small whole numbers (*the law of combining volumes*). For example, two volumes of hydrogen react with one volume of oxygen gas to produce water.

Three years later, the Italian chemist Amedeo Avogadro (1776–1856) interpreted the law of combining volumes in terms of what we now call **Avogadro's law**: *equal volumes of any two gases at the same temperature and pressure contain the same number of molecules*. Thus, two volumes of hydrogen contain twice the number of molecules as in one volume of oxygen, in agreement with the chemical equation for the reaction.

One mole of any gas contains the same number of molecules (Avogadro's number =  $6.02 \times 10^{23}$ ) and by Avogadro's law must occupy the same volume at a given temperature and pressure. This *volume of one mole of gas* is called the **molar gas volume, V<sub>m</sub>**. Volumes of gases are often compared at **standard temperature and pressure (STP)**, *the reference conditions for gases chosen by convention to be 0°C and 1 atm pressure*. At STP, the molar gas volume is found to be 22.4 L/mol (Figure 5.12).

We can re-express Avogadro's law as follows: the molar gas volume at a given temperature and pressure is a specific constant independent of the nature of the gas.

Avogadro's law:  
 $V_m = \text{specific constant} (=22.4 \text{ L/mol at STP})$   
 (depending on  $T$  and  $P$  but independent of the gas)

Table 5.4 lists the molar volumes of several gases. The values agree within about 2% of the value expected from the empirical gas laws (the "ideal gas" value). We will discuss the reason for the deviations from this value at the end of this chapter, in the section on real gases.

**Table 5.4** Molar Volumes of Several Gases at 0.0°C and 1.00 atm

Gas	Molar Volume (L)
He	22.40
H <sub>2</sub>	22.43
O <sub>2</sub>	22.39
CO <sub>2</sub>	22.29
NH <sub>3</sub>	22.09
Ideal gas*	22.41

\*An ideal gas follows the empirical gas laws.

**Figure 5.12** ◀

**The molar volume of a gas** The box has a volume of 22.4 L, equal to the molar volume of a gas at STP. The basketball is shown for comparison.

Life Science

A CHEMIST Looks at . . .

## Nitrogen Monoxide Gas and Biological Signaling

In 1998, the Nobel committee awarded its prize in physiology or medicine to three scientists for the astounding discovery that nitrogen monoxide (nitric oxide) gas,  $\text{NO}$ , functions as the signaling agent between biological cells in a wide variety of chemical processes. Until this discovery, biochemists had thought that the major chemical reactions in a cell always involved very large molecules. Now they discovered that a simple gas,  $\text{NO}$ , could play a central role in cell chemistry.

Prizewinners Robert Furchgott and Louis Ignarro, independently, unraveled the role of nitrogen monoxide in blood-pressure regulation. Cells in the lining of arteries detect increased blood pressure and respond by producing nitrogen monoxide.  $\text{NO}$  rapidly diffuses through the artery wall to cells in the surrounding muscle tissue. In response, the muscle tissue relaxes, the blood vessel expands, and the blood pressure drops.

In a related discovery, another prizewinner, Ferid Murad, explained how nitroglycerin works to alleviate the intense chest pain of an angina attack, which results from reduced blood flow to the heart muscle as a result of partial blockage of arteries by plaque. Physicians have prescribed nitroglycerin for angina for more than a century, knowing only that it works. Murad found that nitroglycerin breaks down in the body to form nitrogen monoxide, which relaxes the arteries, allowing greater blood flow to the heart. Alfred Nobel, were he alive today, would no doubt be stunned by this news. Nobel, who established the prizes bearing his name, made his fortune in the nineteenth century from his invention of dynamite, a mixture of nitroglycerin with clay that tamed the otherwise hazardous explosive. When Nobel had heart trouble, his physician recommended that he eat a small quantity of nitroglycerin; he refused. In a letter, he wrote, "It is ironical that I am now ordered by my physician to eat nitroglycerin." Today, a patient may either

take nitroglycerin pills (containing tenths of a milligram of compound in a stabilized mixture) for occasional use or apply a chest patch to dispense nitroglycerin continuously to the skin, where it is absorbed (Figure 5.13).

Research papers on the biological role of nitrogen monoxide now number in the tens of thousands. For example, scientists have found that white blood cells use nitrogen monoxide in a kind of chemical warfare. These cells emit concentrated clouds of  $\text{NO}$  that surround bacterial or tumor cells, killing them by interfering with certain cell processes. Researchers have also discovered that nitrogen monoxide plays a role in penile erection. Pharmacologists found that the drug Viagra (Figure 5.14) assists in the action of  $\text{NO}$  in dilating arteries, leading to erection.

Figure 5.14 ◀

**Viagra** Viagra is marketed as an aid to erectile dysfunction. Sexual stimulation produces nitrogen monoxide, which in turn aids an enzyme in the production of a substance called cGMP that relaxes arterial muscles, allowing blood to flow to the penis. Viagra enhances the action of  $\text{NO}$  by inhibiting an enzyme that degrades cGMP.

### 5.3 The Ideal Gas Law

In the previous section, we discussed the empirical gas laws. Here we will show that these laws can be combined into one equation, called the *ideal gas equation*. Earlier we combined Boyle's law and Charles's law into the equation

$$V = \text{constant} \times \frac{T}{P} \quad (\text{for a given amount of gas})$$

This "constant" is independent of the temperature and pressure but does depend on the amount of gas. For one mole, the constant will have a specific value, which we will denote as  $R$ . The molar volume,  $V_m$ , is

$$V_m = R \times \frac{T}{P}$$

According to Avogadro's law, the molar volume at a specific value of  $T$  and  $P$  is a constant independent of the nature of the gas, and this implies that  $R$  is a constant independent of the gas. The **molar gas constant,  $R$** , is *the constant of proportionality relating the molar volume of a gas to  $T/P$* . Values of  $R$  in various units are given in Table 5.5.

The preceding equation can be written for  $n$  moles of gas by multiplying both sides by  $n$ .

$$\frac{nV_m}{V} = \frac{nRT}{P} \quad \text{or} \quad PV = nRT$$

Because  $V_m$  is the volume per mole,  $nV_m$  is the total volume  $V$ . The equation  $PV = nRT$ , which combines all of the gas laws, is called the **ideal gas law**.

Ideal gas law:  
 $PV = nRT$

The ideal gas law includes all the information contained in Boyle's, Charles's, and Avogadro's laws. In fact, starting with the ideal gas law, you can derive any of the other gas laws.

**Table 5.5** Molar Gas Constant in Various Units

Value of $R$
0.082058 L·atm/(K·mol)
8.3145 J/(K·mol)*
8.3145 kg·m <sup>2</sup> /(s <sup>2</sup> ·K·mol)
8.3145 kPa·dm <sup>3</sup> /(K·mol)
1.9872 cal/(K·mol)*

\*The units of pressure times volume are the units of energy—for example, joules (J) or calories (cal).

#### Example 5.5 Deriving Empirical Gas Laws from the Ideal Gas Law

##### Gaining Mastery Toolbox

##### Critical Concept 5.5

The ideal gas law can be used to derive relationships between  $n$ ,  $P$ ,  $T$ , and  $V$ . Interpreting the equation  $PV = nRT$  can lead you to the relationships between each of the variables. For example, for a sample of gas the pressure ( $P$ ) is directly proportional to the number of moles ( $n$ ) of gas and the temperature ( $T$ ) of the gas.

##### Solution Essentials:

- Ideal gas law ( $PV = nRT$ )
- Units of pressure (Table 5.2)
- Kelvin temperature

Prove the following statement: the pressure of a given amount of gas at a fixed volume is proportional to the absolute temperature. This is sometimes called *Amontons's law*. In 1702, Guillaume Amontons constructed a thermometer based on measurement of the pressure of a fixed volume of air. The principle he employed is now used in special gas thermometers to establish the Kelvin scale.

**Problem Strategy** Because we need a relationship between pressure and temperature, the ideal gas law is a logical starting place.

**Solution** From the ideal gas law,

$$PV = nRT$$

Solving for  $P$ , you get

$$P = \left( \frac{nR}{V} \right) T$$

Note that everything in parentheses in this equation is constant. Therefore, you can write

$$P = \text{constant} \times T$$

Or, expressing this as a proportion,

$$P \propto T$$

Boyle's law and Charles's law follow from the ideal gas law by a similar derivation.

(continued)

**Example 5.5** (continued)

**Answer Check** We can apply common experience to qualitatively verify this relationship. Think about what happens to the pressure in a tire when the temperature is increased: the hotter the tire gets, the more the pressure increases.

**Exercise 5.5** Show that the moles of gas are proportional to the pressure for constant volume and temperature. See Problems 5.55 and 5.56.

No gas is "ideal." But the ideal gas law is very useful even though it is only an approximation. The behavior of real gases is described at the end of this chapter.

The limitations that apply to Boyle's, Charles's, and Avogadro's laws also apply to the ideal gas law. That is, the ideal gas law is most accurate for low to moderate pressures and for temperatures that are not too low. ◀

**Calculations Using the Ideal Gas Law**

The type of problem to which Boyle's and Charles's laws are applied involves a change in conditions ( $P$ ,  $V$ , or  $T$ ) of a gas. The ideal gas law allows us to solve another type of problem: given any three of the quantities  $P$ ,  $V$ ,  $n$ , and  $T$ , calculate the unknown quantity. Example 5.6 illustrates such a problem.

**Example 5.6 Using the Ideal Gas Law****Gaining Mastery Toolbox****Critical Concept 5.6**

The ideal gas law ( $PV = nRT$ ) is applied to systems that are not changing. Using the ideal gas law you can determine the value of one of the variables ( $P$ ,  $V$ ,  $n$ , or  $T$ ) while the remaining values represented in the equation are known.

**Solution Essentials:**

- Ideal gas law ( $PV = nRT$ )
- Units of pressure (Table 5.2)
- Kelvin temperature

Answer the question asked in the chapter opening: how many grams of oxygen,  $O_2$ , are there in a 50.0-L gas cylinder at  $21^\circ C$  when the oxygen pressure is 15.7 atm?

**Problem Strategy** In asking for the mass of oxygen, we are in effect asking for moles of gas,  $n$ , because mass and moles are directly related. The problem gives  $P$ ,  $V$ , and  $T$ , so you can use the ideal gas law to solve for  $n$ . The proper value to use for  $R$  depends on the units of  $P$  and  $V$ . Here they are in atmospheres and liters, respectively, so you use  $R = 0.0821 \text{ L}\cdot\text{atm}/(\text{K}\cdot\text{mol})$  from Table 5.5. Once you have solved for  $n$ , convert to mass by using the molar mass of oxygen.

**Solution** The data given in the problem are

<i>Variable</i>	<i>Value</i>
$P$	15.7 atm
$V$	50.0 L
$T$	$(21 + 273) \text{ K} = 294 \text{ K}$
$n$	?

Solving the ideal gas law for  $n$  gives

$$n = \frac{PV}{RT}$$

Substituting the data gives

$$n = \frac{15.7 \text{ atm} \times 50.0 \text{ L}}{0.0821 \text{ L}\cdot\text{atm}/(\text{K}\cdot\text{mol}) \times 294 \text{ K}} = 32.5 \text{ mol}$$

and converting moles to mass of oxygen yields

$$32.5 \text{ mol } O_2 \times \frac{32.0 \text{ g } O_2}{1 \text{ mol } O_2} = 1.04 \times 10^3 \text{ g } O_2$$

**Answer Check** If you were to forget that oxygen is a diatomic gas with the formula  $O_2$ , you would not get this problem right. Keep in mind, too, that the other gaseous diatomic elements are  $H_2$ ,  $N_2$ ,  $F_2$ , and  $Cl_2$ .

**Exercise 5.6** What is the pressure in a 50.0-L gas cylinder that contains 3.03 g of oxygen,  $O_2$ , at  $23^\circ C$ ? See Problems 5.57, 5.58, 5.59, 5.60, 5.61, and 5.62.

## Gas Density; Molecular-Weight Determination

The density of a substance is its mass divided by its volume, and because the volume of a gas varies with temperature and pressure, the density of a gas also varies with temperature and pressure (Figure 5.15). In the next example, we use the ideal gas law to calculate the density of a gas at any temperature and pressure. We do this by calculating the moles, and from this the mass, in a liter of gas at the given temperature and pressure; the mass per liter of gas is its density. At the end of this section, we will give an alternative method of solving this problem, using a formula relating density to temperature, pressure, and molecular weight.

### Example 5.7 Calculating Gas Density

#### Gaining Mastery Toolbox

##### Critical Concept 5.7

Gas density varies with temperature and pressure. In a fixed volume, at a given temperature and pressure, the density of the gas will depend on the mass of gas in that volume (e.g., units of g/L).

##### Solution Essentials:

- Ideal gas law ( $PV = nRT$ )
- Units of pressure (Table 5.2)
- Kelvin temperature

What is the density of oxygen,  $O_2$ , in grams per liter at  $25^\circ C$  and  $0.850 \text{ atm}$ ?

**Problem Strategy** The density of a gas is often expressed in g/L. Using the ideal gas law, you can calculate the moles of  $O_2$  in 1 L of  $O_2$ . Next, you can convert the moles of  $O_2$  to a mass of  $O_2$ , keeping in mind that this mass is the amount of  $O_2$  per liter of  $O_2$  (g/1 L), which is the density.

**Solution** The data given are

Variable	Value
$P$	$0.850 \text{ atm}$
$V$	$1 \text{ L (exact value)}$
$T$	$(25 + 273) \text{ K} = 298 \text{ K}$
$n$	?

Therefore,

$$n = \frac{PV}{RT} = \frac{0.850 \text{ atm} \times 1 \text{ L}}{0.0821 \text{ L}\cdot\text{atm}/(\text{K}\cdot\text{mol}) \times 298 \text{ K}} = 0.0347 \text{ mol}$$

Now convert mol  $O_2$  to grams:

$$0.0347 \text{ mol } O_2 \times \frac{32.0 \text{ g } O_2}{1 \text{ mol } O_2} = 1.11 \text{ g } O_2$$

Therefore, the density of  $O_2$  at  $25^\circ C$  and  $0.850 \text{ atm}$  is **1.11 g/L**.

Suppose you wanted the density of  $Cl_2$ , instead of  $O_2$ , at this  $T$  and  $P$ . Only the conversion of moles to mass is affected. The previous calculation becomes

$$0.0347 \text{ mol } Cl_2 \times \frac{70.9 \text{ g } Cl_2}{1 \text{ mol } Cl_2} = 2.46 \text{ g } Cl_2$$

The density of  $Cl_2$  at  $25^\circ C$  and  $0.850 \text{ atm}$  is **2.46 g/L**. Note that the density of a gas is directly proportional to its molecular weight.

**Answer Check** Because gases consist of molecules spread very far apart, you should expect any reasonable answer for gas density to be very low when compared to values for liquids and solids. Therefore, gas densities should be on the order of this answer.

#### Figure 5.15 ►

**Hot-air ballooning** A propane gas burner on board a balloon heats the air. The heated air expands, occupying a larger volume; it therefore has a lower density than the surrounding air. The hot air and balloon rise.

(continued)

**Example 5.7** (continued)

**Exercise 5.7** Calculate the density of helium, He, in grams per liter at 21°C and 752 mmHg. The density of air under these conditions is 1.188 g/L. What is the difference in mass between 1 liter of air and 1 liter of helium? (This mass difference is equivalent to the buoyant, or lifting, force of helium per liter.)

See Problems 5.63, 5.64, 5.65, and 5.66.

© Cengage Learning

**Figure 5.16** ▲

**A gas whose density is greater than that of air** The reddish-brown gas being poured from the flask is bromine. Note how the gas, which is denser than air, hugs the bottom of the beaker.

The previous example demonstrates that the density of a gas is directly proportional to its molecular weight. Bromine, whose molecular weight is five times that of oxygen, is therefore more than five times as dense as air. Figure 5.16 shows bromine gas being poured into a beaker where it displaces the air and fills the beaker.

The relation between density and molecular weight of a gas suggests that you could use a measurement of gas density to determine its molecular weight. In fact, gas-density (vapor-density) measurements provided one of the first methods of determining molecular weight. The method was worked out by the French chemist Jean-Baptiste André Dumas in 1826. It can be applied to any substance that can be vaporized without decomposing.

As an illustration, consider the determination of the molecular weight of halothane, an inhalation anesthetic. The density of halothane vapor at 71°C (344 K) and 768 mmHg (1.01 atm) is 7.05 g/L. To obtain the molecular weight, you calculate the moles of vapor in a given volume. The molar mass equals mass divided by the moles in the same volume. From the density, you see that one liter of vapor has a mass of 7.05 g. The moles in this volume are obtained from the ideal gas law.

$$n = \frac{PV}{RT} = \frac{1.01 \text{ atm} \times 1 \text{ L}}{0.0821 \text{ L}\cdot\text{atm}/(\text{K}\cdot\text{mol}) \times 344 \text{ K}} = 0.0358 \text{ mol}$$

Therefore, the molar mass,  $M_m$ , is

$$M_m = \frac{m}{n} = \frac{7.05 \text{ g}}{0.0358 \text{ mol}} = 197 \text{ g/mol}$$

Thus, the molecular weight is 197 amu.

If you look at what we have done, you will see that all you need to have is the mass of vapor in *any* given volume (for a given  $T$  and  $P$ ). An explicit determination of density is not necessary. You determine the moles of vapor from the volume using the ideal gas law, and then determine the molar mass by dividing the mass by moles for this volume. The next example illustrates this. At the end of this section, we will derive an explicit formula for the molecular weight in terms of the density of a gas, which will provide an alternative way to solve this problem.

**Example 5.8** Determining the Molecular Weight of a Vapor**Gaining Mastery Toolbox****Critical Concept 5.8**

The molar mass of a substance is the grams of substance per mol of substance (g/mol). The ideal gas law can be used to determine the moles of a gas sample when the pressure ( $P$ ), temperature ( $T$ ), and volume ( $V$ ) are known.

Using the apparatus described in Figure 5.17, a 200.0-mL flask at 99°C and a pressure of 733 mmHg is filled with the vapor of a volatile (easily vaporized) liquid. The mass of the substance in the flask is 0.970 g. What is the molecular weight of the liquid?

**Problem Strategy** You can calculate the moles of vapor from the ideal gas law and then calculate the molar mass by dividing mass by moles. Note that the temperature of the vapor is the same as the temperature of the boiling water and that the pressure of the vapor equals the barometric pressure.

(continued)

**Example 5.8** (continued)**Solution Essentials:**

- Ideal gas law ( $PV = nRT$ )
- Units of pressure (Table 5.2)
- Molar mass
- Kelvin temperature

**Figure 5.17** ◀

**Finding the vapor density of a substance** After the flask fills with the vapor of the substance at the temperature of the boiling water, you allow the flask to cool so that the vapor condenses. You obtain the mass of the substance (which was vapor) by weighing the flask and substance and then subtracting the mass of the empty flask. The pressure of the vapor equals the barometric pressure, and the temperature equals that of the boiling water.

**Solution** You have the following data for the vapor.

Variable	Value
$P$	$733 \text{ mmHg} \times \frac{1 \text{ atm}}{760 \text{ mmHg}} = 0.964 \text{ atm}$
$V$	$200.0 \text{ mL} = 0.2000 \text{ L}$
$T$	$(99 + 273) \text{ K} = 372 \text{ K}$
$n$	?

From the ideal gas law,  $PV = nRT$ , you obtain

$$n = \frac{PV}{RT} = \frac{0.964 \text{ atm} \times 0.2000 \text{ L}}{0.0821 \text{ L}\cdot\text{atm}/(\text{K}\cdot\text{mol}) \times 372 \text{ K}}$$

$$n = 0.00631 \text{ mol}$$

Dividing the mass of the vapor by moles gives you the mass per mole (the molar mass).

$$\text{Molar mass} = \frac{\text{grams vapor}}{\text{moles vapor}} = \frac{0.970 \text{ g}}{0.00631 \text{ mol}} = 154 \text{ g/mol}$$

Thus, the molecular weight is **154 amu**.

**Answer Check** No gas has a smaller molar mass than  $\text{H}_2$  at 2 g/mol. Therefore, if you obtain an answer that is smaller than this, it must be incorrect. The upper limit on molar masses that you would expect is less definite, but solids and liquids that readily vaporize will have molar masses not much larger than a few hundred. An answer much larger than this should be regarded with suspicion.

**Exercise 5.8** A sample of a gaseous substance at  $25^\circ\text{C}$  and 0.862 atm has a density of 2.26 g/L. What is the molecular weight of the substance?

See Problems 5.67, 5.68, 5.69, and 5.70.

From the ideal gas law, you can obtain an explicit relationship between the molecular weight and density of a gas. Recall that the molar mass ( $M_m = m/n$ ) when expressed in grams per mole is numerically equal to the molecular weight. If you substitute  $n = m/M_m$  into the ideal gas law,  $PV = nRT$ , you obtain

$$PV = \frac{m}{M_m} RT \quad \text{or} \quad PM_m = \frac{m}{V} RT$$

But  $m/V$  equals the density,  $d$ . Substituting this gives

$$PM_m = dRT$$

We can illustrate the use of this equation by solving Examples 5.7 and 5.8 again. In Example 5.7, we asked, “What is the density of oxygen,  $O_2$ , in grams per liter at  $25^\circ C$  (298 K) and 0.850 atm?” You rearrange the previous equation to give an explicit formula for the density and then substitute into this formula.

$$d = \frac{PM_m}{RT} = \frac{0.850 \text{ atm} \times 32.0 \text{ g/mol}}{0.0821 \text{ L}\cdot\text{atm}/(\text{K}\cdot\text{mol}) \times 298 \text{ K}} = 1.11 \text{ g/L}$$

Note that by giving  $M_m$  in g/mol and  $R$  in  $\text{L}\cdot\text{atm}/(\text{K}\cdot\text{mol})$ , you obtain the density in g/L.

The question in Example 5.8 is equivalent to the following. What is the molecular weight of a substance weighing 0.970 g whose vapor occupies 200.0 mL (0.2000 L) at  $99^\circ C$  (372 K) and 733 mmHg (0.964 atm)? The density of the vapor is  $0.970 \text{ g}/0.2000 \text{ L} = 4.85 \text{ g/L}$ . To obtain the molecular weight directly, you rearrange the equation  $PM_m = dRT$  to give an explicit formula for  $M_m$ , then substitute into it.

$$M_m = \frac{dRT}{P} = \frac{4.85 \text{ g/L} \times 0.0821 \text{ L}\cdot\text{atm}/(\text{K}\cdot\text{mol}) \times 372 \text{ K}}{0.964 \text{ atm}} = 154 \text{ g/mol}$$

### CONCEPT CHECK 5.3

Three 3.0-L flasks, each at a pressure of 878 mmHg, are in a room. The flasks contain He, Ar, and Xe, respectively.

- Which of the flasks contains the most atoms of gas?
- Which of the flasks has the greatest density of gas?
- If the He flask were heated and the Ar flask cooled, which of the three flasks would be at the highest pressure?
- Say the temperature of the He was lowered while that of the Xe was raised. Which of the three flasks would have the greatest number of moles of gas?

## 5.4 Stoichiometry Problems Involving Gas Volumes

In Chapter 3, you learned how to find the mass of one substance in a chemical reaction from the mass of another substance in the reaction. Now that you know how to use the ideal gas law, we can extend these types of problems to include gas volumes.

Consider the following reaction, which is often used to generate small quantities of oxygen gas:

Suppose you heat 0.0100 mol of potassium chlorate,  $\text{KClO}_3$ , in a test tube. How many liters of oxygen can you produce at 298 K and 1.02 atm?

You solve such a problem by breaking it into two problems, one involving stoichiometry and the other involving the ideal gas law. You note that 2 mol  $\text{KClO}_3$  yields 3 mol  $\text{O}_2$ . Therefore,

$$0.0100 \text{ mol KClO}_3 \times \frac{3 \text{ mol O}_2}{2 \text{ mol KClO}_3} = 0.0150 \text{ mol O}_2$$

Now that you have the moles of oxygen produced, you can use the ideal gas law to calculate the volume of oxygen under the conditions given. You rearrange the ideal gas law,  $PV = nRT$ , and solve for the volume.

$$V = \frac{nRT}{P}$$

Then you substitute for  $n$ ,  $T$ , and  $P$ . Because the pressure is given in units of atmospheres, you choose the value of  $R$  in units of L·atm/(K·mol). The answer comes out in liters.

$$V = \frac{0.0150 \text{ mol} \times 0.0821 \text{ L}\cdot\text{atm}/(\text{K}\cdot\text{mol}) \times 298 \text{ K}}{1.02 \text{ atm}} = 0.360 \text{ L}$$

The next example further illustrates this method.

### Example 5.9 Solving Stoichiometry Problems Involving Gas Volumes

#### Gaining Mastery Toolbox

##### Critical Concept 5.9

Balanced chemical equations provide molar conversion factors between the reactants and products. The ideal gas law can be used to determine the number of moles of reactant prior to performing a stoichiometric calculation.

##### Solution Essentials:

- Ideal gas law ( $PV = nRT$ )
- Units of pressure (Table 5.2)
- Kelvin temperature

Automobiles are equipped with air bags that inflate on collision to protect the occupants from injury (Figure 5.18). Air bags can be inflated with nitrogen,  $\text{N}_2$ , using the rapid reaction of sodium azide,  $\text{NaN}_3$ , and iron(III) oxide,  $\text{Fe}_2\text{O}_3$ , which is initiated by a spark. The overall reaction is

How many grams of sodium azide would be required to provide 75.0 L of nitrogen gas at 25°C and 748 mmHg?

**Problem Strategy** This is a stoichiometry problem and a gas-law problem. The chemical equation relates the moles of  $\text{NaN}_3$  to moles of  $\text{N}_2$ . You can use the ideal gas law to relate the volume of  $\text{N}_2$  to moles of  $\text{N}_2$  and hence moles of  $\text{NaN}_3$ . Then you can obtain the grams of  $\text{NaN}_3$  from the moles of  $\text{NaN}_3$ .

The strategy for the stoichiometry portion of the problem is diagrammed as

**Solution** Here are the available data:

Variable	Value
$P$	$748 \text{ mmHg} \times \frac{1 \text{ atm}}{760 \text{ mmHg}} = 0.984 \text{ atm}$
$V$	75.0 L
$T$	$(25 + 273) \text{ K} = 298 \text{ K}$
$n$	?

Azide ion

Figure 5.18 ▲

**Automobile air bag** Automobiles are equipped with air bags that inflate during collisions. In most instances, air bags are inflated with nitrogen that is produced during a rapid reaction. Sodium azide,  $\text{NaN}_3$  (the azide ion is  $\text{N}_3^-$ ), can be used for this purpose.

(continued)

**Example 5.9** (continued)

Note that the pressure was converted from mmHg to atmospheres and the temperature from degrees Celsius to kelvins. Rearrange the ideal gas law to obtain  $n$ .

$$n = \frac{PV}{RT}$$

Substituting from the data gives you the moles of  $N_2$ .

$$n = \frac{0.984 \text{ atm} \times 75.0 \text{ L}}{0.0821 \text{ L}\cdot\text{atm}/(\text{K}\cdot\text{mol}) \times 298 \text{ K}} = 3.02 \text{ mol}$$

From the moles of  $N_2$ , you use the chemical equation to obtain moles of  $NaN_3$ .

$$3.02 \text{ mol } N_2 \times \frac{6 \text{ mol } NaN_3}{9 \text{ mol } N_2} = 2.01 \text{ mol } NaN_3$$

Now you can calculate the grams of  $NaN_3$ . The molar mass of  $NaN_3$  is 65.01 g/mol.

$$2.01 \text{ mol } NaN_3 \times \frac{65.01 \text{ g } NaN_3}{1 \text{ mol } NaN_3} = \mathbf{131 \text{ g } NaN_3}$$

**Answer Check** As with any problem, see whether the context can help you evaluate your answer. Here we determined the mass of a substance used to inflate an air bag. Using this problem context, we would expect the amount of  $NaN_3$  not to be many kilograms; otherwise, it wouldn't fit in a steering wheel. Also, it shouldn't be some minuscule amount (1 mol of gas will occupy a volume of about 22 L at STP), because the air bag has a large volume to fill (75.0 L in this case).

**Exercise 5.9** How many liters of chlorine gas,  $Cl_2$ , can be obtained at  $40^\circ\text{C}$  and 787 mmHg from 9.41 g of hydrogen chloride,  $HCl$ , according to the following equation?

See Problems 5.73, 5.74, 5.75, 5.76, 5.77, and 5.78.

## 5.5 Gas Mixtures; Law of Partial Pressures

While studying the composition of air, John Dalton concluded in 1801 that each gas in a mixture of unreactive gases acts, as far as its pressure is concerned, as though it were the only gas in the mixture. To illustrate, consider two 1-L flasks, one filled with helium to a pressure of 152 mmHg at a given temperature and the other filled with hydrogen to a pressure of 608 mmHg at the same temperature. Suppose all of the helium in the one flask is put in with the hydrogen in the other flask (see Figure 5.19). After the gases are mixed in one flask, each gas occupies a volume of one liter, just as before, and has the same temperature.

According to Dalton, each gas exerts the same pressure it would exert if it were the only gas in the flask. Thus, the pressure exerted by helium in the mixture is 152 mmHg, and the pressure exerted by hydrogen in the mixture is 608 mmHg. The total pressure exerted by the gases in the mixture is  $152 \text{ mmHg} + 608 \text{ mmHg} = 760 \text{ mmHg}$ .

### Partial Pressures and Mole Fractions

The pressure exerted by a particular gas in a mixture is the **partial pressure** of that gas. The partial pressure of helium in the preceding mixture is 152 mmHg; the partial pressure of hydrogen in the mixture is 608 mmHg. According to **Dalton's law of**

Figure 5.19 ▲

**An illustration of Dalton's law of partial pressures** The valve connecting the flasks and the valve at the funnel are opened so that flask A fills with mineral oil. The helium flows into flask B (having the same volume as flask A), where it mixes with hydrogen. Each gas exerts the pressure it would exert if the other were not there.

**partial pressures**, the sum of the partial pressures of all the different gases in a mixture is equal to the total pressure of the mixture.

If you let  $P$  be the total pressure and  $P_A$ ,  $P_B$ ,  $P_C$ , . . . be the partial pressures of the component gases in a mixture, the law of partial pressures can be written as

$$\text{Dalton's law of partial pressures:}$$

$$P = P_A + P_B + P_C + \dots$$

The individual partial pressures follow the ideal gas law. For component  $A$ ,

$$P_A V = n_A R T$$

where  $n_A$  is the number of moles of component  $A$ .

The composition of a gas mixture is often described in terms of the mole fractions of component gases. The **mole fraction** of a component gas is *the fraction of moles of that component in the total moles of gas mixture* (or the fraction of molecules that are component molecules). Because the pressure of a gas is proportional to moles, for fixed volume and temperature ( $P = nRT/V \propto n$ ), the mole fraction also equals the partial pressure divided by total pressure.

$$\text{Mole fraction of } A = \frac{n_A}{n} = \frac{P_A}{P}$$

Mole percent equals mole fraction  $\times 100$ . Mole percent is equivalent to the percentage of the molecules that are component molecules.

**Example 5.10** Calculating Partial Pressures and Mole Fractions of a Gas in a Mixture**Gaining Mastery Toolbox****Critical Concept 5.10**

Each gas in a mixture of gases can be treated independently. This concept is based on ideal gases, with each gas in the mixture having no interaction with the other gases.

**Solution Essentials:**

- Dalton's law of partial pressure
- Partial pressure
- Mole fraction
- Ideal gas law ( $PV = nRT$ )
- Units of pressure (Table 5.2)
- Kelvin temperature

A 1.00-L sample of dry air at 25°C and 786 mmHg contains 0.925 g N<sub>2</sub>, plus other gases including oxygen, argon, and carbon dioxide.

- What is the partial pressure (in mmHg) of N<sub>2</sub> in the air sample?
- What is the mole fraction and mole percent of N<sub>2</sub> in the mixture?

**Problem Strategy** The key to understanding how to solve this problem is to assume that each gas in the container is independent of other gases; that is, it occupies the entire volume of the sample. Therefore, each gas in the mixture follows the ideal gas law. Using the ideal gas law, we can solve for the pressure of just the N<sub>2</sub>, which is its partial pressure. The mole fraction of N<sub>2</sub> can be calculated from the partial pressure of N<sub>2</sub> and the total pressure of all the gases in the sample.

**Solution** a. Each gas in a mixture follows the ideal gas law. To calculate the partial pressure of N<sub>2</sub>, you convert 0.925 g N<sub>2</sub> to moles N<sub>2</sub>.

$$0.925 \text{ g N}_2 \times \frac{1 \text{ mol N}_2}{28.0 \text{ g N}_2} = 0.0330 \text{ mol N}_2$$

You substitute into the ideal gas law (noting that 25°C is 298 K).

$$\begin{aligned} P_{\text{N}_2} &= \frac{n_{\text{N}_2}RT}{V} \\ &= \frac{0.0330 \text{ mol} \times 0.0821 \text{ L}\cdot\text{atm}/(\text{K}\cdot\text{mol}) \times 298 \text{ K}}{1.00 \text{ L}} \\ &= 0.807 \text{ atm} (= 613 \text{ mmHg}) \end{aligned}$$

- The mole fraction of N<sub>2</sub> in air is

$$\text{Mole fraction of N}_2 = \frac{P_{\text{N}_2}}{P} = \frac{613 \text{ mmHg}}{786 \text{ mmHg}} = 0.780$$

Air contains **78.0 mole percent** of N<sub>2</sub>.

**Answer Check** Whenever you are solving for the mole fraction of a substance in a mixture, the number must always be less than 1 (as it was in this problem). Therefore, if you obtain a value greater than 1, it is a sure sign that you have made an error.

**Exercise 5.10** A 10.0-L flask contains 1.031 g O<sub>2</sub> and 0.572 g CO<sub>2</sub> at 18°C. What are the partial pressures of oxygen and carbon dioxide? What is the total pressure? What is the mole fraction of oxygen in the mixture?

See Problems 5.81, 5.82, 5.83, and 5.84.

**CONCEPT CHECK 5.4**

A flask equipped with a valve contains 3.0 mol of H<sub>2</sub> gas. You introduce 3.0 mol of Ar gas into the flask via the valve and then seal the flask.

- What happens to the pressure of just the H<sub>2</sub> gas in the flask after the introduction of the Ar? If it changes, by what factor does it do so?
- How do the pressures of the Ar and the H<sub>2</sub> in the flask compare?
- How does the total pressure in the flask relate to the pressures of the two gases?

**Collecting Gases over Water**

A useful application of the law of partial pressures arises when you collect gases over water (a method used for gases that do not dissolve appreciably in water). Figure 5.20 shows how a gas, produced by chemical reaction in the flask, is collected by leading

**Figure 5.20** ▲  
Collection of gas over water

it to an inverted tube, where it displaces water. As gas bubbles through the water, the gas picks up molecules of water vapor that mix with it. The partial pressure of water vapor in the gas mixture in the collection tube depends only on the temperature. This partial pressure of water vapor is called the *vapor pressure* of water. ► Values of the vapor pressure of water at various temperatures are listed in Table 5.6 (see Appendix B for a more complete table). The following example shows how to find the partial pressure and then the mass of the collected gas.

Vapor pressure is the maximum partial pressure of the vapor in the presence of the liquid. It is defined more precisely in Chapter 11.

**Table 5.6** Vapor Pressure of Water at Various Temperatures\*

Temperature (°C)	Pressure (mmHg)
0	4.6
10	9.2
15	12.8
17	14.5
19	16.5
21	18.7
23	21.1
25	23.8
27	26.7
30	31.8
40	55.3
60	149.4
80	355.1
100	760.0

\*Appendix B contains a more complete table.

**Example 5.11** Calculating the Amount of Gas Collected over Water**Gaining Mastery Toolbox****Critical Concept 5.11**

When gases are collected over water, there will always be water molecules (water vapor) present in the gas mixture. The partial pressure of water vapor depends *only* on temperature.

**Solution Essentials:**

- Vapor pressure
- Dalton's law of partial pressures
- Ideal gas law
- Units of pressure (Table 5.2)
- Kelvin temperature

Hydrogen gas is produced by the reaction of hydrochloric acid, HCl, on zinc metal.

The gas is collected over water. If 156 mL of gas is collected at 19°C (two significant figures) and 769 mmHg total pressure, what is the mass of hydrogen collected?

**Problem Strategy** The gas collected is hydrogen mixed with water vapor. To obtain the amount of hydrogen, you must first find its partial pressure in the mixture, using Dalton's law (Step 1). Then you can calculate the moles of hydrogen from the ideal gas law (Step 2). Finally, you can obtain the mass of hydrogen from the moles of hydrogen (Step 3).

**Solution**

**Step 1:** The vapor pressure of water at 19°C is 16.5 mmHg. From Dalton's law of partial pressures, you know that the total gas pressure equals the partial pressure of hydrogen,  $P_{\text{H}_2}$ , plus the partial pressure of water,  $P_{\text{H}_2\text{O}}$ .

$$P = P_{\text{H}_2} + P_{\text{H}_2\text{O}}$$

Substituting and solving for the partial pressure of hydrogen, you get

$$P_{\text{H}_2} = P - P_{\text{H}_2\text{O}} = (769 - 16.5) \text{ mmHg} = 752 \text{ mmHg}$$

**Step 2:** Now you can use the ideal gas law to find the moles of hydrogen collected. The data are

Variable	Value
$P$	$752 \text{ mmHg} \times \frac{1 \text{ atm}}{760 \text{ mmHg}} = 0.989 \text{ atm}$
$V$	$156 \text{ mL} = 0.156 \text{ L}$
$T$	$(19 + 273) \text{ K} = 292 \text{ K}$
$n$	?

From the ideal gas law,  $PV = nRT$ , you have

$$n = \frac{PV}{RT} = \frac{0.989 \text{ atm} \times 0.156 \text{ L}}{0.0821 \text{ L}\cdot\text{atm}/(\text{K}\cdot\text{mol}) \times 293 \text{ K}} = 0.00641 \text{ mol}$$

**Step 3:** You convert moles of  $\text{H}_2$  to grams of  $\text{H}_2$ .

$$0.00664 \text{ mol H}_2 \times \frac{2.02 \text{ g H}_2}{1 \text{ mol H}_2} = 0.0130 \text{ g H}_2$$

**Answer Check** Note that this problem assumes that the water level in the collection tube is the same as the water level in the beaker (Figure 5.20). This enables us to equate the gas pressure in the collection tube to atmospheric pressure.

**Exercise 5.11** Oxygen can be prepared by heating potassium chlorate,  $\text{KClO}_3$ , with manganese dioxide as a catalyst. The reaction is

How many moles of  $\text{O}_2$  would be obtained from 1.300 g  $\text{KClO}_3$ ? If this amount of  $\text{O}_2$  were collected over water at 23°C and at a total pressure of 745 mmHg, what volume would it occupy?

See Problems 5.87 and 5.88.

## ► Kinetic-Molecular Theory

In the following sections, you will see how the interpretation of a gas in terms of the **kinetic-molecular theory** (or simply **kinetic theory**) leads to the ideal gas law. According to this theory, *a gas consists of molecules in constant random motion.*

The word *kinetic* describes something in motion. Kinetic energy,  $E_k$ , is the energy associated with the motion of an object of mass  $m$ . From physics,

$$E_k = \frac{1}{2}m \times (\text{speed})^2$$

We will use the concept of kinetic energy in describing kinetic theory.

## 5.6 Kinetic Theory of an Ideal Gas

Our present explanation of gas pressure is that it results from the continual bombardment of the container walls by constantly moving molecules (Figure 5.21). This kinetic interpretation of gas pressure was first put forth in 1676 by Robert Hooke, who had been an assistant of Boyle. Hooke did not pursue this idea, however, so the generally accepted interpretation of gas pressure remained the one given by Isaac Newton, a contemporary of Hooke.

According to Newton, the pressure of a gas was due to the mutual repulsions of the gas particles (molecules). These repulsions pushed the molecules against the walls of the gas container, much as coiled springs packed tightly in a box would push against the walls of the box. This interpretation continued to be the dominant view of gas pressure until the mid-nineteenth century.

Despite the dominance of Newton's view, some people followed the kinetic interpretation. In 1738, Daniel Bernoulli, a Swiss mathematician and physicist, gave a quantitative explanation of Boyle's law using the kinetic interpretation. He even suggested that molecules move faster at higher temperatures, in order to explain Amontons's experiments on the temperature dependence of gas volume and pressure. However, Bernoulli's paper attracted little notice. A similar kinetic interpretation of gases was submitted for publication to the Royal Society of London in 1848 by John James Waterston. His paper was rejected as "nothing but nonsense." ▶

Soon afterward, the scientific climate for the kinetic view improved. The kinetic theory of gases was developed by a number of influential physicists, including James Clerk Maxwell (1859) and Ludwig Boltzmann (in the 1870s). Throughout the last half of the nineteenth century, research continued on the kinetic theory, making it a cornerstone of our present view of molecular substances.

### Postulates of Kinetic Theory

Physical theories are often given in terms of *postulates*: the basic statements from which all conclusions or predictions of a theory are deduced. The postulates are accepted as long as the predictions from the theory agree with experiment. If a particular prediction did not agree with experiment, we would limit the area to which the theory applies, modify the postulates, or start over with a new theory.

The kinetic theory of an *ideal gas* (a gas that follows the ideal gas law) is based on five postulates.

**Postulate 1:** *Gases are composed of molecules whose size is negligible compared with the average distance between them. Most of the volume occupied by a gas is empty space. This means that you can usually ignore the volume occupied by the molecules.*

**Postulate 2:** *Molecules move randomly in straight lines in all directions and at various speeds. This means that properties of a gas that depend on the motion of molecules, such as pressure, will be the same in all directions.*

**Postulate 3:** *The forces of attraction or repulsion between two molecules (intermolecular forces) in a gas are very weak or negligible, except when they collide. ▶ This means that a molecule will continue moving in a straight line with undiminished speed until it collides with another gas molecule or with the walls of the container.*

**Postulate 4:** *When molecules collide with one another, the collisions are elastic. In an elastic collision, the total kinetic energy remains constant; no kinetic energy is lost. To understand the difference between an elastic and an inelastic collision, compare the collision of two hard steel spheres with the collision of*

**Figure 5.21** ▲

**Kinetic-theory model of gas pressure** According to kinetic theory, gas pressure is the result of the bombardment of the container walls by constantly moving molecules.

Waterston's paper, with the reviewers' comments, was discovered in the Royal Society's files by Lord Rayleigh in 1892. (Rayleigh codiscovered argon and received the 1904 Nobel Prize in physics.)

The statements that there are no intermolecular forces and that the volume of molecules is negligible are simplifications that lead to the ideal gas law. But intermolecular forces are needed to explain how we get the liquid state from the gaseous state; it is intermolecular forces that hold molecules together in the liquid state.

Figure 5.22 ▶

## Elastic collision of steel balls

two masses of putty. The collision of steel spheres is nearly elastic (that is, the spheres bounce off each other and continue moving), but that of putty is not (Figure 5.22). Postulate 4 says that unless the kinetic energy of molecules is removed from a gas—for example, as heat—the molecules will forever move with the same average kinetic energy per molecule.

**Postulate 5:** *The average kinetic energy of a molecule is proportional to the absolute temperature.* This postulate establishes what we mean by temperature from a molecular point of view: the higher the temperature, the greater the molecular kinetic energy.

### Qualitative Interpretation of the Gas Laws

According to the kinetic theory, the pressure of a gas results from the bombardment of container walls by molecules. Both the concentration of molecules (number per unit volume) and the average speed of the molecules are factors in determining this pressure. Molecular concentration and average speed determine the frequency of collisions with the wall. Average molecular speed determines the average force of a collision.

Let's consider how these terms apply to Avogadro's law, which relates the volume of gas to the moles of gas at constant (fixed) temperature and pressure. Constant temperature means that the average kinetic energy of a molecule is constant (Postulate 5). Therefore, the average molecular speed and thus the average molecular force from collision remain constant. Gas pressure depends on the force and frequency of molecular collisions with container walls. Consider the container depicted in Figure 5.23a, where the pressure of the gas molecules in the container equals atmospheric pressure. What happens when you introduce more gas molecules into the container? More moles of gas increase the number of molecules per unit volume (concentration) and therefore increase the frequency of collisions with the container walls. If the volume of the container were fixed, the pressure would increase (Figure 5.23b). However, Avogadro's law requires that the pressure remain constant, so the container volume expands until the concentration and, therefore, the frequency of collisions with container walls decrease (Figure 5.23c). The result is that when you increase the number of moles of gas in a container at a constant pressure and temperature, the volume increases.

The same concepts can be used to discuss Boyle's law. Suppose you increase the volume of a gas while holding both the temperature and number of moles of gas constant (Figure 5.24). This decreases the concentration of molecules and the frequency of collisions per unit wall area; the pressure must decrease. Thus, when you increase the volume of a gas while keeping the temperature constant, the pressure decreases.

Now consider Charles's law. If you raise the temperature, you increase the average molecular speed. The average force of a collision increases. If all other

**a** A container where the gas molecules are at atmospheric pressure ( $P_{\text{inside}} = P_{\text{atm}}$ ). The pressure in the container is due to the force and frequency of molecular collisions with the container walls.

**b** The container after increasing the number of gas molecules while not allowing the piston to move. Due to the greater concentration of gas (more moles of gas in the same volume), the frequency of collisions of the gas molecules with the walls of the container has increased, causing the pressure to increase ( $P_{\text{inside}} = P_{\text{atm}}$ ).

**c** Container after the molecules are allowed to move the piston and increase the volume. The concentration of gas molecules and frequency of collisions with the container walls have decreased, and the pressure of the gas molecules inside the container is again equal to atmospheric pressure ( $P_{\text{inside}} = P_{\text{atm}}$ ).

**Figure 5.23** ▲

### Molecular description of Avogadro's law

factors remained fixed, the pressure would increase. For the pressure to remain constant as it does in Charles's law, it is necessary for the volume to increase so that the number of molecules per unit volume decreases and the frequency of collisions decreases. Thus, when you raise the temperature of a gas while keeping the pressure constant, the volume increases.

**a** A fixed number of moles of gas in a container at room temperature. The pressure in the container is due to the force and frequency of molecular collisions with the container walls.

**b** The same number of moles of gas at the same temperature as A, but in a container of greater volume. Because of the larger container volume, the gas concentration is now lower, which leads to a decrease in the frequency of molecular collisions per unit of wall area, resulting in a lower pressure.

**Figure 5.24** ▲

### Molecular description of Boyle's law

#### ✓ CONCEPT CHECK 5.5

Consider a sealed glass bottle of helium gas at room temperature. If you immerse the bottle in an ice water bath, how will this immersion affect the pressure of the gas?

- I. Pressure increase
- II. Pressure decrease
- III. No pressure change

The best explanation for your answer is?

- a** The force of the collisions of the helium atoms with the container walls increases with decreasing temperature.
- b** The helium atoms have significantly greater volumes at lower temperatures.
- c** The frequency and force of the collisions of the helium atoms with the container walls decrease with decreasing temperature.
- d** The average kinetic energy of the helium atoms remains constant when the temperature decreases.
- e** The concentration of helium decreases, resulting in a decrease in the frequency of the collisions with the container walls.

This derivation is essentially the one given by Daniel Bernoulli.

Consistent with kinetic theory, we assume that the duration of collision of a molecule with a container wall is the same, regardless of the type of molecule.

Recall that kinetic energy is defined as  $\frac{1}{2} m$  multiplied by (speed)<sup>2</sup>.

### The Ideal Gas Law from Kinetic Theory

One of the most important features of kinetic theory is its explanation of the ideal gas law. To show how you can get the ideal gas law from kinetic theory, we will first find an expression for the pressure of a gas. ◀

According to kinetic theory, the pressure of a gas,  $P$ , will be proportional to the frequency of molecular collisions with a surface and to the average force exerted by a molecule in collision.

$$P \propto \text{frequency of collisions} \times \text{average force}$$

The average force exerted by a molecule during a collision depends on its mass  $m$  and its average speed  $u$ —that is, on its average momentum  $mu$ . ◀ In other words, the greater the mass of the molecule and the faster it is moving, the greater the force exerted during collision. The frequency of collisions is also proportional to the average speed  $u$ , because the faster a molecule is moving, the more often it strikes the container walls. Frequency of collisions is inversely proportional to the gas volume  $V$ , because the larger the volume, the less often a given molecule strikes the container walls. Finally, the frequency of collisions is proportional to the number of molecules  $N$  in the gas volume. Putting these factors together gives

$$P \propto \left( u \times \frac{1}{V} \times N \right) \times mu$$

Bringing the volume to the left side, you get

$$PV \propto Nmu^2$$

Because the average kinetic energy of a molecule of mass  $m$  and average speed  $u$  is  $\frac{1}{2} mu^2$ ,  $PV$  is proportional to the average kinetic energy of a molecule. ◀ Moreover, the average kinetic energy is proportional to the absolute temperature (Postulate 5). Noting that the number of molecules,  $N$ , is proportional to the moles of molecules,  $n$ , you have

$$PV \propto nT$$

You can write this as an equation by inserting a constant of proportionality,  $R$ , which you can identify as the molar gas constant.

$$PV = nRT$$

The next two sections give additional deductions from kinetic theory.

**Figure 5.25** ▲

**Maxwell's distribution of molecular speeds** The distributions of speeds of  $H_2$  molecules are shown for  $0^\circ C$  and  $500^\circ C$ . Note that the speed corresponding to the maximum in the curve (the most probable speed) increases with temperature.

## 5.7 Molecular Speeds; Diffusion and Effusion

The principal tenet of kinetic theory is that molecules are in constant random motion. Now we will look at the speeds of molecules and at some conclusions of kinetic theory regarding molecular speeds.

### Molecular Speeds

According to kinetic theory, the speeds of molecules in a gas vary over a range of values. The British physicist James Clerk Maxwell (1831–1879) showed theoretically—and it has since been demonstrated experimentally—that molecular speeds are distributed as shown in Figure 5.25. This distribution of speeds depends on the temperature. At any temperature, the molecular speeds vary widely, but most are close to the average speed, which is close to the speed corresponding to the maximum in the distribution curve. As the temperature increases, the average speed increases.

The **root-mean-square (rms) molecular speed**,  $u$ , is a type of average molecular speed, equal to the speed of a molecule having the average molecular kinetic energy. It is given by the following formula:

$$u = \sqrt{\frac{3RT}{M_m}} = \left( \frac{3RT}{M_m} \right)^{\frac{1}{2}}$$

where  $R$  is the molar gas constant,  $T$  is the absolute temperature, and  $M_m$  is the molar mass for the gas. This result follows from Postulate 5 of kinetic theory. ▶ Note that of two gases, the one with the higher molar mass will have the lower rms speed.

In applying this equation, *care must be taken to use consistent units*. If SI units are used for  $R$  ( $= 8.31 \text{ kg}\cdot\text{m}^2/(\text{s}^2\cdot\text{K}\cdot\text{mol})$ ),  $T$  (K), and  $M_m$  (kg/mol), as in the following example, the rms speed will be in meters per second. Note that in these units,  $\text{H}_2$ , whose molecular weight is 2.02 amu, has a molar mass of  $2.02 \times 10^{23} \text{ kg/mol}$ .

Values of the rms speed calculated from this formula indicate that molecular speeds are astonishingly high. For example, the rms speed of  $\text{H}_2$  molecules at  $20^\circ\text{C}$  is  $1.90 \times 10^3 \text{ m/s}$  (over 4000 mi/hr).

According to kinetic theory, the total kinetic energy of a mole of any gas equals  $\frac{3}{2}RT$ . The average kinetic energy of a molecule, which by definition is  $\frac{1}{2}mu^2$ , is obtained by dividing  $\frac{3}{2}RT$  by Avogadro's number,  $N_A$ . Therefore, the kinetic energy is  $\frac{1}{2}mu^2 = 3RT/(2N_A)$ . Hence  $u^2 = 3RT/(N_A m)$ . Or, noting that  $N_A m$  equals the molar mass  $M_m$ , you get  $u^2 = 3RT/M_m$ , from which you get the text equation.

### Example 5.12 Calculating the rms Speed of Gas Molecules

#### Gaining Mastery Toolbox

##### Critical Concept 5.12

The rms (root-mean-square) speed of a gas depends on the temperature and molar mass of the gas. The rms speed is directly proportional to the square root of the kelvin temperature (greater temperature equals greater rms speed) and inversely proportional to the square root of the molar mass (more mass equals less rms speed).

##### Solution Essentials:

- Root-mean-square (rms) molecular speed
- rms equation  

$$u = \sqrt{\frac{3RT}{M_m}} = \left(\frac{3RT}{M_m}\right)^{\frac{1}{2}}$$
- Kinetic molecular theory
- Molar mass

Calculate the rms speed of  $\text{O}_2$  molecules in a cylinder at  $21^\circ\text{C}$  and 15.7 atm. See Table 5.5 for the appropriate value of  $R$ .

**Problem Strategy** The rms speed of a gas can be determined by substituting the appropriate values into the preceding equation.

**Solution** The rms molecular speed is independent of pressure but does depend on the absolute temperature, which is  $(21 + 273) \text{ K} = 294 \text{ K}$ . To calculate  $u$ , it is best to use SI units throughout. In these units, the molar mass of  $\text{O}_2$  is  $32.0 \times 10^{-3} \text{ kg/mol}$ , and  $R = 8.31 \text{ kg}\cdot\text{m}^2/(\text{s}^2\cdot\text{K}\cdot\text{mol})$ . Hence,

$$u = \left(\frac{3 \times 8.31 \text{ kg}\cdot\text{m}^2/(\text{s}^2\cdot\text{K}\cdot\text{mol}) \times 294 \text{ K}}{32.0 \times 10^{-3} \text{ kg/mol}}\right)^{\frac{1}{2}} = 479 \text{ m/s}$$

**Answer Check** When performing calculations that involve this formula, be sure to use the appropriate value of  $R$ ,  $(8.31 \text{ kg}\cdot\text{m}^2/(\text{s}^2\cdot\text{K}\cdot\text{mol}))$ , and to express the molar mass in units of kg/mol, and the temperature in kelvins.

**Exercise 5.12** What is the rms speed (in m/s) of a carbon tetrachloride molecule at  $22^\circ\text{C}$ ? See Problems 5.89, 5.90, 5.91, and 5.92.

**Exercise 5.13** At what temperature do hydrogen molecules,  $\text{H}_2$ , have the same rms speed as nitrogen molecules,  $\text{N}_2$ , at  $455^\circ\text{C}$ ? At what temperature do hydrogen molecules have the same average kinetic energy? See Problems 5.93 and 5.94.

## Diffusion and Effusion

The pleasant odor of apple pie baking in the oven quickly draws people to the kitchen. The spread of an odor is easily explained by kinetic theory. All molecules are in constant, chaotic motion, and eventually a cluster of molecules of a particular substance will spread out to occupy a larger and larger space. Gaseous **diffusion** is the process whereby a gas spreads out through another gas to occupy the space uniformly. Figure 5.26 is a kinetic-theory explanation of the diffusion of two gases. An individual molecule moves chaotically as it is buffeted by other molecules. After sufficient time, this constant chaotic motion of molecules results in a complete mixing of the gases. Figure 5.27 demonstrates the diffusion of ammonia gas through air.

When you think about the kinetic-theory calculations of molecular speed, you might ask why diffusion is not even much faster than it is. Why does it take minutes for the gas to diffuse throughout a room when the molecules are moving at perhaps a thousand miles per hour? This was, in fact, one of the first criticisms of kinetic theory. The answer is simply that a molecule never travels very far in one direction (at ordinary pressures) before it collides with another molecule and moves off in another direction. If you could trace out the path of an individual molecule, it would be a zigzagging trail. For a molecule to cross a room, it has to travel many times the straight-line distance.

Figure 5.26 ▲

#### Kinetic-theory model of gas diffusion

A vessel contains two different gases. For clarity, the figure shows the motion of only one molecule. The path of the molecule is chaotic because of the constant collisions with other molecules. After some time, the “green” molecule has by its random motion mixed with the “red” gas. Similar motions of other molecules eventually result in the complete mixing of the two gases.

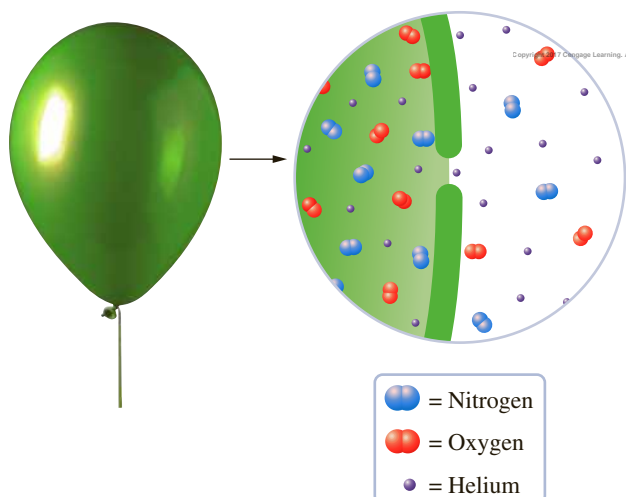

**Figure 5.27** ▶  
**Gaseous diffusion**

**Figure 5.28** ▼

#### Model of gaseous effusion

According to kinetic theory, gas molecules are in constant random motion. When a molecule in the container (balloon, in this case) happens to hit the small opening, it passes (or effuses) to the outside. The rate of effusion depends on the speed of the molecules—the faster the molecules move, the more likely they are to encounter the opening and pass from the inside of the container to the outside.

Although the rate of diffusion certainly depends in part on the average molecular speed, the effect of molecular collisions makes the theoretical picture a bit complicated. *Effusion*, like diffusion, is a process involving the flow of a gas but is theoretically much simpler.

If you place a container of gas in a vacuum and then make a very small hole in the container, the gas molecules escape through the hole at the same speed they had in the container (Figure 5.28). *The process in which a gas flows through a small hole in a container is called effusion.* It was first studied by Thomas Graham, who discovered in 1846 that the rate of effusion of a gas is inversely proportional to the square root of its density. Today we usually state **Graham's law of effusion** in terms of molecular weight: *the rate of effusion of gas molecules from a particular hole is inversely proportional to the square root of the molecular weight of the gas at constant temperature and pressure.*

Let us consider a kinetic-theory analysis of an effusion experiment. Suppose the hole in the container is made small enough so that the gas molecules continue to move randomly (rather than moving together as they would in a wind). When a molecule happens to encounter the hole, it leaves the container. The collection of molecules leaving the container by chance encounters with the hole constitutes the effusing gas. All you have to consider for effusion is the rate at which molecules encounter the hole in the container.

© Cengage Learning

**Figure 5.29** ▲**The hydrogen fountain**

The rate of effusion of molecules from a container depends on three factors: the cross-sectional area of the hole (the larger it is, the more likely molecules are to escape); the number of molecules per unit volume (the more crowded the molecules are, the more likely they are to encounter the hole); and the average molecular speed (the faster the molecules are moving, the sooner they will find the hole and escape).

If you compare the effusion of different gases from the same container, at the same temperature and pressure, the first two factors will be the same. The average molecular speeds will be different, however.

Because the average molecular speed essentially equals  $\sqrt{3RT/M_m}$ , where  $M_m$  is the molar mass, the rate of effusion is proportional to  $\sqrt{M_m}$ . That is, the rate of effusion is inversely proportional to the square root of the molar mass (or molecular weight), as Graham's law states. The derivation of Graham's law from kinetic theory was considered a triumph of the theory and greatly strengthened confidence in its validity.

Graham's law of effusion:

$$\text{Rate of effusion of molecules} \propto \frac{1}{\sqrt{M_m}} \quad (\text{for the same container at constant } T \text{ and } P)$$

The hydrogen fountain, shown in Figure 5.29, is dependent on the differences in rates of effusion of gases. (Can you explain why a helium-filled balloon loses pressure after a few hours?)

**Example 5.13** Calculating the Ratio of Effusion Rates of Gases**Gaining Mastery Toolbox****Critical Concept 5.13**

For gases in a container at a constant temperature and pressure, the effusion rate of the gas *only* depends on the molar mass of the gas. Gases with greater molar mass will effuse more slowly than those with lower molar mass.

**Solution Essentials:**

- Effusion
- Graham's law of effusion: rate of

$$\text{effusion of molecules} \propto \frac{1}{\sqrt{M_m}}$$

Calculate the ratio of effusion rates of molecules of carbon dioxide,  $\text{CO}_2$ , and sulfur dioxide,  $\text{SO}_2$ , from the same container and at the same temperature and pressure.

**Problem Strategy** Here we need to compare the rates of effusion of two gases having different molar masses. We can use Graham's law of effusion for the two gases to set up a relationship

$$\frac{\text{Rate of effusion of } \text{CO}_2}{\text{Rate of effusion of } \text{SO}_2} = \frac{\frac{1}{\sqrt{M_m(\text{CO}_2)}}}{\frac{1}{\sqrt{M_m(\text{SO}_2)}}}$$

(continued)

**Example 5.13** (continued)

(for the same container at constant  $T$  and  $P$ )

- Kinetic molecular theory
- Molar mass

where  $M_m(\text{SO}_2)$  is the molar mass of  $\text{SO}_2$  (64.1 g/mol) and  $M_m(\text{CO}_2)$  is the molar mass of  $\text{CO}_2$  (44.0 g/mol). This equation can be simplified to

$$\frac{\text{Rate of effusion of CO}_2}{\text{Rate of effusion of SO}_2} = \sqrt{\frac{M_m(\text{SO}_2)}{M_m(\text{CO}_2)}}$$

(Note that the two rates of effusion are inversely proportional to the square roots of the molar masses.)

**Solution** Substituting these molar masses into the formula gives

$$\frac{\text{Rate of effusion of CO}_2}{\text{Rate of effusion of SO}_2} = \sqrt{\frac{64.1 \text{ g/mol}}{44.0 \text{ g/mol}}} = \mathbf{1.21}$$

In other words, carbon dioxide effuses 1.21 times faster than sulfur dioxide (because  $\text{CO}_2$  molecules move 1.21 times faster on average than  $\text{SO}_2$  molecules).

**Answer Check** Analyze your answer to make sure that the gas with the lower molar mass has the greater rate of effusion. In this case, the  $\text{CO}_2$  would be expected to have the greater effusion rate, so we should expect the effusion rate ratio of  $\text{CO}_2$  to  $\text{SO}_2$  to be greater than 1.

**Exercise 5.14** If it takes 3.52 s for 10.0 mL of helium to effuse through a hole in a container at a particular temperature and pressure, how long would it take for 10.0 mL of oxygen,  $\text{O}_2$ , to effuse from the same container at the same temperature and pressure? (Note that the rate of effusion can be given in terms of volume of gas effused per second.)

See Problems 5.95, 5.96, 5.97, and 5.98.

**Exercise 5.15** If it takes 4.67 times as long for a particular gas to effuse as it takes hydrogen under the same conditions, what is the molecular weight of the gas? (Note that the rate of effusion is inversely proportional to the time it takes for a gas to effuse.)

See Problems 5.99 and 5.100.

Graham's law has practical application in the preparation of fuel rods for nuclear fission reactors. Such reactors depend on the fact that the uranium-235 nucleus undergoes fission (splits) when bombarded with neutrons. When the nucleus splits, several neutrons are emitted and a large amount of energy is liberated. These neutrons bombard more uranium-235 nuclei, and the process continues with the evolution of more energy. However, natural uranium consists of 99.27% uranium-238 (which does not undergo fission) and only 0.72% uranium-235 (which does undergo fission). A uranium fuel rod must contain about 3% uranium-235 to sustain the nuclear reaction.

To increase the percentage of uranium-235 in a sample of uranium (a process called *enrichment*), one first prepares uranium hexafluoride,  $\text{UF}_6$ , a white, crystalline solid that is easily vaporized. ◀ Uranium hexafluoride vapor is allowed to pass through a series of porous membranes. Each membrane has many small holes through which the vapor can effuse. Because the  $\text{UF}_6$  molecules with the lighter

Uranium hexafluoride vapor has a density of 13.0 g/L at 57°C (the temperature at which the solid sublimates). This is more than 12 times as dense as air at the same temperature.

isotope of uranium travel about 0.4% faster than the  $\text{UF}_6$  molecules with the heavier isotope, the gas that passes through first is somewhat richer in uranium-235. When this vapor passes through another membrane, the uranium-235 vapor becomes further concentrated. It takes many effusion stages to reach the necessary enrichment.

### CONCEPT CHECK 5.6

Consider the experimental apparatus shown. In this setup, each round flask contains a gas, and the long tube contains no gas (that is, it is a vacuum).

**a** We use 1.0 mol of He for experiment X and 1.0 mol of Ar for experiment Y. If both valves are opened at the same time, which gas would you expect to reach the end of the long tube first?

**b** If you wanted the Ar to reach the end of the long tube at the same time as the He, what experimental condition (that is, you cannot change the equipment) could you change to make this happen?

## 5.8 Real Gases

In Section 5.2, we found that, contrary to Boyle's law, the pressure–volume product for  $\text{O}_2$  at  $0^\circ\text{C}$  was not quite constant, particularly at high pressures (see  $PV$  column in Table 5.3). Experiments show that the ideal gas law describes the behavior of real gases quite well at low pressures and moderate temperatures, but not at high pressures and low temperatures.

Figure 5.30 shows the behavior of the pressure–volume product at various pressures for several gases. The gases deviate noticeably from Boyle's law (ideal gas) behavior at high pressures. Also, the deviations differ for each kind of gas. We can explain why this is so by examining the postulates of kinetic theory, from which the ideal gas law can be derived.

**Figure 5.30** ▲

**Pressure–volume product of gases at different pressures** *Right:* The pressure–volume product of one mole of various gases at  $0^\circ\text{C}$  and at different pressures. *Left:* Values at low pressure. For an ideal gas, the pressure–volume product is constant.

**a** At low pressures, the volume of molecules is a small fraction of the total volume and can be neglected, as in the ideal gas law

**b** At high pressures, the volume of molecules is a significant fraction of the total volume and cannot be neglected. The ideal gas law is no longer a good approximation.

**Figure 5.31** ▲

**Effect of molecular volume at high pressure**

Postulate 1 of kinetic theory says that the volume of space occupied by molecules is negligible compared with the total gas volume. To derive the ideal gas law from kinetic theory, we must assume that each molecule is free to move throughout the entire gas volume,  $V$ . At low pressures, where the volume of individual molecules is negligible compared with the total volume available (Figure 5.31a), the ideal gas law is a good approximation. At higher pressures, where the volume of individual molecules becomes important (Figure 5.31b), the space through which a molecule can move is significantly different from  $V$ .

Postulate 3 says that the forces of attraction between molecules (intermolecular forces) in a gas are very weak or negligible. This is a good approximation at low pressures, where molecules tend to be far apart, because these forces diminish rapidly as the distance between molecules increases. Intermolecular forces become significant at higher pressures, though, because the molecules tend to be close together. Because of these intermolecular forces, the actual pressure of a gas is less than that predicted by ideal gas behavior. As a molecule begins to collide with a wall surface, neighboring molecules pull this colliding molecule slightly away from the wall, giving a reduced pressure (Figure 5.32).

The Dutch physicist J. D. van der Waals (1837–1923) was the first to account for these deviations of a real gas from ideal gas behavior. The **van der Waals equation** is an equation similar to the ideal gas law, but includes two constants,  $a$  and  $b$ , to account for deviations from ideal behavior.

$$\left(P + \frac{n^2a}{V^2}\right)(V - nb) = nRT$$

The constants  $a$  and  $b$  are chosen to fit experiment as closely as possible. Table 5.7 gives values of van der Waals constants for several gases.

You can obtain the van der Waals equation from the ideal gas law,  $PV = nRT$ , by making the following replacements:

<i>Ideal Gas Equation</i>		<i>van der Waals Equation</i>
$V$	becomes	$V - nb$
$P$	becomes	$P + n^2a/V^2$

To obtain these substitutions, van der Waals reasoned as follows. The volume available for a molecule to move in equals the gas volume,  $V$ , minus the volume occupied by molecules. So he replaced  $V$  in the ideal gas law with  $V - nb$ , where  $nb$  represents the volume occupied by  $n$  moles of molecules. Then he noted that the total force of attraction on any molecule about to hit a wall is proportional to the concentration of neighboring molecules,  $n/V$ . However, the number of molecules about to hit the wall per unit wall area is also proportional to the concentration,  $n/V$ . Therefore, the force per unit wall area, or pressure, is reduced from that assumed in the ideal gas law by a factor proportional to  $n^2/V^2$ . Letting  $a$  be the proportionality constant, we can write

$$P(\text{actual}) = P(\text{ideal}) - n^2a/V^2$$

or

$$P(\text{ideal}) = P(\text{actual}) + n^2a/V^2$$

In other words, you replace  $P$  in the ideal gas law by  $P + n^2a/V^2$ .

The next example illustrates the use of the van der Waals equation to calculate the pressure exerted by a gas under given conditions.

**Figure 5.32** ▲

**Effect of intermolecular attractions on gas pressure**

Gas pressure on a wall is due to molecules colliding with it. Here a molecule (shown in red) about to collide with the wall is attracted away from the wall by the weak attractive forces of neighboring molecules (intermolecular forces). As a result, the pressure exerted by the gas is less than that expected in the absence of those forces.

**Table 5.7** van der Waals Constants for Some Gases

Gas	$a$	$b$
	L <sup>2</sup> ·atm/mol <sup>2</sup>	L/mol
CO <sub>2</sub>	3.658	0.04286
C <sub>2</sub> H <sub>6</sub>	5.570	0.06499
C <sub>2</sub> H <sub>5</sub> OH	12.56	0.08710
He	0.0346	0.0238
H <sub>2</sub>	0.2453	0.02651
O <sub>2</sub>	1.382	0.03186
SO <sub>2</sub>	6.865	0.05679
H <sub>2</sub> O	5.537	0.03049

### Example 5.14 Using the van der Waals Equation

#### Gaining Mastery Toolbox

##### Critical Concept 5.14

Real gases do not always behave as ideal gases. Gases behave most ideally under low pressure-high temperature conditions. At higher pressures intermolecular forces (attractions between molecules) and the space occupied by the gas particles must be taken into account when making predictions about gas behavior. At low temperatures intermolecular forces must be taken into account.

##### Solution Essentials:

- Van der Waals equation

$$\left(P + \frac{n^2a}{V^2}\right)(V - nb) = nRT$$

- Real gas
- Kinetic-molecular theory
- Ideal gas

If sulfur dioxide were an ideal gas, the pressure at 0.0°C exerted by 1.000 mole occupying 22.41 L would be 1.000 atm (22.41 L is the molar volume of an ideal gas at STP). Use the van der Waals equation to estimate the pressure of this volume of 1.000 mol SO<sub>2</sub> at 0.0°C. See Table 5.7 for values of  $a$  and  $b$ .

**Problem Strategy** You first rearrange the van der Waals equation to give  $P$  in terms of the other variables.

$$P = \frac{nRT}{V - nb} - \frac{n^2a}{V^2}$$

Now you substitute  $R = 0.08206 \text{ L}\cdot\text{atm}/(\text{K}\cdot\text{mol})$ ,  $T = 273.2 \text{ K}$ ,  $V = 22.41 \text{ L}$ ,  $a = 6.865 \text{ L}^2\cdot\text{atm}/\text{mol}^2$ , and  $b = 0.05679 \text{ L}/\text{mol}$ .

#### Solution

$$\begin{aligned} P &= \frac{1.000 \text{ mol} \times 0.08206 \text{ L}\cdot\text{atm}/(\text{K}\cdot\text{mol}) \times 273.2 \text{ K}}{22.41 \text{ L} - (1.000 \text{ mol} \times 0.05679 \text{ L}/\text{mol})} \\ &\quad - \frac{(1.000 \text{ mol})^2 \times 6.865 \text{ L}^2\cdot\text{atm}/\text{mol}^2}{(22.41 \text{ L})^2} \\ &= 1.003 \text{ atm} - 0.014 \text{ atm} = \mathbf{0.989 \text{ atm}} \end{aligned}$$

Note that the first term,  $nRT/(V - nb)$ , gives the pressure corrected for molecular volume. This pressure, 1.003 atm, is slightly higher than the ideal value, 1.000 atm, because the volume through which a molecule is free to move,  $V - nb$ , is smaller than what is assumed for an ideal gas ( $V$ ). Therefore, the concentration of molecules in this volume is greater, and the number of collisions per unit surface area is expected to be greater. However, the last term,  $n^2a/V^2$ , corrects for intermolecular forces, which reduce the force of the collisions, and this reduces the pressure to 0.989 atm.

**Answer Check** Make sure that you used the appropriate value for the ideal gas constant and that the units of volume and pressure match those given for the constants  $a$  and  $b$ .

**Exercise 5.16** Use the van der Waals equation to calculate the pressure of 1.000 mol ethane, C<sub>2</sub>H<sub>6</sub>, that has a volume of 22.41 L at 0.0°C. Compare the result with the value predicted by the ideal gas law.

See Problems 5.101 and 5.102.

## Environment

A CHEMIST Looks at . . .

# Carbon Dioxide Gas and the Greenhouse Effect

Yes, I know, I shouldn't have left that chocolate bar on the seat of my car, which I parked on a sunny street near the university. You and I know that the interior of such a car can become quite hot. Have you ever wondered why? If the sun's heat energy can get into the car through its window glass, why can't it leave equally well?

Parked cars are similar to greenhouses, which people have used for centuries to protect plants from cold weather. The Swedish chemist Svante Arrhenius, whom you may remember from the previous chapter (for his theory of ionic solutions), realized that carbon dioxide in the atmosphere

acts like the glass in a greenhouse. His calculations, published in 1898, were the first to show how sensitive the temperature of the earth might be to the percentage of carbon dioxide in the atmosphere. Arrhenius's reference to the earth's atmospheric envelope, with its carbon dioxide, as a "hothouse" has evolved into our present-day term *greenhouse effect*.

Here is the explanation of the greenhouse effect. The principal gases in the atmosphere are oxygen,  $O_2$ , and nitrogen,  $N_2$ . These gases are transparent to visible light from the sun, and when this light reaches the surface of

Figure 5.33 ►

**Greenhouse effect of certain gases in the atmosphere** The atmosphere is transparent to sunlight, except for radiation in the far ultraviolet. When sunlight reaches the earth's surface, it is absorbed. The heated surface then radiates the energy back as infrared radiation. The major components of the atmosphere,  $O_2$  and  $N_2$ , are transparent to this radiation, but gases such as  $CO_2$ ,  $H_2O$ ,  $CH_4$ , and chlorofluorocarbons, do absorb infrared rays. These substances in the atmosphere then reradiate the infrared rays, with the result that a significant fraction of the radiation returns to Earth. In effect, these gases trap the radiation, acting like the glass on a greenhouse.

(continued)

### CONCEPT CHECK 5.7

A 1.00-L container is filled with an ideal gas and the recorded pressure is 350 atm. We then put the same amount of a real gas into the container and measure the pressure.

- If the real gas molecules occupy a relatively small volume and have large intermolecular attractions, how would you expect the pressures of the two gases to compare?
- If the real gas molecules occupy a relatively large volume and there are negligible intermolecular attractions, how would you expect the pressures of the two gases to compare?
- If the real gas molecules occupy a relatively large volume and have large intermolecular attractions, how would you expect the pressures of the two gases to compare?

## A CHEMIST Looks at . . . Carbon Dioxide Gas and the Greenhouse Effect *(continued)*

the earth, it is absorbed and converted to heat. This heat causes atoms in the earth's surface to vibrate, which then radiate the heat energy as infrared radiation, or heat rays (Figure 5.33). Neither oxygen nor nitrogen absorb infrared radiation, so if the earth's atmosphere contained only these gases, the infrared radiation, or heat rays, would simply escape into outer space; there would be no greenhouse effect. However, other gases in the atmosphere, especially carbon dioxide, do absorb infrared radiation, and it is this absorption that warms the atmosphere and eventually also the earth's surface, giving us a greenhouse effect. The greater the percentage of carbon dioxide in the atmosphere, the warmer the earth should be. (Glass, acting like carbon dioxide, allows visible light to pass into a greenhouse, but absorbs infrared radiation, effectively trapping the heat.)

The greenhouse effect has become associated with the concept of *global warming*. Records kept since the nineteenth century clearly show that the amount of carbon dioxide in the atmosphere has increased dramatically, from about 284 ppm (parts per million) in 1830 to about 370 ppm in 2000 (Figure 5.34). (Parts per million is equivalent to mole percent  $\times 10^{-4}$ .) Scientists believe that our burning of fossil fuels (coal, oil, and natural gas) is responsible for this change. Moreover, temperature measurements made at the surface of the earth during the past 100 years indicate an average temperature increase of between 0.4°C and 0.8°C. Changes due to global warming that have started to emerge include the melting of polar ice and rising sea levels. Thus, many climate scientists believe that human activities are at least partially responsible for global warming, and hence, they predict drastic changes in climate.

**Figure 5.34** ▶

### Concentrations of carbon dioxide in the atmosphere (average annual values)

Concentrations of carbon dioxide in the atmosphere have been increasing steadily since about 1830. (Source of blue curve: D. M. Etheridge, L. P. Steele, R. L. Langenfelds, R. J. Francey, J. M. Barnola, and V. I. Morgan. 1998. Historical CO<sub>2</sub> records from the Law Dome DE08, DE08-2, and DSS ice cores.)

## A Checklist for Review

### Summary of Facts and Concepts

The *pressure* of a gas equals the force exerted per unit area of surface. It is measured by a *manometer* in units of *pas-*  
*cals*, *millimeters of mercury*, or *atmospheres*.

Gases at low to moderate pressures and moderate temperatures follow the same simple relationships, or gas laws. Thus, for a given amount of gas at constant temperature, the volume varies inversely with pressure (*Boyle's law*).

Also, for a given amount of gas at constant pressure, the volume is directly proportional to the absolute temperature (*Charles's law*). These two laws, together with *Avogadro's law* (equal volumes of any two gases at the same temperature and pressure contain the same number of molecules), can be formulated as one equation,  $PV = nRT$  (*ideal gas law*). This equation gives the relationship among  $P$ ,  $V$ ,  $n$ ,

and  $T$  for a gas. It also relates these quantities for each component in a gas mixture. The total gas pressure,  $P$ , equals the sum of the partial pressures of each component (*law of partial pressures*).

The ideal gas law can be explained by the *kinetic-molecular theory*. We define an ideal gas as consisting of molecules with negligible volume that are in constant random motion. In the ideal gas model, there are no intermolecular forces between molecules, and the average kinetic energy of molecules is proportional to the absolute temperature. From kinetic theory, one can show that

the *rms molecular speed* equals  $\sqrt{3RT/M_m}$ . Given this result, one can derive *Graham's law of effusion*: the rate of effusion of gas molecules under identical conditions is inversely proportional to the square root of the molecular weight.

Real gases deviate from the ideal gas law at high pressure and low temperature. From kinetic theory, we expect these deviations, because real molecules do have volume and intermolecular forces do exist. These two factors are partially accounted for in the *van der Waals equation*.

## Learning Objectives

## Important Terms

### 5.1 Gas Pressure and Its Measurement

- Define *pressure* and its units.
- Convert units of pressure. **Example 5.1**

pressure  
pascal (Pa)  
barometer  
manometer  
millimeters of mercury (mmHg or torr)  
atmosphere (atm)  
bar

### 5.2 Empirical Gas Laws

- Express *Boyle's law* in words and as an equation.
- Use Boyle's law. **Example 5.2**
- Express *Charles's law* in words and as an equation.
- Use Charles's law. **Example 5.3**
- Express the *combined gas law* as an equation.
- Use the combined gas law. **Example 5.4**
- State *Avogadro's law*.
- Define *standard temperature and pressure (STP)*.

Boyle's law  
Charles's law  
Avogadro's law  
molar gas volume ( $V_m$ )  
standard temperature and pressure (STP)

### 5.3 The Ideal Gas Law

- State what makes a gas an *ideal gas*.
- Learn the *ideal gas law* equation.
- Derive the empirical gas laws from the ideal gas law. **Example 5.5**
- Use the ideal gas law. **Example 5.6**
- Calculate gas density. **Example 5.7**
- Determine the molecular weight of a vapor. **Example 5.8**
- Use an equation to calculate gas density.

molar gas constant ( $R$ )  
ideal gas law

### 5.4 Stoichiometry Problems Involving Gas Volumes

- Solve stoichiometry problems involving gas volumes. **Example 5.9**

### 5.5 Gas Mixture; Law of Partial Pressures

- Learn the equation for *Dalton's law of partial pressures*.
- Define the *mole fraction* of a gas.
- Calculate the partial pressure and mole fractions of a gas in a mixture. **Example 5.10**
- Describe how gases are collected over water and how to determine the *vapor pressure* of water.
- Calculate the amount of gas collected over water. **Example 5.11**

partial pressure  
Dalton's law of partial pressures  
mole fraction

## Questions and Problems

### Self-Assessment and Review Questions

**Key:** These questions test your understanding of the ideas you worked with in the chapter. These problems vary in difficulty and often can be used for the basis of discussion.

**5.1** Define *pressure*. From the definition, obtain the SI unit of pressure in terms of SI base units.

**5.2** For what purpose is a manometer used? How does it work?

**5.3** What variables determine the height of the liquid in a manometer?

**5.4** Starting with Boyle's law (stated as an equation), obtain an equation for the final volume occupied by a gas from the initial volume when the pressure is changed at constant temperature.

**5.5** The volume occupied by a gas depends linearly on degrees Celsius at constant pressure, but it is not directly

proportional to degrees Celsius. However, it is directly proportional to kelvins. What is the difference between a linear relationship and a direct proportion?

**5.6** Explain how you would set up an absolute temperature scale based on the Fahrenheit scale, knowing that absolute zero is  $-273.15^\circ\text{C}$ .

**5.7** Starting with Charles's law (stated as an equation), obtain an equation for the final volume of a gas from its initial volume when the temperature is changed at constant pressure.

**5.8** State Avogadro's law in words. How does this law explain the law of combining volumes? Use the gas reaction

as an example in your explanation.

- 5.9 What are the standard conditions for comparing gas volumes?
- 5.10 What does the term *molar gas volume* mean? What is the molar gas volume (in liters) at STP for an ideal gas?
- 5.11 Starting from Boyle's, Charles's, and Avogadro's laws, obtain the ideal gas law,  $PV = nRT$ .
- 5.12 What variables are needed to describe a gas that obeys the ideal gas law? What are the SI units for each variable?
- 5.13 What is the value of  $R$  in units of  $\text{L}\cdot\text{mmHg}/(\text{K}\cdot\text{mol})$ ?
- 5.14 The ideal gas law relates four variables. An empirical gas law relates two variables, assuming the other two are constant. How many empirical gas laws can be obtained? Give statements of each.
- 5.15 Give the postulates of kinetic theory and state any evidence that supports them.
- 5.16 Explain Boyle's law in terms of the kinetic theory.
- 5.17 What is the origin of gas pressure, according to kinetic theory?
- 5.18 How does the rms molecular speed depend on absolute temperature? On molar volume?
- 5.19 Explain why a gas appears to diffuse more slowly than average molecular speeds might suggest.
- 5.20 What is effusion? Why does a gas whose molecules have smaller mass effuse faster than one whose molecules have larger mass?
- 5.21 Under what conditions does the behavior of a real gas begin to differ significantly from the ideal gas law?
- 5.22 What is the physical meaning of the  $a$  and  $b$  constants in the van der Waals equation?
- 5.23 Which of the following is *not* part of the kinetic molecular theory?
- The greater the volume occupied by a given amount of gas, the higher the intermolecular forces.
  - The average kinetic energy is proportional to the absolute temperature.

- Gas particles are in constant motion.
  - Total kinetic energy is conserved during the collision.
  - Gas molecules have no volume.
- 5.24 A sample of nitrogen gas is placed into a container at 200 K. If the temperature of the container is reduced by 100°C and the measured pressure decreases by 50%, how does the volume of the container change?
- The container volume increases by less than 50%.
  - The container volume increases by more than 50%.
  - The container volume doesn't change.
  - The container volume increases by 50%.
  - The container volume decreases by 50%.
- 5.25 At standard temperature and pressure, a 1.00-mol sample of argon gas is vented into a 22.4-L rigid box that already contains 1.00 mol of nitrogen gas. We would expect the argon gas to
- decrease the total gas pressure in the box by 50%.
  - occupy the entire 22.4-L volume of the box.
  - increase the total gas pressure in the box by less than 50%.
  - spread out into the box, but the actual volume occupied by the gas cannot be known without pressure information.
  - occupy only a volume of 11.2 L of the box, since there is already 1.0 mol of nitrogen present in the container.
- 5.26 A 1-liter container is filled with 2.0 mol Ar, 2.0 mol  $\text{H}_2$ , and 4.0 mol Kr. Which of the following statements about these gases is *false*?
- The Kr is the densest of the three gases.
  - The mole fraction of Ar in the flask is 0.25.
  - The total pressure in the flask is four times the pressure of the Ar.
  - The Ar atoms hit the walls of the flask with the greatest force of the three gases.
  - $\text{H}_2$  has the highest rms velocity of the three gases.

## Concept Explorations

**Key:** Concept explorations are comprehensive problems that provide a framework that will enable you to explore and learn many of the critical concepts and ideas in each chapter. If you master the concepts associated with these explorations, you will have a better understanding of many important chemistry ideas and will be more successful in solving all types of chemistry problems. These problems are well suited for group work and for use as in-class activities.

### 5.27 Gas Laws and Kinetic Theory of Gases I

Shown here are two identical containers labeled A and B. Container A contains a molecule of an ideal gas, and container B contains two molecules of an ideal gas. Both containers are at the same temperature. (Note that small numbers of molecules and atoms are being represented in these examples in order that you can easily compare the

amounts. Real containers with so few molecules and atoms would be unlikely.)

- How do the pressures in the two containers compare? Be sure to explain your answer.

- Shown below are four different containers (C, D, E, and F), each with the same volume and at the same temperature. How do the pressures of the gases in the containers compare?

- c Container H below has twice the volume of container G. How will the pressure in the containers compare? Explain your reasoning.

- d How will the pressure of containers G and H compare if you add two more gas molecules to container H?
- e Consider containers I and J below. Container J has twice the volume of container I. Container I is at a temperature of 100 K, and container J is at 200 K. How does the pressure in container I compare with that in container J? Include an explanation as part of your answer.

### 5.28 Gas Laws and Kinetic Theory of Gases II

Consider the box below that contains a single atom of an ideal gas.

- a Assuming that this gas atom is moving, describe how it creates pressure inside the container.

- b Now consider the two containers below, each at the same temperature. If we were to measure the gas pressure in each container, how would they compare? Explain your answer.

- c Consider the two containers below, labeled C and D, one with an ideal gas atom and one with ideal gas molecules, each at the same temperature. The gas molecule has more mass than the gas atom. How do the pressures of the two containers compare? Why?

- d For the containers C and D above, which would have the higher root-mean-square (rms) molecular speed? How does the difference in rms speeds support or contradict the answer you obtained above when you compared the pressures?
- e Consider containers E and F below. How do the pressures in these containers compare? Be sure to explain your answer.

- f Consider containers G and H below, one with a gas atom and one with a gas molecule. As before, the gas molecule has more mass than the gas atom. Explain how the pressures in these containers compare.

- g Now think about the containers below, I and J. How do the pressures in these containers compare? Be sure to justify your answer.

- h Finally, how do the pressures in containers K and L compare?

## Conceptual Problems

**Key:** These problems are designed to check your understanding of the concepts associated with some of the main topics presented in each chapter. A strong conceptual understanding of chemistry is the foundation for both applying chemical knowledge and solving chemical problems. These problems vary in level of difficulty and often can be used as a basis for group discussion.

5.29 Using the concepts developed in this chapter, explain the following observations.

- Automobile tires are flatter on cold days.
- You are not supposed to dispose of aerosol cans in a fire.
- The lid of a water bottle pops off when the bottle sits in the sun.
- A balloon pops when you squeeze it.

5.30 You have three identical flasks, each containing equal amounts of  $\text{N}_2$ ,  $\text{O}_2$ , and He. The volume of the  $\text{N}_2$  flask is doubled, the  $\text{O}_2$  flask volume is halved, and the He flask volume is reduced to one-third of the original volume. Rank the flasks from highest to lowest pressure both before and after the volume is changed and indicate by what factor the pressure has changed.

5.31 Consider the following gas container equipped with a movable piston.

- By what factor (increase by 1, decrease by 1.5, etc.) would you change the pressure if you wanted the volume to change from volume C to volume D?
  - If the piston were moved from volume C to volume A, by what factor would the pressure change?
  - By what factor would you change the temperature in order to change from volume C to volume B?
  - If you increased the number of moles of gas in the container by a factor of 2, by what factors would the pressure and the volume change?
- 5.32 A 3.00-L flask containing 2.0 mol of  $\text{O}_2$  and 1.0 mol of  $\text{N}_2$  is in a room that is at  $22.0^\circ\text{C}$ .
- How much (what fraction) of the total pressure in the flask is due to the  $\text{N}_2$ ?

- The flask is cooled and the pressure drops. What happens, if anything, to the mole fraction of the  $\text{O}_2$  at the lower temperature?

- 1.0 L of liquid water is introduced into the flask containing both gases. The pressure is then measured about 45 minutes later. Would you expect the measured pressure to be higher or lower?
- Given the information in this problem and the conditions in part c, would it be possible to calculate the pressure in the flask after the introduction of the water? If it is not possible with the given information, what further information would you need to accomplish this task?

5.33 Consider the following setup, which shows identical containers connected by a tube with a valve that is presently closed. The container on the left has 1.0 mol of  $\text{H}_2$  gas; the container on the right has 1.0 mol of  $\text{O}_2$ .

*Note:* Acceptable answers to some of these questions might be “both” or “neither one.”

- Which container has the greatest density of gas?
  - Which container has molecules that are moving at a faster average molecular speed?
  - Which container has more molecules?
  - If the valve is opened, will the pressure in each of the containers change? If it does, how will it change (increase, decrease, or no change)?
  - 2.0 mol of Ar is added to the system with the valve open. What fraction of the total pressure will be due to the  $\text{H}_2$ ?
- 5.34 Two identical He-filled balloons, each with a volume of 20 L, are allowed to rise into the atmosphere. One rises to an altitude of 3000 m while the other rises to 6000 m.
- Assuming that the balloons are at the same temperature, which balloon has the greater volume?
  - What information would you need in order to calculate the volume of each of the balloons at their respective heights?

**5.35** You have a balloon that contains  $O_2$ . What could you do to the balloon in order to double the volume? Be specific in your answers; for example, you could increase the number of moles of  $O_2$  by a factor of 2.

**5.36** Three 25.0-L flasks are placed next to each other on a shelf in a chemistry stockroom. The first flask contains He at a pressure of 1.0 atm, the second contains Xe at

1.50 atm, and the third contains  $F_2$  and has a label that says 2.0 mol  $F_2$ . Consider the following questions about these flasks.

- Which flask has the greatest number of moles of gas?
- If you wanted each of the flasks to be at the same pressure as the He flask, what general things could you do to the other two containers to make this happen?

## Practice Problems

**Key:** These problems are for practice in applying problem-solving skills. They are divided by topic, and some are keyed to exercises (see the ends of the exercises). The problems are arranged in matching pairs; the odd-numbered problem of each pair is listed first, and its answer is given in the back of the book.

**Note:** In these problems, the final zeros given in temperatures and pressures (for example, 20°C, 760 mmHg) are significant figures.

### Units of Pressure

**5.37** A gas in a closed-tube manometer (Figure 5.4) has a measured pressure of 0.047 atm. Calculate the pressure in mmHg.

**5.38** The barometric pressure measured outside an airplane at 9 km (30,000 ft) was 266 torr. Calculate the pressure in kPa.

### Empirical Gas Laws

**5.39** Suppose you had a 4.10-L sample of neon gas at 21°C and a pressure of 0.959 atm. What would be the volume of this gas if the pressure were increased to 1.210 atm while the temperature remained constant?

**5.40** You fill a balloon with helium gas to a volume of 2.68 L at 23°C and 789 mmHg. Now you release the balloon. What would be the volume of helium if its pressure changed to 499 mmHg but the temperature were unchanged?

**5.41** You have a cylinder of argon gas at 19.8 atm pressure at 19°C. The volume of argon in the cylinder is 50.0 L. What would be the volume of this gas if you allowed it to expand to the pressure of the surrounding air (0.974 atm)? Assume the temperature remains constant.

**5.42** A diving bell is a container open at the bottom. As the bell descends, the water level inside changes so that the pressure inside equals the pressure outside. Initially, the volume of air is 8.58 m<sup>3</sup> at 1.020 atm and 20°C. What is the volume at 1.212 atm and 20°C?

**5.43** A McLeod gauge measures low gas pressures by compressing a known volume of the gas at constant temperature. If 315 cm<sup>3</sup> of gas is compressed to a volume of 0.0457 cm<sup>3</sup> under a pressure of 2.51 kPa, what was the original gas pressure?

**5.44** If 456 dm<sup>3</sup> of krypton at 101 kPa and 21°C is compressed into a 30.1-dm<sup>3</sup> tank at the same temperature, what is the pressure of krypton in the tank?

**5.45** A sample of nitrogen gas at 17°C and 760 mmHg has a volume of 8.06 mL. What is the volume at -9°C and 1 atm of pressure?

**5.46** A mole of gas at 0°C and 760 mmHg occupies 22.41 L. What is the volume at 20°C and 760 mmHg?

**5.47** Helium gas, He, at 22°C and 1.00 atm occupied a vessel whose volume was 2.54 L. What volume would this gas occupy if it were cooled to liquid-nitrogen temperature (-197°C)?

**5.48** An experiment called for 4.83 L of sulfur dioxide,  $SO_2$ , at 0°C and 1.00 atm. What would be the volume of this gas at 29°C and 1.00 atm?

**5.49** A vessel containing 39.5 cm<sup>3</sup> of helium gas at 25°C and 106 kPa was inverted and placed in cold ethanol. As the gas contracted, ethanol was forced into the vessel to maintain the same pressure of helium. If this required 7.5 cm<sup>3</sup> of ethanol, what was the final temperature of the helium?

**5.50** A sample of 62.3 cm<sup>3</sup> of argon gas at 18°C was contained at a pressure of 155 kPa in a J-shaped tube with mercury, as in Figure 5.5. Later the temperature changed. When the mercury level was adjusted to give the same pressure of argon, the gas volume changed to 61.2 cm<sup>3</sup>. What was the final temperature of the argon?

**5.51** A bacterial culture isolated from sewage produced 51.5 mL of methane,  $CH_4$ , at 33°C and 752 mmHg. What is the volume of this methane at standard temperature and pressure (0°C, 760 mmHg)?

**5.52** Pantothenic acid is a B vitamin. Using the Dumas method, you find that a sample weighing 71.6 mg gives 3.84 mL of nitrogen gas at 23°C and 785 mmHg. What is the volume of nitrogen at STP?

**5.53** In the presence of a platinum catalyst, ammonia,  $NH_3$ , burns in oxygen,  $O_2$ , to give nitric oxide,  $NO$ , and water vapor. How many volumes of nitric oxide are obtained from one volume of ammonia, assuming each gas is at the same temperature and pressure?

**5.54** Methanol,  $CH_3OH$ , can be produced in industrial plants by reacting carbon dioxide with hydrogen in the presence of a catalyst. Water is the other product. How many volumes of hydrogen are required for each volume of carbon dioxide when each gas is at the same temperature and pressure?

### Ideal Gas Law

**5.55** Starting from the ideal gas law, prove that the volume of a mole of gas is inversely proportional to the pressure at constant temperature (Boyle's law).

**5.56** Starting from the ideal gas law, prove that the volume of a mole of gas is directly proportional to the absolute temperature at constant pressure (Charles's law).

**5.57** A cylinder of oxygen gas contains 91.3 g O<sub>2</sub>. If the volume of the cylinder is 8.58 L, what is the pressure of the O<sub>2</sub> if the gas temperature is 21°C?

**5.58** In an experiment, you fill a heavy-walled 6.00-L flask with methane gas, CH<sub>4</sub>. If the flask contains 7.13 g of methane at 19°C, what is the gas pressure?

**5.59** An experiment calls for 3.70 mol of chlorine, Cl<sub>2</sub>. What volume will this be if the gas volume is measured at 36°C and 3.30 atm?

**5.60** According to your calculations, a reaction should yield 5.67 g of oxygen, O<sub>2</sub>. What do you expect the volume to be at 23°C and 0.894 atm?

**5.61** The maximum safe pressure that a certain 4.00-L vessel can hold is 3.50 atm. If the vessel contains 0.410 mol of gas, what is the maximum temperature (in degrees Celsius) to which this vessel can be subjected?

**5.62** A 2.50-L flask was used to collect a 5.65-g sample of propane gas, C<sub>3</sub>H<sub>8</sub>. After the sample was collected, the gas pressure was found to be 741 mmHg. What was the temperature of the propane in the flask?

**5.63** What is the density of ammonia gas, NH<sub>3</sub>, at 31°C and 751 mmHg? Obtain the density in grams per liter.

**5.64** Calculate the density of hydrogen sulfide gas, H<sub>2</sub>S, at 49°C and 967 mmHg. Obtain the density in grams per liter.

**5.65** Butane, C<sub>4</sub>H<sub>10</sub>, is an easily liquefied gaseous fuel. Calculate the density of butane gas at 0.857 atm and 22°C. Give the answer in grams per liter.

**5.66** Chloroform, CHCl<sub>3</sub>, is a volatile (easily vaporized) liquid solvent. Calculate the density of chloroform vapor at 98°C and 797 mmHg. Give the answer in grams per liter.

**5.67** A chemist vaporized a liquid compound and determined its density. If the density of the vapor at 90°C and 753 mmHg is 1.585 g/L, what is the molecular weight of the compound?

**5.68** You vaporize a liquid substance at 100°C and 755 mmHg. The volume of 0.548 g of vapor is 237 mL. What is the molecular weight of the substance?

**5.69** A 2.56-g sample of a colorless liquid was vaporized in a 250-mL flask at 121°C and 786 mmHg. What is the molecular weight of this substance?

**5.70** A 2.30-g sample of white solid was vaporized in a 345-mL vessel. If the vapor has a pressure of 985 mmHg at 148°C, what is the molecular weight of the solid?

**5.71** Ammonium chloride, NH<sub>4</sub>Cl, is a white solid. When heated to 325°C, it gives a vapor that is a mixture of ammonia and hydrogen chloride.

Suppose someone contends that the vapor consists of NH<sub>4</sub>Cl molecules rather than a mixture of NH<sub>3</sub> and HCl. Could you decide between these alternative views on the basis of gas-density measurements? Explain.

**5.72** Phosphorus pentachloride, PCl<sub>5</sub>, is a white solid that sublimates (vaporizes without melting) at about 100°C. At

higher temperatures, the PCl<sub>5</sub> vapor decomposes to give phosphorus trichloride, PCl<sub>3</sub>, and chlorine, Cl<sub>2</sub>.

How could gas-density measurements help to establish that PCl<sub>5</sub> vapor is decomposing?

### Stoichiometry with Gas Volumes

**5.73** Calcium carbide reacts with water to produce acetylene gas, C<sub>2</sub>H<sub>2</sub>.

Calculate the volume (in liters) of acetylene produced at 26°C and 684 mmHg from 0.075 mol CaC<sub>2</sub> and excess H<sub>2</sub>O.

**5.74** Magnesium metal reacts with hydrochloric acid to produce hydrogen gas, H<sub>2</sub>.

Calculate the volume (in liters) of hydrogen produced at 33°C and 665 mmHg from 0.0840 mol Mg and excess HCl.

**5.75** Lithium hydroxide, LiOH, is used in spacecraft to recondition the air by absorbing the carbon dioxide exhaled by astronauts. The reaction is

What volume of carbon dioxide gas at 21°C and 781 mmHg could be absorbed by 327 g of lithium hydroxide?

**5.76** Magnesium burns in air to produce magnesium oxide, MgO, and magnesium nitride, Mg<sub>3</sub>N<sub>2</sub>. Magnesium nitride reacts with water to give ammonia.

What volume of ammonia gas at 24°C and 753 mmHg will be produced from 3.93 g of magnesium nitride?

**5.77** Urea, NH<sub>2</sub>CONH<sub>2</sub>, is a nitrogen fertilizer that is manufactured from ammonia and carbon dioxide.

What volume of ammonia at 25°C and 3.00 atm is needed to produce 908 g (2 lb) of urea?

**5.78** Nitric acid is produced from nitrogen monoxide, NO, which in turn is prepared from ammonia by the Ostwald process:

What volume of oxygen at 35°C and 2.15 atm is needed to produce 100.0 g of nitrogen monoxide?

**5.79** Ammonium sulfate is used as a nitrogen and sulfur fertilizer. It is produced by reacting ammonia with sulfuric acid. Write the balanced equation for the reaction of gaseous ammonia with sulfuric acid solution. What volume (in liters) of ammonia at 15°C and 1.15 atm is required to produce 150.0 g of ammonium sulfate?

**5.80** Sodium hydrogen carbonate is also known as baking soda. When this compound is heated, it decomposes to sodium carbonate, carbon dioxide, and water vapor. Write the balanced equation for this reaction. What volume (in

liters) of carbon dioxide gas at 77°C and 756 mmHg will be produced from 26.8 g of sodium hydrogen carbonate?

### Gas Mixtures

**5.81** Calculate the total pressure (in atm) of a mixture of 0.0200 mol of helium, He, and 0.0100 mol of hydrogen, H<sub>2</sub>, in a 2.50-L flask at 10°C. Assume ideal gas behavior.

**5.82** Calculate the total pressure (in atm) of a mixture of 0.0300 mol of helium, He, and 0.0400 mol of oxygen, O<sub>2</sub>, in a 4.00-L flask at 20°C. Assume ideal gas behavior.

**5.83** A 900.0-mL flask contains 1.16 mg O<sub>2</sub> and 0.42 mg He at 15°C. Calculate the partial pressures of oxygen and of helium in the flask. What is the total pressure?

**5.84** The atmosphere in a sealed diving bell contained oxygen and helium. If the gas mixture has 0.200 atm of oxygen and a total pressure of 3.00 atm, calculate the mass of helium in 10.0 L of the gas mixture at 40°C.

**5.85** The gas from a certain volcano had the following composition in mole percent (that is, mole fraction × 100): 65.0% CO<sub>2</sub>, 25.0% H<sub>2</sub>, 5.4% HCl, 2.8% HF, 1.7% SO<sub>2</sub>, and 0.1% H<sub>2</sub>S. What would be the partial pressure of each of these gases if the total pressure of volcanic gas were 760 mmHg?

**5.86** In a series of experiments, the U.S. Navy developed an undersea habitat. In one experiment, the mole percent composition of the atmosphere in the undersea habitat was 79.0% He, 17.0% N<sub>2</sub>, and 4.0% O<sub>2</sub>. What will the partial pressure of each gas be when the habitat is 58.8 m below sea level, where the pressure is 6.91 atm?

**5.87** Formic acid, HCHO<sub>2</sub>, is a convenient source of small quantities of carbon monoxide. When warmed with sulfuric acid, formic acid decomposes to give CO gas.

If 3.85 L of carbon monoxide was collected over water at 25°C and 689 mmHg, how many grams of formic acid were consumed?

**5.88** An aqueous solution of ammonium nitrite, NH<sub>4</sub>NO<sub>2</sub>, decomposes when heated to give off nitrogen, N<sub>2</sub>.

This reaction may be used to prepare pure nitrogen. How many grams of ammonium nitrite must have reacted if 4.00 dm<sup>3</sup> of nitrogen gas was collected over water at 26°C and 97.8 kPa?

### Molecular Speeds; Effusion

**5.89** Calculate the rms speeds of N<sub>2</sub> molecules at 25°C and at 125°C. Sketch approximate curves of the molecular speed distributions of N<sub>2</sub> at 25°C and at 125°C.

**5.90** Calculate the rms speed of Br<sub>2</sub> molecules at 23°C and 1.00 atm. What is the rms speed of Br<sub>2</sub> at 23°C and 2.00 atm?

**5.91** Uranium hexafluoride, UF<sub>6</sub>, is a white solid that sublimes (vaporizes without melting) at 57°C under normal atmospheric pressure. The compound is used to separate uranium isotopes by effusion. What is the rms speed (in m/s) of a uranium hexafluoride molecule at 57°C?

**5.92** For a spacecraft or a molecule to leave the moon, it must reach the escape velocity (speed) of the moon, which is 2.37 km/s. The average daytime temperature of the moon's surface is 365 K. What is the rms speed (in m/s) of a hydrogen molecule at this temperature? How does this compare with the escape velocity?

**5.93** At what temperature would CO<sub>2</sub> molecules have an rms speed equal to that of H<sub>2</sub> molecules at 25°C?

**5.94** At what temperature does the rms speed of O<sub>2</sub> molecules equal 475. m/s?

**5.95** What is the ratio of rates of effusion of N<sub>2</sub> and O<sub>2</sub> under the same conditions?

**5.96** Obtain the ratio of rates of effusion of H<sub>2</sub> and H<sub>2</sub>Se under the same conditions.

**5.97** If 0.10 mol of I<sub>2</sub> vapor can effuse from an opening in a heated vessel in 39 s, how long will it take 0.10 mol H<sub>2</sub> to effuse under the same conditions?

**5.98** If it takes 11.2 hours for 1.00 L of nitrogen, N<sub>2</sub>, to effuse through the pores in a balloon, how long would it take for 1.00 L of helium, He, to effuse under the same conditions?

**5.99** If 4.83 mL of an unknown gas effuses through a hole in a plate in the same time it takes 9.23 mL of argon, Ar, to effuse through the same hole under the same conditions, what is the molecular weight of the unknown gas?

**5.100** A given volume of nitrogen, N<sub>2</sub>, required 68.3 s to effuse from a hole in a chamber. Under the same conditions, another gas required 85.6 s for the same volume to effuse. What is the molecular weight of this gas?

### van der Waals Equation

**5.101** Calculate the pressure of ethanol vapor, C<sub>2</sub>H<sub>5</sub>OH(g), at 82.0°C if 1.000 mol C<sub>2</sub>H<sub>5</sub>OH(g) occupies 30.00 L. Use the van der Waals equation (see Table 5.7 for data). Compare with the result from the ideal gas law.

**5.102** Calculate the pressure of water vapor at 120.0°C if 1.000 mol of water vapor occupies 32.50 L. Use the van der Waals equation (see Table 5.7 for data). Compare with the result from the ideal gas law.

**5.103** Calculate the molar volume of ethane at 1.00 atm and 0°C and at 10.0 atm and 0°C, using the van der Waals equation. The van der Waals constants are given in Table 5.7. To simplify, note that the term  $n^2a/V^2$  is small compared with  $P$ . Hence, it may be approximated with negligible error by substituting  $nRT/P$  from the ideal gas law for  $V$  in this term. Then the van der Waals equation can be solved for the volume. Compare the results with the values predicted by the ideal gas law.

**5.104** Calculate the molar volume of oxygen at 1.00 atm and 0°C and at 10.0 atm and 0°C, using the van der Waals equation. The van der Waals constants are given in Table 5.7. (See the note on solving the equation given in Problem 5.103.) Compare the results with the values predicted by the ideal gas law. Also compare with the values obtained from Table 5.3.

## General Problems

**Key:** These problems provide more practice but are not divided by topic or keyed to exercises. Each section ends with essay questions, each of which is color coded to refer to the *A Chemist Looks at Life Science* (pink) or *A Chemist Looks at Environment* (green) chapter essay on which it is based. Odd-numbered problems and the even-numbered problems that follow are similar; answers to all odd-numbered problems except the essay questions are given in the back of the book.

**5.105** A glass tumbler containing 243 cm<sup>3</sup> of air at 1.00 × 10<sup>2</sup> kPa (the barometric pressure) and 20°C is turned upside down and immersed in a body of water to a depth of 25.5 m. The air in the glass is compressed by the weight of water above it. Calculate the volume of air in the glass, assuming the temperature and barometric pressure have not changed.

**5.106** The density of air at 20°C and 1.00 atm is 1.205 g/L. If this air were compressed at the same temperature to equal the pressure at 50.0 m below sea level, what would be its density? Assume the barometric pressure is constant at 1.00 atm. The density of seawater is 1.025 g/cm<sup>3</sup>.

**5.107** A flask contains 201 mL of argon at 21°C and 738 mmHg. What is the volume of gas, corrected to STP?

**5.108** A steel bottle contains 12.0 L of a gas at 11.0 atm and 20°C. What is the volume of gas at STP?

**5.109** A balloon containing 5.0 dm<sup>3</sup> of gas at 14°C and 100.0 kPa rises to an altitude of 2000. m, where the temperature is 20°C. The pressure of gas in the balloon is now 79.0 kPa. What is the volume of gas in the balloon?

**5.110** A volume of air is taken from the earth's surface, at 19°C and 1.00 atm, to the stratosphere, where the temperature is -21°C and the pressure is 1.00 × 10<sup>-3</sup> atm. By what factor is the volume increased?

**5.111** A radioactive metal atom decays (goes to another kind of atom) by emitting an alpha particle (He<sup>2+</sup> ion). The alpha particles are collected as helium gas. A sample of helium with a volume of 9.050 mL was obtained at 765 mmHg and 23°C. How many atoms decayed during the period of the experiment?

**5.112** The combustion method used to analyze for carbon and hydrogen can be adapted to give percentage N by collecting the nitrogen from combustion of the compound as N<sub>2</sub>. A sample of a compound weighing 8.75 mg gave 1.59 mL N<sub>2</sub> at 25°C and 749 mmHg. What is the percentage N in the compound?

**5.113** Dry air at STP has a density of 1.2929 g/L. Calculate the average molecular weight of air from the density.

**5.114** A hydrocarbon gas has a density of 1.22 g/L at 20°C and 1.00 atm. An analysis gives 80.0% C and 20.0% H. What is the molecular formula?

**5.115** A person exhales about 5.8 × 10<sup>2</sup> L of carbon dioxide per day (at STP). The carbon dioxide exhaled by an astronaut is absorbed from the air of a space capsule by reaction with lithium hydroxide, LiOH.

How many grams of lithium hydroxide are required per astronaut per day?

**5.116** Pyruvic acid, HC<sub>3</sub>H<sub>3</sub>O<sub>3</sub>, is involved in cell metabolism. It can be assayed for (that is, the amount of it determined) by using a yeast enzyme. The enzyme makes the following reaction go to completion:

If a sample containing pyruvic acid gives 21.2 mL of carbon dioxide gas, CO<sub>2</sub>, at 349 mmHg and 30°C, how many grams of pyruvic acid are there in the sample?

**5.117** Liquid oxygen was first prepared by heating potassium chlorate, KClO<sub>3</sub>, in a closed vessel to obtain oxygen at high pressure. The oxygen was cooled until it liquefied.

If 171 g of potassium chlorate reacts in a 2.70-L vessel, which was initially evacuated, what pressure of oxygen will be attained when the temperature is finally cooled to 25°C? Use the preceding chemical equation and ignore the volume of solid product.

**5.118** Raoul Pictet, the Swiss physicist who first liquefied oxygen, attempted to liquefy hydrogen. He heated potassium formate, KCHO<sub>2</sub>, with KOH in a closed 2.50-L vessel.

If 75.0 g of potassium formate reacts in a 2.50-L vessel, which was initially evacuated, what pressure of hydrogen will be attained when the temperature is finally cooled to 25°C? Use the preceding chemical equation and ignore the volume of solid product.

**5.119** A 24.9-mL volume of hydrochloric acid reacts completely with 55.0 mL of aqueous Na<sub>2</sub>CO<sub>3</sub>. The reaction is

The volume of CO<sub>2</sub> formed is 141 mL at 27°C and 727 mmHg. What is the molarity of the HCl solution?

**5.120** A 21.4-mL volume of hydrochloric acid reacts completely with a solid sample of MgCO<sub>3</sub>. The reaction is

The volume of CO<sub>2</sub> formed is 159 mL at 23°C and 731 mmHg. What is the molarity of the HCl solution?

**5.121** A 41.41-mL sample of a 0.1250 M acid reacts with an excess of Na<sub>2</sub>CO<sub>3</sub> to form 150.0 mL CO<sub>2</sub> at 646 mmHg and 27°C. If the acid is either HCl or H<sub>2</sub>SO<sub>4</sub>, which is it?

**5.122** A 48.90-mL sample of a 0.2040 M acid reacts with an excess of Na<sub>2</sub>CO<sub>3</sub> to form 125.0 mL CO<sub>2</sub> at 722 mmHg and 17°C. If the acid is either HCl or H<sub>2</sub>SO<sub>4</sub>, which is it?

**5.123** If the rms speed of NH<sub>3</sub> molecules is found to be 0.600 km/s, what is the temperature (in degrees Celsius)?

**5.124** If the rms speed of He atoms in the exosphere (highest region of the atmosphere) is 3.53 × 10<sup>3</sup> m/s, what is the temperature (in kelvins)?

**5.125** Calculate the ratio of rates of effusion of  $^{235}\text{UF}_6$  and  $^{238}\text{UF}_6$ , where  $^{235}\text{U}$  and  $^{238}\text{U}$  are isotopes of uranium. The atomic weights are  $^{235}\text{U}$ , 235.04 amu;  $^{238}\text{U}$ , 238.05 amu;  $^{19}\text{F}$  (the only naturally occurring isotope), 18.998 amu. Carry five significant figures in the calculation.

**5.126** Hydrogen has two stable isotopes,  $^1\text{H}$  and  $^2\text{H}$ , with atomic weights of 1.0078 amu and 2.0141 amu, respectively. Ordinary hydrogen gas,  $\text{H}_2$ , is a mixture consisting mostly of  $^1\text{H}_2$  and  $^1\text{H}^2\text{H}$ . Calculate the ratio of rates of effusion of  $^1\text{H}_2$  and  $^1\text{H}^2\text{H}$  under the same conditions.

**5.127** A 1.000-g sample of an unknown gas at  $0^\circ\text{C}$  gives the following data:

$P$ (atm)	$V$ (L)
0.2500	3.1908
0.5000	1.5928
0.7500	1.0601
1.0000	0.7930

Use these data to calculate the value of the molar mass at each of the given pressures from the ideal gas law (we will call this the “apparent molar mass” at this pressure). Plot the apparent molar masses against pressure and extrapolate to find the molar mass at zero pressure. Because the ideal gas law is most accurate at low pressures, this extrapolation will give an accurate value for the molar mass. What is the accurate molar mass?

**5.128** Plot the data given in Table 5.3 for oxygen at  $0^\circ\text{C}$  to obtain an accurate molar mass for  $\text{O}_2$ . To do this, calculate a value of the molar mass at each of the given pressures from the ideal gas law (we will call this the “apparent molar mass” at this pressure). On a graph show the apparent molar mass versus the pressure and extrapolate to find the molar mass at zero pressure. Because the ideal gas law is

most accurate at low pressures, this extrapolation will give an accurate value for the molar mass. What is the accurate molar mass?

**5.129** Carbon monoxide,  $\text{CO}$ , and oxygen,  $\text{O}_2$ , react according to

Assuming that the reaction takes place and goes to completion, determine what substances remain and what their partial pressures are after the valve is opened in the apparatus represented in the accompanying figure. Also assume that the temperature is fixed at 300 K.

**5.130** Suppose the apparatus shown in the figure accompanying Problem 5.129 contains  $\text{H}_2$  at 0.500 atm in the left vessel separated from  $\text{O}_2$  at 1.00 atm in the other vessel. The valve is then opened. If  $\text{H}_2$  and  $\text{O}_2$  react to give  $\text{H}_2\text{O}$  when the temperature is fixed at 300 K, what substances remain and what are their partial pressures after reaction?

■ **5.131** How does nitrogen monoxide,  $\text{NO}$ , function in the body to regulate blood pressure?

■ **5.132** How does nitroglycerine alleviate the pain of an angina attack?

■ **5.133** What famous chemist first predicted the greenhouse effect of carbon dioxide gas?

■ **5.134** Explain the greenhouse effect.

## Strategy Problems

**Key:** As noted earlier, all of the practice and general problems are matched pairs. This section is a selection of problems that are not in matched-pair format. These challenging problems require that you employ many of the concepts and strategies that were developed in the chapter. In some cases, you will have to integrate several concepts and operational skills in order to solve the problem successfully.

**5.135** A 19.9-mL volume of a hydrochloric acid solution reacts completely with a solid sample of magnesium carbonate, producing 183 mL of  $\text{CO}_2$  that is collected over water at  $24.0^\circ\text{C}$  and 738 torr total pressure. The reaction is

What is the molarity of the  $\text{HCl}$  solution?

**5.136** The graph here represents the distribution of molecular speeds of hydrogen and neon at 200 K.

- Match each curve to the appropriate gas.
- Calculate the rms speed (in m/s) for each of the gases at 200 K.
- Which of the gases would you expect to have the greater effusion rate at 200 K? Justify your answer.
- Calculate the temperature at which the rms speed of the hydrogen gas would equal the rms speed of the neon at 200 K.

**5.137** A submersible balloon is sent to the bottom of the ocean. On shore, the balloon had a capacity of 162 L when it was filled at 21.0°C and standard pressure. When it reaches the ocean floor, which is at 5.92°C, the balloon occupies 18.8 L of space. What is the pressure on the ocean floor?

**5.138** A given mass of gas occupies a volume of 435 mL at 28°C and 740 mmHg. What will be the new volume at STP?

**5.139** A container is filled with 16.0 g of O<sub>2</sub> and 14.0 g of N<sub>2</sub>.

- What is the volume of the container at STP?
- What is the partial pressure of the O<sub>2</sub> gas?
- What are the mole fraction and the mole percent of the N<sub>2</sub> in the mixture.

**5.140** Sulfur-containing compounds give skunks their potent smell. One of the principal smelly compounds in skunk spray is (*E*)-2-butene-1-thiol, C<sub>4</sub>H<sub>7</sub>S.

- What is the root-mean-square (rms) molecular speed of a gas molecule of this compound at 25°C?
- Using the value from part a, calculate how long it would take a molecule of C<sub>4</sub>H<sub>7</sub>S to reach your nose if you were 150 m from the skunk.
- Does the calculation that you performed in part b provide an accurate estimate for the length of time it would take for the molecule to travel 150 m, or is there something that was overlooked in performing the calculation?

**5.141** Sulfur hexafluoride, SF<sub>6</sub>, is an extremely dense gas. How does its density compare with the density of air? Use a molar mass for air of 29.0 g/mol.

**5.142** A rigid 1.0-L container at 75°C is fitted with a gas pressure gauge. A 1.0-mol sample of ideal gas is introduced into the container.

- What would the pressure gauge in the container be reading in mmHg?
- Describe the interactions in the container that are causing the pressure.
- Say the temperature in the container were increased to 150°C. Describe the effect this would have on the pressure, and, in terms of kinetic theory, explain why this change occurred.

**5.143** The reaction  $8\text{H}_2(\text{g}) + \text{S}_8(\text{l}) \longrightarrow 8\text{H}_2\text{S}(\text{g})$  is run at 125°C and a constant pressure of 12.0 atm. Assuming complete reaction, what mass of S<sub>8</sub> would be required to produce  $5.00 \times 10^2$  mL of H<sub>2</sub>S gas under these conditions?

**5.144** Shown below are three containers of an ideal gas (A, B, and C), each equipped with a movable piston (assume that atmospheric pressure is 1.0 atm).

- How do the pressures in these containers compare?
- Are all the gases at the same temperature? If not, compare the temperatures.
- If you cooled each of the containers in an ice-water bath to 0.0°C, describe how the volumes and pressures of the gases in these containers would compare.

**5.145** A 275-mL sample of CO gas is collected over water at 31°C and 755 mmHg. If the temperature of the gas collection apparatus rises to 39°C, what is the new volume of the sample? Assume that the barometric pressure does not change.

**5.146** Ethanol, the alcohol used in automobile fuels, is produced by the fermentation of sugars present in plants. Corn is often used as the sugar source. The following equation represents the fermentation of glucose, the sugar in corn, by yeast to produce ethanol and carbon dioxide.

Ethanol is combusted in an automobile engine according to the equation

What would be the *total* volume of CO<sub>2</sub> gas formed at STP when 3.00 kg of sugar is fermented and the ethanol is then combusted in an automobile engine?

**5.147** Silicon nitride, Si<sub>3</sub>N<sub>4</sub>, is a material that is used in computer chips as an insulator. Silicon nitride can be prepared according to the chemical equation

If you wanted to prepare a surface film of Si<sub>3</sub>N<sub>4</sub>(s) that had an area of 9.0 mm<sup>2</sup> and was  $4.0 \times 10^{-5}$  mm thick, what volume of SiH<sub>4</sub> gas would you need to use at  $1.0 \times 10^{-5}$  torr and 775 K? The density of Si<sub>3</sub>N<sub>4</sub> is 3.29 g/cm<sup>3</sup>.

**5.148** A sample of neon gas is placed into a 22.4-L rigid container that already contains 1.00 mol of nitrogen gas. Indicate which statement is correct in describing the change that occurs when the neon gas is added to the container. Assume ideal gas behavior.

- The partial pressure of the nitrogen gas in the container would double.
- The partial pressure of the nitrogen gas would increase by some amount, but we cannot know the exact amount without more information.
- The partial pressure of the nitrogen gas in the container would decrease by 1/2 (50%).
- The partial pressure of the nitrogen gas in the container would decrease by some amount, but we cannot know the exact amount without more information.
- The partial pressure of the nitrogen gas would not change.

**5.149** If you have a 150-L cylinder filled with chlorine gas to a density of 2.8 g/L, how many moles of chlorine would you need to add to the cylinder? If you were to double the temperature of the cylinder, would the gas density change?

**5.150** A sample of carbon dioxide gas is placed in a container. The volume of the container is reduced to 1/3 of its original volume while the pressure is observed to double. In this system did the temperature change? Explain your answer.

## Capstone Problems

**Key:** The problems under this heading combine skills, strategies, and concepts learned in previous chapters with those introduced in the current one.

**5.151** A sample of natural gas is 85.2% methane,  $\text{CH}_4$ , and 14.8% ethane,  $\text{C}_2\text{H}_6$ , by mass. What is the density of this mixture at  $18^\circ\text{C}$  and 771 mmHg?

**5.152** A sample of a breathing mixture for divers contained 34.3% helium, He; 51.7% nitrogen,  $\text{N}_2$ ; and 14.0% oxygen,  $\text{O}_2$  (by mass). What is the density of this mixture at  $22^\circ\text{C}$  and 775 mmHg?

**5.153** A sample of sodium peroxide,  $\text{Na}_2\text{O}_2$ , was reacted with an excess of water.

All of the sodium peroxide reacted, and the oxygen was collected over water at  $21^\circ\text{C}$ . The barometric pressure was 771 mmHg. The apparatus was similar to that shown in Figure 5.20. However, the level of water inside the tube was 25.0 cm above the level of water outside the tube. If the volume of gas in the tube is 31.0 mL, how many grams of sodium peroxide were in the sample?

**5.154** A sample of zinc metal was reacted with an excess of hydrochloric acid.

All of the zinc reacted, and the hydrogen gas was collected over water at  $17^\circ\text{C}$ ; the barometric pressure was 751 mmHg. The apparatus was similar to that shown in Figure 5.20, but the level of water inside the tube was 29.7 cm above the level outside the tube. If the volume of gas in the tube is 22.1 mL, how many grams of zinc were there in the sample?

**5.155** A mixture contained calcium carbonate,  $\text{CaCO}_3$ , and magnesium carbonate,  $\text{MgCO}_3$ . A sample of this mixture weighing 7.85 g was reacted with excess hydrochloric acid. The reactions are

If the sample reacted completely and produced 1.94 L of carbon dioxide,  $\text{CO}_2$ , at  $25^\circ\text{C}$  and 785 mmHg, what were the percentages of  $\text{CaCO}_3$  and  $\text{MgCO}_3$  in the mixture?

**5.156** A mixture contained zinc sulfide,  $\text{ZnS}$ , and lead sulfide,  $\text{PbS}$ . A sample of the mixture weighing 6.12 g was reacted with an excess of hydrochloric acid. The reactions are

If the sample reacted completely and produced 1.049 L of hydrogen sulfide,  $\text{H}_2\text{S}$ , at  $23^\circ\text{C}$  and 762 mmHg, what were the percentages of  $\text{ZnS}$  and  $\text{PbS}$  in the mixture?

**5.157** A mixture of  $\text{N}_2$  and Ne contains equal moles of each gas and has a total mass of 10.0 g. What is the density of this gas mixture at 500 K and 15.00 atm? Assume ideal gas behavior.

**5.158** A mixture of Ne and Ar gases at 350 K contains twice as many moles of Ne as of Ar and has a total mass of 50.0 g. If the density of the mixture is 4.00 g/L, what is the partial pressure of Ne?

**5.159** An ideal gas with a density of 3.00 g/L has a pressure of 675 mmHg at  $25^\circ\text{C}$ . What is the root-mean-square speed of the molecules of this gas?

**5.160** The root-mean-square speed of the molecules of an ideal gas at  $25^\circ\text{C}$  and a pressure of 2.50 atm is  $5.00 \times 10^2$  m/s. What is the density of this gas?

**5.161** Power plants driven by fossil-fuel combustion generate substantial greenhouse gases (e.g.,  $\text{CO}_2$  and  $\text{H}_2\text{O}$ ) as well as gases that contribute to poor air quality (e.g.,  $\text{SO}_2$ ). To evaluate exhaust emissions for regulation purposes, the generally inert nitrogen supplied with air must be included in the balanced reactions; it is further assumed that air is composed of only  $\text{N}_2$  and  $\text{O}_2$  with a volume/volume ratio of 3.76:1.00, respectively. In addition to the water produced, the fuel's C and S are converted to  $\text{CO}_2$  and  $\text{SO}_2$  at the stack. Given these stipulations, answer the following for a power plant running on a fossil fuel having the formula  $\text{C}_{18}\text{H}_{10}\text{S}$ .

- Including the  $\text{N}_2$  supplied in air, write a balanced combustion equation for the complex fuel assuming 120% stoichiometric combustion (i.e., when excess oxygen is present in the product gases). Except for  $\text{N}_2$ , use only integer coefficients. (See problem 3.141.)
- What gas law is used to effectively convert the given  $\text{N}_2/\text{O}_2$  volume ratio to a molar ratio when deriving the balanced combustion equation in (a)?
  - Boyle's law
  - Charles's law
  - Avogadro's law
  - ideal gas law
- Assuming the product water condenses, use the result from (b) to determine the stack gas composition on a "dry" basis by calculating the volume/volume percentages for  $\text{CO}_2$ ,  $\text{N}_2$ , and  $\text{SO}_2$ .
- Assuming the product water remains as vapor, repeat (c) on a "wet" basis.
- Some fuels are cheaper than others, particularly those with higher sulfur contents that lead to poorer air quality. In port, when faced with ever-increasing air quality regulations, large ships operate power plants on more costly, higher-grade fuels; with regulations nonexistent at sea, ships' officers make the cost-saving switch to lower-grade fuels. Suppose two fuels are available, one having the general formula  $\text{C}_{18}\text{H}_{10}\text{S}$  and the other  $\text{C}_{32}\text{H}_{18}\text{S}$ . Based on air quality concerns alone, which fuel is more likely to be used when idling in port?
- Support your answer to (d) by calculating the mass ratio of  $\text{SO}_2$  produced to fuel burned for  $\text{C}_{18}\text{H}_{10}\text{S}$  and  $\text{C}_{32}\text{H}_{18}\text{S}$ , assuming 120% stoichiometric combustion.

## CONTENTS AND CONCEPTS

### Understanding Heats of Reaction

The first part of the chapter lays the groundwork for understanding what we mean by heats of reaction.

- 6.1 Energy and Its Units
- 6.2 First Law of Thermodynamics; Work and Heat
- 6.3 Heat of Reaction; Enthalpy of Reaction
- 6.4 Thermochemical Equations
- 6.5 Applying Stoichiometry to Heats of Reaction
- 6.6 Measuring Heats of Reaction

### Using Heats of Reaction

Now that we understand the basic properties of heats of reaction and how to measure them, we can explore how to use them.

- 6.7 Hess's Law
- 6.8 Standard Enthalpies of Formation
- 6.9 Fuels—Foods, Commercial Fuels, and Rocket Fuels

Nearly all chemical reactions involve either the release or the absorption of heat, a form of energy. The burning of coal and gasoline are dramatic examples of chemical reactions in which a great deal of heat is released. Such reactions are important sources of warmth and energy. Chemical reactions that absorb heat are usually less dramatic. The reaction of barium hydroxide with an ammonium salt is an exception. If crystals of barium hydroxide octahydrate,  $\text{Ba}(\text{OH})_2 \cdot 8\text{H}_2\text{O}$ , are mixed with crystals of ammonium nitrate,  $\text{NH}_4\text{NO}_3$ , in a flask, the solids form first a slush, then a liquid. Because the reaction mixture absorbs heat from the surroundings, the flask feels cool. It soon becomes so cold that if it is set in a puddle of water on a board, the water freezes; the board can then be inverted with the flask frozen to it (Figure 6.1).

In this chapter, we will be concerned with the quantity of heat released or absorbed in a chemical reaction. We will address several questions: How do you measure the quantity of heat released or absorbed by a chemical reaction? To what extent can you relate the quantity of heat involved in a given reaction to the quantities of heat in other reactions? And how can you use this information?

## ► Understanding Heats of Reaction

*Thermodynamics* is the science of the relationships between heat and other forms of energy. *Thermochemistry* is one area of thermodynamics. It concerns the study of the quantity of heat absorbed or evolved (given off) by chemical reactions. An example of a heat-evolving reaction is the burning of fuel. There may be practical reasons why you want to know the quantity of heat evolved during the burning of a fuel: you could calculate the cost of the fuel per unit of heat energy produced; you could calculate the quantity of heat obtained per unit mass of rocket fuel; and so forth. But there are also theoretical reasons for wanting to know the quantity of heat involved in a reaction. For example, knowing such values, you are able to calculate the amount of energy needed to break a particular kind of chemical bond and so learn something about the strength of that bond. Heat measurements also provide data needed to determine whether a particular chemical reaction occurs and, if so, to what extent. ►

We have just used the terms *energy* and *heat*, assuming you have some idea of what they mean. But to proceed, you will need precise definitions of these and other terms. In the following section, we will define energy and its different forms and introduce units of energy.

These questions concern chemical equilibrium and will be discussed in Chapter 18.

Figure 6.1 ◀

**A reaction that absorbs heat** Two crystalline substances, barium hydroxide octahydrate and an ammonium salt, are mixed thoroughly in a flask. The substances react, producing a solution. Then the flask, which feels quite cold to the touch, is set in a puddle of water on a board. In a couple of minutes, the flask and board are frozen solidly together. The board can then be inverted with the flask frozen to it.

## 6.1 Energy and Its Units

We can define **energy** briefly as *the potential or capacity to move matter*. According to this definition, energy is not a material thing but rather a property of matter. Energy exists in different forms that can be interconverted. You can see the relationship of a given form of energy to the motion of matter by following its interconversions into different forms.

Consider the interconversions of energy in a steam-driven electrical generator. A fuel is burned to heat water and generate steam. The steam expands against a piston (or turbine), which is connected to a drive shaft that turns an electrical coil in a magnetic field. Electricity is generated in the coil. The fuel contains chemical energy, which is converted to heat. Part of the heat is then converted to motion of the drive shaft, and this motion is converted to electrical energy. The electrical energy could be used to run a motor, transforming the electrical energy back to the energy of motion. Or you could send the electricity into a lightbulb, converting electrical energy to heat energy and light energy. Photovoltaic cells can convert light back to electricity, which could be used to run a motor that can move matter (Figure 6.2). These examples show that energy can exist in different forms, including heat, light, and electrical energy, and these different forms can be interconverted. You also see their relationship to the energy of motion.

Figure 6.2 ▲

### Conversion of light energy to kinetic energy

Solar-powered vehicles use panels of photovoltaic cells.

In this chapter, we will be especially concerned with the energy of substances, or chemical energy, and its transformation during chemical reaction into heat energy. To prepare for this, we will first explore the quantitative meaning of the energy of motion (*kinetic energy*). Then we will look at the concepts of *potential energy* and of the *internal energy* of substances, which is defined in terms of the kinetic and potential energies of the particles making up the substance.

### Kinetic Energy; Units of Energy

**Kinetic energy** is *the energy associated with an object by virtue of its motion*. An object of mass  $m$  and speed or velocity  $v$  has kinetic energy  $E_k$  equal to

$$E_k = \frac{1}{2}mv^2$$

This formula shows that the kinetic energy of an object depends on both its mass and its speed. A heavy object can move more slowly than a light object and still have the same kinetic energy. ◀

Consider the kinetic energy of a person whose mass is 59.0 kg and whose speed is 26.8 m/s. (This is equivalent to a person with a mass of 130 lb traveling in an automobile going 60 miles per hour.) You substitute the mass and speed into the formula.

$$E_k = \frac{1}{2} \times (59.0 \text{ kg}) \times (26.8 \text{ m/s})^2 = 2.12 \times 10^4 \text{ kg} \cdot \text{m}^2/\text{s}^2$$

Note that the unit of energy comes out of the calculation. Because you substituted SI units of mass and speed, you obtain the SI unit of energy. *The SI unit of energy,  $\text{kg} \cdot \text{m}^2/\text{s}^2$ , is given the name **joule (J)** (pronounced “jewl”) after the English physicist James Prescott Joule (1818–1889), who studied the energy concept. You see that a person weighing 130 lb and traveling 60 miles per hour has a kinetic energy equal to  $2.12 \times 10^4 \text{ J}$ , or 21.2 kJ (21.2 kilojoules).*

The joule is an extremely small unit. To appreciate its size, note that the *watt* is a measure of the quantity of energy used per unit time and equals 1 joule per second. A 100-watt bulb, for example, uses 100 joules of energy every second. A kilowatt-hour, the unit by which electric energy is sold, equals 3600 kilowatt-seconds (there are 3600 seconds in 1 hour), or 3.6 million joules. A household might use something like 1000 kilowatt-hours (3.6 billion joules) of electricity in a month.

In the previous chapter, we used the symbol  $u$  for average molecular speed. Here  $v$  is the speed of an individual object or particle.

The **calorie (cal)** is a non-SI unit of energy commonly used by chemists, originally defined as the amount of energy required to raise the temperature of one gram of water by one degree Celsius. This is only an approximate definition, however, because we now know that the energy needed to heat water depends slightly on the temperature of the water. In 1925 the calorie was defined in terms of the joule:

$$1 \text{ cal} = 4.184 \text{ J} \quad (\text{exact definition})$$

A person weighing 130 lb and traveling 60 miles per hour has a kinetic energy of

$$2.12 \times 10^4 \text{ J} \times \frac{1 \text{ cal}}{4.184 \text{ J}} = 5.07 \times 10^3 \text{ cal} \text{ (5.07 kcal)}$$

### Example 6.1 Calculating Kinetic Energy

#### Gaining Mastery Toolbox

##### Critical Concept 6.1

Kinetic energy is the energy associated with an object's motion and depends on its mass and speed. When performing calculations, express quantities in SI units to obtain the energy in joules.

##### Solution Essentials:

- Kinetic energy:  $E_k = \frac{1}{2}mv^2$
- Energy

A good pitcher can throw a baseball so that it travels between 60 and 90 miles per hour (although speeds in excess of 100 miles per hour have been recorded). A regulation baseball weighing 143 g (0.143 kg) travels 75 miles per hour (33.5 m/s). What is the kinetic energy of this baseball in joules? in calories?

**Problem Strategy** Kinetic energy is defined by the formula  $E_k = \frac{1}{2}mv^2$ . You simply substitute into this formula, making certain that  $m$  and  $v$  are expressed in the same system of units.

**Solution** Substitute into the defining equation for the kinetic energy, using SI units.

$$E_k = \frac{1}{2} \times 0.143 \text{ kg} \times (33.5 \text{ m/s})^2 = \mathbf{80.2 \text{ J}}$$

Using the conversion factor 1 cal/4.184 J, we obtain

$$80.2 \text{ J} \times \frac{1 \text{ cal}}{4.184 \text{ J}} = \mathbf{19.2 \text{ cal}}$$

**Answer Check** Make sure that the values for  $m$  and  $v$  are in the same system of units; SI units are generally appropriate. The SI unit of mass is kg, and the SI unit of speed is m/s. The answer then comes out in SI units (joules in this case).

**Exercise 6.1** An electron, whose mass is  $9.11 \times 10^{-31}$  kg, is accelerated by a positive charge to a speed of  $5.0 \times 10^6$  m/s. What is the kinetic energy of the electron in joules? in calories?

See Problems 6.45, 6.46, 6.47, and 6.48.

## Potential Energy

**Potential energy** is the energy an object has by virtue of its position in a field of force. For example, water at the top of a dam has potential energy (in addition to whatever kinetic energy it may possess), because the water is at a relatively high position in the gravitational force field of the earth. You can calculate this potential energy of the water from the formula  $E_p = mgh$ . Here  $E_p$  is the potential energy of a quantity of water at the top of the dam,  $m$  is the mass of the water,  $g$  is the constant acceleration of gravity (equal to  $9.807 \text{ m/s}^2$ ), and  $h$  is the height of the water measured from some standard level. The choice of this standard level is arbitrary, because only differences of potential energy are important in any physical situation. It is convenient to choose the standard level to be the surface of the earth. As a quantity of water falls over the dam, its potential energy decreases from  $mgh$  at the top of the dam to zero at the earth's surface.

The potential energy of the water at the top of the dam is converted to kinetic energy when the water falls to a lower level. As the water falls, it moves more

Tennessee Valley Authority

**Figure 6.3** ▲

**Potential energy and kinetic energy**

Water at the top of the dam has potential energy. As the water falls over the dam, this potential energy is converted to kinetic energy.

quickly. The potential energy decreases and the kinetic energy increases. Figure 6.3 shows the potential energy of water being converted to kinetic energy as the water falls over a dam.

**Internal Energy**

Consider the total energy of a quantity of water as it moves over the dam. This water as a whole has kinetic energy and potential energy. However, we know that water is made up of molecules, which are made up of smaller particles, electrons and nuclei. Each of these particles also has kinetic energy and potential energy. *The sum of the kinetic and potential energies of the particles making up a substance* is referred to as the **internal energy**,  $U$ , of the substance. Therefore, the total energy,  $E_{tot}$ , of a quantity of water equals the sum of its kinetic and potential energies as a whole ( $E_k + E_p$ ) plus its internal energy.

$$E_{tot} = E_k + E_p + U$$

Normally when you study a substance in the laboratory, the substance is at rest in a vessel. Its kinetic energy as a whole is zero. Moreover, its potential energy as a whole is constant, and you can take it to be zero. In this case, the total energy of the substance equals its internal energy,  $U$ .

**Law of Conservation of Energy**

We have discussed situations in which one form of energy can be converted into another form of energy. For example, when water falls over a dam, potential energy is converted into kinetic energy. Some of the kinetic energy of the water may also be converted into random molecular motion—that is, into internal energy of the water. The total energy,  $E_{tot}$ , of the water, however, remains constant, equal to the sum of the kinetic energy,  $E_k$ , the potential energy,  $E_p$ , and the internal energy,  $U$ , of the water.

This result can be stated more generally as the **law of conservation of energy**: *energy may be converted from one form to another, but the total quantity of energy remains constant.* We say energy is conserved. The *first law of thermodynamics* is a specific statement of the conservation of energy, especially useful in discussing chemical reactions. We describe this law in the next section.

**Figure 6.4** ▲

**Illustration of a thermodynamic system** The *system* consists of the portion of the universe that we choose to study; in this case, it is a solution of  $\text{Ba}(\text{OH})_2$  and  $\text{NH}_4\text{NO}_3$  and the flask. Everything else constitutes the *surroundings*.

**CONCEPT CHECK 6.1**

A solar-powered water pump has photovoltaic cells that protrude from top panels. These cells collect energy from sunlight, storing it momentarily in a battery, which later runs an electric motor that pumps water up to a storage tank on a hill. What energy conversions are involved in using sunlight to pump water into the storage tank?

**6.2 First Law of Thermodynamics; Work and Heat**

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. WCN 02-200-203

The first law of thermodynamics relates the change in internal energy of a physical or chemical change taking place in a container to the flows (transfers) of energy into or out of the container. These energy transfers are of two kinds: work and heat. Although you may have some idea of what these terms mean, to be quantitative we will need to define them precisely, which in turn will require us to first define what we mean by a thermodynamic system and its surroundings.

**Thermodynamic System and Its Surroundings**

In the chapter opening, we looked at the reaction between crystals of barium hydroxide octahydrate,  $\text{Ba}(\text{OH})_2 \cdot 8\text{H}_2\text{O}$ , and crystals of ammonium nitrate,  $\text{NH}_4\text{NO}_3$ , taking place in a flask. Suppose we decide to study the change of internal energy of the chemical substances in this flask as the reaction occurs. We refer to these chemical substances as the thermodynamic system and everything around the system as the surroundings (Figure 6.4). (We might include the flask with the chemical substances

Figure 6.5 ◀

**Work done by a system** Gasoline burning in a cylinder produces gases that expand against the piston attached to a wheel and pulley. As the piston moves outward, the cord wraps around the wheel, pulling the weight upward.

as our system, or not, depending on what we decide to include in our study.) In general, *the substance or mixture of substances that we single out for study (perhaps including the vessel) in which a change occurs* is called the **thermodynamic system**, or simply the **system**. *Everything in the vicinity of the thermodynamic system (its environment)*, we refer to as the **surroundings**.

### Definition of Work

**Work** is an energy transfer (or energy flow) into or out of a thermodynamic system whose effect on the surroundings is equivalent to moving an object through a field of force. Imagine a system consisting of a cylinder in which gasoline burns to produce gases (Figure 6.5). These gases push against the surroundings, consisting of a piston attached to a wheel and pulley, which in turn lifts a weight. As the weight moves upward against gravity (a field of force), it gains potential energy, while the chemical substances within the engine lose an equivalent quantity of energy (in order to conserve energy—neglecting any losses due to friction). ▶ Thus, energy flows from the engine to its surroundings (to the weight). We say the engine (the system) does work on its surroundings.

You can also have the surroundings do work on the thermodynamic system. Consider a piston-type air pump with its air outlet closed off (Figure 6.6). Imagine that you hang a weight across the pump handle so that the handle is pulled down and air within the pump is compressed. As the weight falls downward, it loses potential energy, and the system (air within the pump) gains energy. We say that the falling weight has done work on the system.

We denote *work* by the symbol  $w$ . The algebraic sign of  $w$  is chosen to be positive when work is done on the thermodynamic system and negative when work is done by the thermodynamic system. (Notice that in this convention  $w$  has been defined from the perspective of the system.) You can remember the signs this way: when you do work on a system, you add (+) energy to it; when the system does work on the surroundings, energy is subtracted (−) from it.

### Definition of Heat

**Heat** is an energy transfer (energy flow) into or out of a thermodynamic system that results from a temperature difference between the system and its surroundings. As long as the system and its surroundings are in thermal contact (not insulated from one another), energy (heat) flows between them to establish equal temperatures, or thermal equilibrium. Heat flows from a region of higher temperature to one of lower temperature; once the temperatures become equal, heat flow stops. Note that when heat flows into a system, it appears in the system as an increase in the system's internal energy. We do not say that the system has heat because heat is only an energy flow; you can obtain the same increase in internal energy by doing work on the system as by adding heat to it.

The potential energy,  $E_{p_i}$ , of a mass  $m$  lifted by a height  $h$  equals  $mgh$ , where  $g$  is the constant acceleration due to gravity ( $g = 9.81 \text{ m/s}^2$ ).

Figure 6.6 ▲

**Work done on a system** A weight hangs across the handle of a piston-type air pump (with the air outlet closed). As the weight falls downward, it loses potential energy and the system (air within the cylinder) gains energy.

**Figure 6.7** ▲

**A kinetic-theory explanation of heat** The vessel on the left contains oxygen molecules at a higher temperature than the oxygen molecules on the right. Molecules collide with the vessel walls, thereby losing or gaining energy. The faster molecules tend to slow down, and the slower molecules tend to speed up. The net result is that energy is transferred through the vessel walls from the hot gas to the cold gas. We call this energy transfer *heat*.

We can explain this flow of energy between two regions of different temperatures in terms of kinetic-molecular theory. Imagine two vessels in contact, each containing oxygen gas and the one on the left being hotter (Figure 6.7). According to kinetic theory, the average speed of molecules in the hotter gas is greater than that of molecules in the colder gas. But as the molecules in their random motions collide with the vessel walls, they lose energy to or gain energy from the walls. The faster molecules tend to slow down, while the slower molecules tend to speed up. Eventually, the average speeds of the molecules in the two vessels (and therefore the temperatures of the two gases) become equal. The net result is that energy is transferred through the vessel walls from the hot gas to the cold gas; that is, heat has flowed from the hotter vessel to the cooler one.

Heat and temperature are sometimes confused. The distinction is clear in the kinetic picture of a gas. According to kinetic theory, the absolute temperature of a gas is directly proportional to the average kinetic energy of the molecules. When you add heat to a gas, you increase its internal energy—and therefore its total kinetic energy. This increase in kinetic energy will be distributed over the molecules in the sample. Therefore, the increase in average kinetic energy per molecule (and thus the increase in temperature) depends on the size of the gas sample. A given quantity of heat will raise the temperature of a sample more if the sample is small.

Heat is denoted by the symbol  $q$ . The algebraic sign of  $q$  is chosen to be positive when the thermodynamic system absorbs heat and negative when the thermodynamic system evolves heat. (This convention for  $q$ , like the one for  $w$ , is from the perspective of the system.) You can remember the signs this way: when a system absorbs heat, energy is added (+) to it; when a system evolves heat, energy is subtracted (–) from it.

### Change of Internal Energy

As we mentioned earlier, the internal energy,  $U$ , of a thermodynamic system is the sum of the kinetic and potential energies of all the particles of the system. We generally do not need to know the total internal energy of a thermodynamic system; what interests us is the *change of internal energy* when the system changes in some way.

For example, suppose you have 1.00 g of water at 0.00°C and 1.00 atm pressure. Let's consider this quantity of water to be our thermodynamic system and denote its internal energy as  $U_i$  (the initial internal energy). Suppose you change the system by adding 4.184 J (1.00 cal) of heat to it. You now have 1.00 g of water at 1.00°C and 1.00 atm. Let's denote the internal energy of this system as  $U_f$  (the final internal energy). The change in internal energy in going from the initial to final conditions is

$$\Delta U = U_f - U_i$$

where we have used the symbol  $\Delta$  to mean “change in.” (You read  $\Delta U$  as “delta  $U$ ” or “change in  $U$ .”) When you add 4.184 J of heat to 1.00 g of water, the change in internal energy of the water,  $\Delta U$ , is 4.184 J.

Internal energy is an *extensive property*, that is, it depends on the amount of substances in the system. If you double the amount of substances in the system under given conditions, you double the system's quantity of internal energy. Other examples of extensive properties are mass and volume.

Internal energy is also a state function. A **state function** is a property of a system that depends only on its present state, which is determined by variables such as temperature and pressure and which is independent of any previous history of the system. This means that any change in internal energy of a system depends only on the initial state and the final state of the system and not on how the change was made. If you start with 1.00 g of water at 0.00°C and 1.00 atm pressure and if you add 4.184 J (1.00 cal) of energy to it, you will obtain 1.00 g of water at 1.00°C and 1.00 atm. It doesn't matter how the energy is added, whether as heat or as work, or some combination of both.

An analogy might clarify the concept of a state function. Suppose you are hiking in mountainous terrain. You start walking from campsite A, which is at an altitude of 1200 ft above sea level according to your pocket altimeter, and you take the curving graded path upward to campsite B, which you find has an altitude of 4800 ft (Figure 6.8). You could take a more direct but more difficult route to campsite B. The distances traveled are different; the distance by the graded path is longer than by the more direct route. However, the difference in altitudes between campsite A and campsite B is independent of how you go from A to B (independent of any history). It is 3600 ft by whatever path you take. Altitude is analogous to a state function, whereas distance traveled is not.

### First Law of Thermodynamics

Thermodynamics is described in terms of three laws. The first law of thermodynamics, as we noted, is essentially the law of conservation of energy applied to a thermodynamic system and relates the change in internal energy of the system,  $\Delta U$ , to transfers of energy (heat,  $q$ , and work,  $w$ ) into or out of the system. We can express the first law as follows:

$$\Delta U = q + w$$

Thus, the **first law of thermodynamics** states that *the change in internal energy of a system,  $\Delta U$ , equals  $q + w$  (heat plus work)*. We will discuss the second and third laws of thermodynamics in Chapter 18.

Figure 6.9 illustrates the addition of heat to a system that consists of a gas in a cylindrical vessel fitted with a piston. On top of the piston is a weight, which we will consider to be part of the surroundings. We momentarily fix the position of the piston so it does not move, and then raise the temperature of the surroundings above that of the system so that heat passes from the surroundings to the system. As you add heat to the system, its temperature rises until it equals that of the surroundings. Suppose the total heat added to the system is 165 J. Using the sign convention that  $q$  is positive when heat is added to (or absorbed by) the system, we write  $q = +165$  J.

As the temperature of the gas in the vessel increases, the gas pressure increases at fixed volume (Boyle's law). We now allow the piston to move so that the gas expands and lifts the piston and the weight on top of it. In lifting the weight, the system does work. The energy gained by the weight equals the force of gravity on the weight times the height to which the weight was raised (the distance it was moved). Suppose this energy is 92 J. Because the surroundings, which include the weight, have gained 92 J of energy, the system must have lost 92 J by the conservation of energy. The system has done work on the surroundings. Adhering to the sign convention that work done by the system is negative (energy is subtracted from the system), we write  $w = -92$  J.

The system in Figure 6.9 gains internal energy from the heat absorbed and loses internal energy via the work done. The net change of internal energy according to the first law is

$$\Delta U = q + w = (+165 \text{ J}) + (-92 \text{ J}) = +73 \text{ J}$$

Figure 6.8 ▲

**An analogy to illustrate a state function** The two campsites differ by 3600 ft in altitude. This difference in altitude is independent of the path taken between the campsites. The distance traveled and the things encountered along the way, however, do depend on the path taken. Altitude here is analogous to a thermodynamic state function.

Figure 6.9 ▲

**Exchanges of heat and work with the surroundings** A gas is enclosed in a vessel with a piston. Heat flows into the vessel from the surroundings, which are at a higher temperature. As the temperature of the gas increases, the gas expands, lifting the weight (doing work).

**Exercise 6.2** A gas is enclosed in a system similar to that shown in Figure 6.9. More weights are added to the piston, giving a total mass of 2.20 kg. As a result, the gas is compressed, and the weights are lowered 0.250 m. At the same time, 1.50 J of heat evolves from the system. What is the change in internal energy of the system,  $\Delta U$ ? The force of gravity on a mass  $m$  is  $mg$ , where  $g$  is the constant acceleration of gravity ( $g = 9.81 \text{ m/s}^2$ ).

See Problems 6.49 and 6.50.

**✓ CONCEPT CHECK 6.2**

In closed breathing systems, such as in space ships, it is necessary to remove carbon dioxide exhaled during breathing from the air as well as to replenish oxygen. One way to remove exhaled carbon dioxide is to circulate the air through a solution of LiOH with which  $\text{CO}_2$  reacts:

Imagine a setup in which a piston and weight (the surroundings) enclose a cylinder containing  $\text{CO}_2$  gas above a solution of LiOH (the system).

As  $\text{CO}_2$  reacts with LiOH, the gas volume decreases, and the piston and weight moves downward. When 1.0 mol  $\text{CO}_2$  reacts, 89.1 kJ of heat evolves, and the piston and weight do 2.5 kJ of work on the system. The change of internal energy is (choose one):

- a** +91.6 kJ    **b** -91.6 kJ    **c** +86.6 kJ    **d** -86.6 kJ

Explain how you arrived at your answer; in particular, what signs would you attach to the heat of reaction and work done on the system?

### 6.3 Heat of Reaction; Enthalpy of Reaction

Generally when a chemical reaction occurs, the temperature of the reaction vessel or system begins to change as a result of the reaction. It may start to increase or perhaps decrease. If we imagine the system in thermal contact with its surroundings, however, heat will flow either into or out of the system. For example, if the system temperature begins to rise as a result of chemical reaction, heat flows from the system to the surroundings (heat evolves from the system). Or if the system temperature begins to fall, heat flows from the surroundings to the system (the system absorbs heat).

#### Heat of Reaction

The **heat of reaction** (at a given temperature) is *the heat,  $q$ , absorbed or evolved from a reaction system to retain a fixed temperature of the system under the conditions specified for the reaction (such as a fixed pressure)*. Chemical reactions or physical changes are classified as exothermic or endothermic, depending on the sign of  $q$ . An **exothermic process** is a chemical reaction or a physical change in which heat is evolved or is released from the system ( $q$  is negative); see Figure 6.10. An **endothermic process** is a chemical reaction or a physical change in which heat is absorbed by the system ( $q$  is positive). Experimentally, you note that in the exothermic reaction, the reaction flask initially warms; in the endothermic reaction, the reaction flask cools. We can summarize as follows:

Type of Reaction	Experimental Effect Noted	Result on System	Sign of $q$
Endothermic	Reaction vessel cools (heat is absorbed)	Energy added	+
Exothermic	Reaction vessel warms (heat is evolved)	Energy subtracted	-

Figure 6.10 ◀

An exothermic process

© Cengage Learning/Melissa Kelly Photography

The test tube contains anhydrous copper(II) sulfate (white crystals) and a thermometer that registers 24.4°C. The graduated cylinder contains water.

Water from the graduated cylinder has been added to the test tube, where the copper(II) sulfate forms hydrated copper(II) ion (blue color). The thermometer now registers 90.0°C, because the hydration process is exothermic.

Suppose that in an experiment 1 mol of methane burns in oxygen and evolves 890 kJ of heat:  $\text{CH}_4(g) + 2\text{O}_2(g) \longrightarrow \text{CO}_2(g) + 2\text{H}_2\text{O}(l)$ . The reaction is exothermic. Therefore the heat of reaction,  $q$ , is  $-890$  kJ. The minus sign indicates that heat has left the system.

Or consider the reaction described in the chapter opening, in which crystals of barium hydroxide octahydrate,  $\text{Ba}(\text{OH})_2 \cdot 8\text{H}_2\text{O}$ , react with crystals of ammonium nitrate,  $\text{NH}_4\text{NO}_3$ .

When 1 mol  $\text{Ba}(\text{OH})_2 \cdot 8\text{H}_2\text{O}$  reacts with 2 mol  $\text{NH}_4\text{NO}_3$ , the reaction mixture absorbs 170.8 kJ of heat. The reaction is endothermic. Therefore the heat of reaction,  $q$ , is  $+170.8$  kJ. The positive sign indicates that heat has been added to the system.

**Exercise 6.3** Ammonia burns in the presence of a platinum catalyst to give nitric oxide, NO.

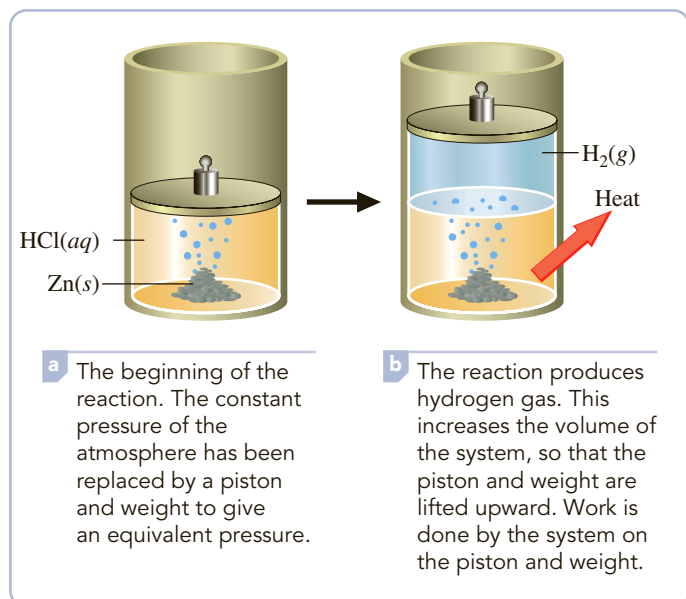

In an experiment, 4 mol  $\text{NH}_3$  is burned and evolves  $+170$  kJ of heat. Is the reaction endothermic or exothermic? What is the value of  $q$ ?

See Problems 6.51, 6.52, 6.53, and 6.54.

### Pressure-Volume Work

In general, a reaction system may involve work as well as heat, depending on the conditions under which the reaction occurs. Often we carry out a reaction in a beaker or flask open to the atmosphere, in which case the reaction occurs at the fixed pressure of the atmosphere,  $P$ . If the reaction system changes volume,  $\Delta V$ , pressure-volume work is either done by the system (if it expands against the surrounding atmosphere) or pressure-volume work is done on the system (as the system contracts from the pressure of the surrounding atmosphere). We can show that this **pressure-volume work**,  $w$ , equals *the negative of the pressure times the change in volume of the system*.

$$w = -P\Delta V$$

(Note that the negative sign results from the convention that  $w$  is defined from the perspective of the system. When  $\Delta V$  is positive, the system expands, doing work on the surroundings, and thus the system loses energy, hence the negative sign.)

Consider the reaction of zinc metal with hydrochloric acid in a beaker open to the atmosphere at pressure  $P$ .

This is an exothermic reaction, with  $q = -152.4$  kJ per mole of zinc consumed. Also, pressure-volume work is done: as hydrogen gas evolves, the system expands, pushing back the surrounding atmosphere. The effect is to lift a mass of air upward against gravity. (See Figure 6.11 in which the atmosphere has been replaced by an equivalent weight to make it clear that a mass has been lifted.) The work done by the system equals the force of gravity,  $F$ , on the system times the height,  $h$ , that the mass of air is moved upward. This work is energy lost by the system so that  $w$  is negative:

$$w = -F \times h$$

The atmospheric pressure,  $P$ , equals the force,  $F$ , exerted per cross-sectional area,  $A$ , of the beaker:  $P = F/A$ . Therefore, the force  $F$  equals  $PA$ . The change in volume of the reaction system equals the cross-sectional area,  $A$ , times the height it is raised,  $h$ . Thus,  $\Delta V = A \times h$ , and so  $h = \Delta V/A$ . Substituting for  $F$  and  $h$  in the formula for work gives

$$w = -F \times h = -(PA) \times (\Delta V/A) = -P\Delta V$$

We can use this result to calculate the pressure-volume work for the reaction of zinc with hydrochloric acid. When 1.00 mol Zn reacts with excess HCl, the reaction produces 1.00 mol  $\text{H}_2$ , which at  $25^\circ\text{C}$  and 1.00 atm ( $= 1.01 \times 10^5$  Pa) occupies 24.5 L ( $= 24.5 \times 10^{-3}$  m<sup>3</sup>), according to the ideal gas law. The work done by the chemical system in pushing back the atmosphere is

$$\begin{aligned} w &= -P\Delta V = -(1.01 \times 10^5 \text{ Pa}) \times (24.5 \times 10^{-3} \text{ m}^3) \\ &= -2.47 \times 10^3 \text{ J, or } -2.47 \text{ kJ} \end{aligned}$$

Note that we used SI units throughout the calculation to obtain the work in SI units (joules).

Suppose we would like to know the change of internal energy for this reaction. We apply the first law of thermodynamics to the system: The internal energy change for the system,  $\Delta U$ , equals the heat absorbed,  $q$  ( $= -152.4$  kJ), plus the work done,  $w$  (which equals  $-P\Delta V = -2.47$  kJ):

$$\Delta U = q - P\Delta V$$

$$\Delta U = -152.4 \text{ kJ} - 2.47 \text{ kJ} = -154.9 \text{ kJ}$$

In summary, when 1.00 mol Zn reacts with excess hydrochloric acid, the internal energy changes as kinetic and potential energies of electrons and nuclei change in going from reactants to products; the internal energy change is  $-154.9$  kJ. Energy leaves the system mostly as heat ( $q = -152.4$  kJ) but also partly as expansion work ( $w = -2.47$  kJ).

Figure 6.11 ▲

Reaction of zinc metal with hydrochloric acid at constant pressure

**Exercise 6.4** Consider the combustion (burning) of methane,  $\text{CH}_4$ , in oxygen.

The heat of reaction at  $77^\circ\text{C}$  and 1.00 atm is  $-885.5$  kJ. What is the change in volume when 1.00 mol  $\text{CH}_4$  reacts with 2.00 mol  $\text{O}_2$ ? (You can ignore the volume of liquid water, which is insignificant compared with volumes of gases.) What is  $w$  for this change? Calculate  $\Delta U$  for the change indicated by the chemical equation.

See Problems 6.55 and 6.56.

## Enthalpy and Enthalpy of Reaction

We began this chapter by discussing the heat of reaction, noting that we have a special interest in heat. How much heat can we obtain from a fuel? What can the quantity of heat tell us about a chemical reaction? As you will see, we can often directly measure this heat. For reactions in which the volume does not change, this heat equals the change of internal energy,  $\Delta U$ . In general, though, the reaction system also involves work, in which case the heat of reaction is not immediately related to  $\Delta U$ .

When the reaction occurs against a constant external pressure (say the atmosphere), the heat of reaction instead equals the change of another thermodynamic quantity, this one called the enthalpy (pronounced en-THAL-py) and denoted by the symbol  $H$ . The **enthalpy** of a thermodynamic system is defined as *its internal energy,  $U$ , plus pressure,  $P$ , times volume,  $V$* .

$$H = U + PV$$

Because  $U$ ,  $P$ , and  $V$  are state functions,  $H$  is also a state function. This means that for a given temperature and pressure, a given amount of substance has a definite enthalpy. In addition, enthalpy is an extensive property (it depends on the amount of substance). And like the internal energy, we are normally interested only in changes of the property enthalpy. This change of enthalpy,  $\Delta H$ , equals the final enthalpy  $H_f$  minus the initial enthalpy  $H_i$ ,

$$\Delta H = H_f - H_i$$

Let's now show that the heat for a reaction occurring at constant pressure (and involving only pressure-volume work) equals the enthalpy change. To begin, we write the first law of thermodynamics for this reaction,

$$\Delta U = q + w = q - P\Delta V$$

and solve for the heat of reaction,  $q$ .

$$q = \Delta U + P\Delta V = (U_f - U_i) + P(V_f - V_i)$$

Now we regroup the terms:

$$q = (U_f + PV_f) - (U_i + PV_i) = H_f - H_i$$

The result is the central equation for this chapter: The heat of reaction at a fixed pressure and a given temperature is

$$q = \Delta H \text{ (At fixed pressure and a given temperature)}$$

We refer to *the change in enthalpy,  $\Delta H$ , for a reaction at a given temperature and fixed pressure* (for which there is only pressure-volume work) as the **enthalpy of reaction**.

As an illustration of the ideas introduced in this section, consider the reaction at 25°C of sodium metal and water, carried out in a beaker open to the atmosphere at 1.00 atm pressure.

The metal and water react vigorously and evolve heat (heat is released). Experiments have been done to show that 2 moles of sodium metal reacts with 2 moles of water and evolves 368.6 kJ of heat. Therefore, the enthalpy of reaction (or enthalpy change for the reaction) is  $\Delta H = -368.6$  kJ. Figure 6.12 shows this change as an *enthalpy diagram* in which the reactants  $2\text{Na}(s) + 2\text{H}_2\text{O}(aq)$  are shown at higher enthalpy than the products  $2\text{NaOH}(aq) + \text{H}_2(g)$ . When the reaction occurs, the enthalpy changes, as shown by the downward arrow, whose length equals the heat of reaction.

What is the change of internal energy in this sodium–water reaction? We know that this change is related to the enthalpy of reaction, but there is a small

**Figure 6.12** ▲

**An enthalpy diagram** When 2 mol  $\text{Na}(s)$  and 2 mol  $\text{H}_2\text{O}(l)$  react to give 2 mol  $\text{NaOH}(aq)$  and 1 mol  $\text{H}_2(g)$ , 368.6 kJ of heat is released, and the enthalpy of the system decreases by 368.6 kJ.

correction due to the pressure-volume work. Let's begin by writing the first law of thermodynamics, then substituting  $\Delta H$  for  $q$  and  $-P\Delta V$  for  $w$ :

$$\Delta U = q + w = \Delta H - P\Delta V$$

As we noted in the preceding paragraph, the enthalpy of reaction is  $-368.6$  kJ; earlier we showed that the pressure-volume work done when a system increases in volume by 1 mole of gas at  $25^\circ\text{C}$  and  $1.00$  atm is  $-2.47$  kJ. So, the change of internal energy of the reaction system is

$$\Delta U = -368.6 \text{ kJ} - 2.47 \text{ kJ} = -371.1 \text{ kJ}$$

## 6.4 Thermochemical Equations

We will often find it convenient to write the enthalpy of reaction,  $\Delta H$ , with the chemical equation. A **thermochemical equation** is *the chemical equation for a reaction (including phase labels) in which the equation is given a molar interpretation, and the enthalpy of reaction for these molar amounts is written directly after the equation.* For the reaction of sodium and water, you would write

This equation says that 2 mol of sodium reacts with 2 mol of water to produce 2 mol of sodium hydroxide and 1 mol of hydrogen gas, and 368.6 kJ of heat evolves or is released.

Note that the thermochemical equation includes phase labels. This is because the enthalpy change,  $\Delta H$ , depends on the phases of the substances. Consider the reaction of hydrogen and oxygen to produce water. If the product is water vapor, 2 mol of  $\text{H}_2$  burn to release 483.7 kJ of heat.

On the other hand, if the product is liquid water, the heat released is 571.7 kJ.

In this case, additional heat is released when water vapor condenses to liquid. ◀

It takes 44.0 kJ of heat to vaporize  
1 mol of liquid water at  $25^\circ\text{C}$ .

### Example 6.2 Writing Thermochemical Equations

#### Gaining Mastery Toolbox

##### Critical Concept 6.2

A thermochemical equation is the balanced chemical equation, which is interpreted in molar terms with the enthalpy of reaction,  $\Delta H$ , written directly after it.

##### Solution Essentials:

- Thermochemical equation
- Enthalpy of reaction,  $\Delta H$
- Heat of reaction,  $q$
- Chemical formula from the name
- Balanced chemical equation

Aqueous sodium hydrogen carbonate solution (baking soda solution) reacts with hydrochloric acid to produce aqueous sodium chloride, water, and carbon dioxide gas. The reaction absorbs 12.7 kJ of heat at constant pressure for each mole of sodium hydrogen carbonate. Write the thermochemical equation for the reaction.

**Problem Strategy** Remember that the thermochemical equation is the balanced equation for the reaction, given a molar interpretation, with the enthalpy of reaction written directly after it. You need to translate the names of substances given in the problem statement into their formulas and then balance the equation. (This is an acid–base reaction; refer to Section 4.4 for a discussion.) The problem statement gives you the quantity of heat absorbed (heat is added to the system), so the enthalpy change is a positive quantity. Note too that this is the heat absorbed for each mole of sodium hydrogen carbonate.

**Solution** You first write the balanced chemical equation.

The equation is for 1 mol  $\text{NaHCO}_3$ , with the absorption of 12.7 kJ of heat. The corresponding  $\Delta H$  is  $+12.7$  kJ. The thermochemical equation is

(continued)

**Example 6.2** (continued)

**Answer Check** Check that the formulas of the substances in the equation are correct and that the equation is balanced. Also check that the enthalpy of reaction has the correct sign and that its value is for the correct amount of reactant given in the problem statement (1 mol NaHCO<sub>3</sub>).

**Exercise 6.5** A propellant for rockets is obtained by mixing the liquids hydrazine, N<sub>2</sub>H<sub>4</sub>, and dinitrogen tetroxide, N<sub>2</sub>O<sub>4</sub>. These compounds react to give gaseous nitrogen, N<sub>2</sub>, and water vapor, evolving 1049 kJ of heat at constant pressure when 1 mol N<sub>2</sub>O<sub>4</sub> reacts. Write the thermochemical equation for this reaction.

See Problems 6.57 and 6.58.

The following are two important rules for manipulating thermochemical equations:

1. When a thermochemical equation is multiplied by any factor, the value of  $\Delta H$  for the new equation is obtained by multiplying the value of  $\Delta H$  in the original equation by that same factor.
2. When a chemical equation is reversed, the value of  $\Delta H$  is reversed in sign.

Consider the thermochemical equation for the synthesis of ammonia.

Suppose you want the thermochemical equation to show what happens when twice as many moles of nitrogen and hydrogen react to produce ammonia. Because double the amounts of substances are present, the enthalpy of reaction is doubled (enthalpy is an extensive quantity). Doubling the previous equation, you obtain

Suppose you reverse the first equation we wrote for the synthesis of ammonia. Then the reaction is the dissociation of 2 mol of ammonia into its elements. The thermochemical equation is

If you want to express this in terms of 1 mol of ammonia, you simply multiply this equation by a factor of  $\frac{1}{2}$ . ▶

The next example further illustrates the use of these rules of thermochemical equations.

If you use the molar interpretation of a chemical equation, there is nothing unreasonable about using such coefficients as  $\frac{1}{2}$  and  $\frac{3}{2}$ .

**Example 6.3** Manipulating Thermochemical Equations**Gaining Mastery Toolbox****Critical Concept 6.3**

The rules for manipulating thermochemical equations are: (1) When multiplying an equation by any factor, multiply  $\Delta H$  by the same factor; (2) When reversing an equation, change the sign of  $\Delta H$ .

**Solution Essentials:**

- Rules for manipulating thermochemical equations
- Thermochemical equation
- Enthalpy of reaction,  $\Delta H$
- Heat of reaction,  $q$

When 2 mol H<sub>2</sub>(g) and 1 mol O<sub>2</sub>(g) react to give liquid water, 572 kJ of heat evolves.

Write this equation for 1 mol of liquid water. Give the reverse equation, in which 1 mol of liquid water dissociates into hydrogen and oxygen.

**Problem Strategy** Recall the rules for manipulating thermochemical equations. When you multiply an equation by a factor, you also multiply  $\Delta H$  by the same factor. When you reverse an equation, you multiply  $\Delta H$  by  $-1$ .

(continued)

**Example 6.3** (continued)**Solution** You multiply the coefficients and  $\Delta H$  by  $\frac{1}{2}$ :

Reversing the equation, you get

**Answer Check** If you multiply an equation by a factor, check that every formula and  $\Delta H$  have been multiplied by that factor.**Exercise 6.6** a. Write the thermochemical equation for the reaction described in Exercise 6.5 for the case involving 1 mol  $\text{N}_2\text{H}_4$ .  
b. Write the thermochemical equation for the reverse of the reaction described in Exercise 6.5.

See Problems 6.59, 6.60, 6.61, and 6.62.

 **CONCEPT CHECK 6.3**Natural gas consists primarily of methane,  $\text{CH}_4$ . It is used in a process called *steam reforming* to prepare a gaseous mixture of carbon monoxide and hydrogen for industrial use.

The reverse reaction, the reaction of carbon monoxide and hydrogen, has been explored as a way to prepare methane (synthetic natural gas). Which of the following are exothermic? Of these, which one is the most exothermic?

- a**  $\text{CH}_4(\text{g}) + \text{H}_2\text{O}(\text{g}) \longrightarrow \text{CO}(\text{g}) + 3\text{H}_2(\text{g})$
- b**  $2\text{CH}_4(\text{g}) + 2\text{H}_2\text{O}(\text{g}) \longrightarrow 2\text{CO}(\text{g}) + 6\text{H}_2(\text{g})$
- c**  $\text{CO}(\text{g}) + 3\text{H}_2(\text{g}) \longrightarrow \text{CH}_4(\text{g}) + \text{H}_2\text{O}(\text{g})$
- d**  $2\text{CO}(\text{g}) + 6\text{H}_2(\text{g}) \longrightarrow 2\text{CH}_4(\text{g}) + 2\text{H}_2\text{O}(\text{g})$

**6.5 Applying Stoichiometry to Heats of Reaction**

As you might expect, the quantity of heat obtained from a reaction will depend on the amount of reactants. We can extend the method used to solve stoichiometry problems, described in Chapter 3, to problems involving the quantity of heat.

Consider the reaction of methane,  $\text{CH}_4$  (the principal constituent of natural gas), burning in oxygen at constant pressure. How much heat could you obtain from 10.0 g of methane, assuming you had an excess of oxygen? You can answer this question if you know the enthalpy change for the reaction of 1 mol of methane. The thermochemical equation is

The calculation involves the following conversions:

Grams of  $\text{CH}_4 \longrightarrow$  moles of  $\text{CH}_4 \longrightarrow$  kilojoules of heat

$$10.0 \text{ g } \text{CH}_4 \times \frac{1 \text{ mol } \text{CH}_4}{16.0 \text{ g } \text{CH}_4} \times \frac{-890.3 \text{ kJ}}{1 \text{ mol } \text{CH}_4} = -556 \text{ kJ}$$

You get the conversion factor 1 mol  $\text{CH}_4$ /16.0 g  $\text{CH}_4$  from the molar mass of  $\text{CH}_4$  and the conversion factor  $-890.3 \text{ kJ}/1 \text{ mol } \text{CH}_4$  from the thermochemical equation, which says that 1 mol of  $\text{CH}_4$  evolves 890.3 kJ of heat. Figure 6.14 illustrates the general calculation. ◀

If you wanted the result in kilocalories, you could convert this answer as follows:

$$556 \text{ kJ} \times \frac{1 \text{ kcal}}{4.184 \text{ kJ}} = 133 \text{ kcal}$$

Daily Life

A CHEMIST Looks at . . .

## Lucifers and Other Matches

Samuel Jones, an Englishman, patented one of the first kinds of matches in 1828. It consisted of a glass bead containing sulfuric acid surrounded by a coating of sugar with an oxidizing agent. You ignited the match by breaking the bead using a pair of pliers or, if you were more daring, your teeth. This action released the acid, which ignited an exothermic reaction in the surrounding combustible materials.

Later Jones began to market a friction match discovered, but not patented, by John Walker. Walker, who had been experimenting with explosives, discovered this match one day when he tried to remove a small glob of a dried mixture of antimony sulfide and potassium chlorate from a stick. He rubbed the stick on the floor and was surprised when it burst into flame. Jones called his matches "Lucifers." They were well named; when lighted, they gave off a shower of sparks and smoky fumes with the acrid odor of sulfur dioxide. Jones had every box inscribed with the warning "Persons whose lungs are delicate should by no means use Lucifers."

A few years later, a Frenchman, Charles Sauria, invented the white phosphorus match, which became an immediate success. When rubbed on a rough surface, the match lighted easily, without hazardous sparks, and smelled better than Lucifers. The match head contained white phosphorus, an oxidizing agent, and glue. White phosphorus is a yellowish-white, waxy substance, often sold in the form of sticks looking something like fat crayons. Unlike crayons, though, white phosphorus ignites spontaneously in air (so it is generally stored under water). The glue in the match mixture had two purposes: it protected the white phosphorus from air, and it held the match mixture firmly together. The white phosphorus match had one serious drawback.

White phosphorus is quite poisonous. Workers in match factories often began to show the agonizing symptoms of "phossy jaw," from white phosphorus poisoning, in which the jawbone disintegrates. The manufacture of white phosphorus matches was outlawed in the early 1900s.

The head of the "strike-anywhere" match contains the relatively nontoxic tetraphosphorus trisulfide,  $P_4S_3$ , and potassium chlorate,  $KClO_3$  (Figure 6.13). By rubbing the match head against a surface, you create enough heat to ignite the match. Tetraphosphorus trisulfide then burns in a very exothermic reaction.

Safety matches have a head containing mostly an oxidizing agent and require a striking surface containing nonpoisonous red phosphorus.

The head of the match contains tetraphosphorus trisulfide and potassium chlorate.

The substances in the match head react when frictional heat ignites the mixture.

Figure 6.14 ▲

**Calculating the heat obtained from a reaction** Convert the grams of a reactant or product to moles (using the molar mass). Then convert these moles to kilojoules of heat (using the enthalpy of reaction).

**Example 6.4 Calculating the Heat of Reaction from the Stoichiometry****Gaining Mastery Toolbox****Critical Concept 6.4**

Stoichiometry can be extended to include the heat of reaction; starting from the thermochemical equation, you write the conversion factor from moles of substance to heat of reaction.

**Solution Essentials:**

- Conversion of amount of substance to quantity of heat
- Enthalpy of reaction,  $\Delta H$
- Heat of reaction,  $q$
- Stoichiometry

How much heat is evolved when  $9.07 \times 10^5$  g of ammonia is produced according to the following equation? (Assume that the reaction occurs at constant pressure.)

**Problem Strategy** The calculation involves converting grams of  $\text{NH}_3$  to moles of  $\text{NH}_3$  and then to kilojoules of heat.

You obtain the conversion factor for the second step from the thermochemical equation, which says that the production of 2 mol  $\text{NH}_3$  is accompanied by  $q = -91.8$  kJ.

**Solution**  $9.07 \times 10^5 \text{ g-NH}_3 \times \frac{1 \text{ mol-NH}_3}{17.0 \text{ g-NH}_3} \times \frac{-91.8 \text{ kJ}}{2 \text{ mol-NH}_3} = -2.45 \times 10^6 \text{ kJ}$

Thus,  $2.45 \times 10^6$  kJ of heat evolves.

**Answer Check** Make sure that the units in the calculation cancel to give the units of heat. Also note the sign of  $\Delta H$  to decide whether heat is evolved or absorbed.

**Exercise 6.7** How much heat evolves when 10.0 g of hydrazine reacts according to the reaction described in Exercise 6.5?

See Problems 6.63, 6.64, 6.65, and 6.66.

**6.6 Measuring Heats of Reaction**

So far we have introduced the concept of heat of reaction and have related it to the enthalpy change. We also showed how to display the enthalpy change in a thermochemical equation, and from this equation how to calculate the heat of reaction for any given amount of substance. Now that you have a firm idea of what heats of reaction are, how would you measure them?

First, we need to look at the heat required to raise the temperature of a substance, because a thermochemical measurement is based on the relationship between heat and temperature change. The heat required to raise the temperature of a substance is called its *heat capacity*.

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. WCN 02-200-203

**Heat Capacity and Specific Heat**

Heat is required to raise the temperature of a given amount of substance, and the quantity of heat depends on the temperature change. The **heat capacity** ( $C$ ) of a sample of substance is *the quantity of heat needed to raise the temperature of the sample of substance one degree Celsius (or one kelvin)*. Changing the temperature of the sample from an initial temperature  $t_i$  to a final temperature  $t_f$  requires heat equal to

$$q = C\Delta t$$

where  $\Delta t$  is the change of temperature and equals  $t_f - t_i$ .

Suppose a piece of iron requires 6.70 J of heat to raise the temperature by one degree Celsius. Its heat capacity is therefore 6.70 J/°C. The quantity of heat required to raise the temperature of the piece of iron from 25.0°C to 35.0°C is

$$q = C\Delta t = (6.70 \text{ J/}^\circ\text{C}) \times (35.0^\circ\text{C} - 25.0^\circ\text{C}) = 67.0 \text{ J}$$

The heat capacity will depend on whether the process is constant-pressure or constant-volume. We will assume a constant-pressure process unless otherwise stated.

Heat capacity is directly proportional to the amount of substance. Often heat capacities are listed for molar amounts of substances. The *molar heat capacity* of a substance is its heat capacity for one mole of substance.

Heat capacities are also compared for one-gram amounts of substances. The **specific heat capacity** (or simply **specific heat**) is *the quantity of heat required to raise the temperature of one gram of a substance by one degree Celsius (or one kelvin) at constant pressure*. To find the heat  $q$  required to raise the temperature of a sample, you multiply the specific heat of the substance,  $s$ , by the mass in grams,  $m$ , and the temperature change,  $\Delta t$ .

$$q = s \times m \times \Delta t$$

The specific heats and molar heat capacities of a few substances are listed in Table 6.1. Values depend somewhat on temperature, and those listed are for 25°C. Water has a specific heat of 4.18 J/(g·°C)—that is, 4.18 joules per gram per degree Celsius. In terms of calories, the specific heat of water is 1.00 cal/(g·°C). Example 6.5 illustrates the use of the preceding equation.

**Table 6.1** Specific Heats and Molar Heat Capacities of Some Substances\*

Substance	Specific Heat J/(g·°C)	Molar Heat Capacity J/(mol·°C)
Aluminum, Al	0.901	24.3
Copper, Cu	0.384	24.4
Ethanol, C <sub>2</sub> H <sub>5</sub> OH	2.43	112.2
Iron, Fe	0.449	25.1
Water, H <sub>2</sub> O	4.18	75.3

\*Values are for 25°C.

### Example 6.5 Relating Heat and Specific Heat

#### Gaining Mastery Toolbox

##### Critical Concept 6.5

The heat  $q$  required to raise the temperature  $\Delta t$  of a given mass  $m$  of a substance depends on the substance's specific heat  $s$ ; given any three of these quantities, the fourth one can be calculated.

##### Solution Essentials:

- Equation relating heat to specific heat ( $q = s \times m \times \Delta t$ )
- Specific heat,  $s$
- Heat capacity

Calculate the heat absorbed by 15.0 g of water to raise its temperature from 20.0°C to 50.0°C (at constant pressure). The specific heat of water is 4.18 J/(g·°C).

**Problem Strategy** Note that specific heat is the heat needed to raise the temperature of one gram of substance one degree Celsius. To get the total heat, multiply specific heat by the grams of substance and by the change in degrees Celsius.

**Solution** You substitute into the equation

$$q = s \times m \times \Delta t$$

The temperature change is

$$\Delta t = t_f - t_i = 50.0^\circ\text{C} - 20.0^\circ\text{C} = +30.0^\circ\text{C}$$

Therefore,

$$q = 4.18 \text{ J/(g}\cdot^\circ\text{C)} \times 15.0 \text{ g} \times (+30.0^\circ\text{C)} = \mathbf{1.88 \times 10^3 \text{ J}}$$

**Answer Check** Be sure to put units on quantities in your calculation and to note whether units cancel to give units of heat.

**Exercise 6.8** Iron metal has a specific heat of 0.449 J/(g·°C). How much heat is transferred to a 5.00-g piece of iron, initially at 20.0°C, when it is placed in a pot of boiling water? Assume that the temperature of the water is 100.0°C and that the water remains at this temperature, which is the final temperature of the iron.

See Problems 6.69 and 6.70.

## Measurement of Heat of Reaction

You measure the heat of reaction in a **calorimeter**, *a device used to measure the heat absorbed or evolved during a physical or chemical change*. The device can be as simple as the apparatus sketched in Figure 6.15, which consists of an insulated container (for example, a pair of polystyrene coffee cups) with a thermometer. More elaborate calorimeters are employed when precise measurements are needed for research, although the basic idea remains the same—to measure temperature changes under controlled circumstances and relate these temperature changes to heat.

**Figure 6.15** ▲

**A simple coffee-cup calorimeter** This calorimeter is made of two nested polystyrene coffee cups. The outer cup helps to insulate the reaction mixture from its surroundings. After the reactants are added to the inner cup, the calorimeter is covered to reduce heat loss by evaporation and convection. The heat of reaction is determined by noting the temperature rise or fall.

**Figure 6.16** ▲

**A bomb calorimeter** This type of calorimeter can be used to determine the heat of combustion of a substance. The figure shows a sample of graphite being burned in oxygen within a vessel called the bomb. An electric current passing through the ignition coil starts the graphite burning. The temperature of the water surrounding the bomb rises as heat flows from the exothermic reaction of graphite and oxygen. Example 6.6 illustrates the calculations involved in determining the heat of combustion in such an experiment.

The coffee-cup calorimeter shown in Figure 6.15 is a constant-pressure calorimeter. The heat of the reaction is calculated from the temperature change caused by the reaction, and since this is a constant-pressure process, the heat can be directly related to the enthalpy change,  $\Delta H$ . Research versions of a constant-pressure calorimeter are available, and these are used when gases are not involved.

For reactions involving gases, a *bomb calorimeter* is generally used (Figure 6.16). Consider the heat of combustion of graphite, the form of carbon used in the “lead” of a pencil. To measure the heat released when graphite burns in oxygen, a sample of graphite is placed in a small cup in the calorimeter. The graphite is surrounded by oxygen, and the graphite and oxygen are sealed in a steel vessel, or bomb. An electrical circuit is activated to start the burning of the graphite. The bomb is surrounded by water in an insulated container, and the heat of reaction is calculated from the temperature change of the calorimeter caused by the reaction.

Because the reaction in a bomb calorimeter occurs in a closed vessel, the pressure does not generally remain constant. Rather, the volume remains constant. In this case, the heat of reaction equals the change in internal energy,  $\Delta U$ , and to obtain  $\Delta H$ , a small correction is needed. This correction is normally small and is negligible when the reaction does not involve gases or when the moles of reactant gases equals the moles of product gases, as in the combustion of graphite to carbon dioxide.

The next example describes the calculations needed to obtain the heat of reaction from calorimetric measurements. Note that the heat of reaction in a constant-pressure calorimeter equals the enthalpy of reaction,  $\Delta H$ , whereas the heat of reaction in a bomb (constant volume) calorimeter equals  $\Delta H$  (approximately) only when the moles of gas remain constant.

**Example 6.6 Calculating  $\Delta H$  from Calorimetric Data****Gaining Mastery Toolbox****Critical Concept 6.6**

By running an exothermic reaction in a calorimeter (whose heat capacity is known and whose temperature rise is noted), you can deduce the heat released by the reaction, and from the mass of reactant, you can calculate the heat of reaction (equal to  $\Delta H$ , assuming the moles of gas remain constant).

**Solution Essentials:**

- Equation relating heat to specific heat ( $q = s \times m \times \Delta t$ )
- Specific heat,  $s$
- Heat capacity
- Conversion of amount of substance to quantity of heat
- Thermochemical equation
- Enthalpy of reaction,  $\Delta H$
- Heat of reaction,  $q$
- Stoichiometry

Suppose 0.562 g of graphite is placed in a bomb calorimeter with an excess of oxygen at 25.00°C and 1 atm pressure (Figure 6.16). Excess  $O_2$  ensures that all carbon burns to form  $CO_2$ . The graphite is ignited, and it burns according to the equation

On reaction, the calorimeter temperature rises from 25.00°C to 25.89°C. The heat capacity of the calorimeter and its contents was determined in a separate experiment to be 20.7 kJ/°C. What is the heat of reaction at 25.00°C and 1 atm pressure? Express the answer as a thermochemical equation. (Note that moles of gas remain constant, so the pressure is constant and the heat of reaction is essentially the enthalpy of reaction.)

**Problem Strategy** First, you need to obtain the heat absorbed by the calorimeter when the sample burns, using the calorimeter's temperature rise and its heat capacity. Note that the heat released by reaction of the sample (a negative quantity) equals the heat absorbed by the calorimeter (a positive quantity), except for this sign change. Then, you need to convert this heat to the heat released per mole to obtain  $\Delta H$ .

**Step 1:** To obtain heat absorbed by the calorimeter, you reason as follows. The heat released by the reaction is absorbed by the calorimeter and its contents. Let  $q_{rxn}$  be the quantity of heat from the reaction mixture, and let  $C_{cal}$  be the heat capacity of the calorimeter and contents. The quantity of heat absorbed by the calorimeter is  $C_{cal}\Delta t$ . This will have the same magnitude as  $q_{rxn}$ , but the opposite sign:  $q_{rxn} = -C_{cal}\Delta t$ . Substituting values of  $C_{cal}$  and  $\Delta t$ , you obtain the heat  $q_{rxn}$  from the sample of C (0.562 g).

**Step 2:** Let us now convert the heat  $q_{rxn}$  obtained by burning the sample (0.562 g C) to the heat obtained by burning 1 mol C. This gives us the  $\Delta H$  associated with the chemical equation as written in the problem statement. Note that ( $q_{rxn}/0.562$  g C) is the heat released by 1 g C. It is essentially the factor that converts grams carbon to kJ heat.

We start with 1 mol C, convert it to grams C (using the molar mass of C, 12.0 g/mol), then to kJ heat (using the factor  $q_{rxn}/0.562$  g C); this heat equals  $\Delta H$  for the reaction of graphite with oxygen gas.

**Solution**

**Step 1:** The heat from the graphite sample is

$$\begin{aligned} q_{rxn} &= -C_{cal}\Delta t = -20.7 \text{ kJ}/^\circ\text{C} \times (25.89^\circ\text{C} - 5.00^\circ\text{C}) \\ &= -20.7 \text{ kJ}/^\circ\text{C} \times 0.89^\circ\text{C} = -18.4 \text{ kJ} \end{aligned}$$

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. WCH 02-200-203

An extra figure is retained in  $q_{rxn}$  for further computation. The negative sign indicates that the reaction is exothermic, as expected for a combustion.

**Step 2:** The factor to convert grams C to kJ heat is 18.4 kJ/0.562 g C. The conversion of 1 mol C to kJ heat for 1 mol ( $\Delta H$ ) is

$$1 \text{ mol C} \times \frac{12.0 \text{ g C}}{1 \text{ mol C}} \times \frac{-18.4 \text{ kJ}}{0.562 \text{ g C}} = -3.9 \times 10^2 \text{ kJ}$$

(The final answer has been rounded to two significant figures.) When 1 mol of carbon burns,  $3.9 \times 10^2$  kJ of heat is released. You can summarize the results by the thermochemical equation:

(continued)

**Example 6.6** (continued)

**Answer Check** Go over your calculations carefully. Check that the units within each step cancel properly. Also check that you have the right sign for  $\Delta H$ ; an exothermic reaction will have a negative sign.

**Exercise 6.9** Suppose 33 mL of 1.20 M HCl is added to 42 mL of a solution containing excess sodium hydroxide, NaOH, in a coffee-cup calorimeter. The solution temperature, originally 25.0°C, rises to 31.8°C. Give the enthalpy change,  $\Delta H$ , for the reaction:

Express the answer as a thermochemical equation. For simplicity, assume that the heat capacity and the density of the final solution in the cup are those of water. (In more accurate work, these values must be determined.) Also assume that the total volume of the solution equals the sum of the volumes of HCl(aq) and NaOH(aq).

See Problems 6.73, 6.74, 6.75, and 6.76.

## ► Using Heats of Reaction

In the first part of this chapter, we looked at the basic properties of the heat of reaction and how to measure it. Now we want to find how heats of reaction can be used. We will see that the  $\Delta H$  for one reaction can be obtained from the  $\Delta H$ 's of other reactions. This means that we can tabulate a small number of values and use them to calculate others.

### 6.7 Hess's Law

Enthalpy, you may recall, is a state function (Section 6.3). This means that the enthalpy change for a chemical reaction is independent of the path by which the products are obtained. In 1840, the Russian chemist Germain Henri Hess, a professor at the University of St. Petersburg, discovered this result by experiment. **Hess's law of heat summation** states that *for a chemical equation that can be written as the sum of two or more steps, the enthalpy change for the overall equation equals the sum of the enthalpy changes for the individual steps*. In other words, no matter how you go from given reactants to products (whether in one step or several), the enthalpy change for the overall chemical change is the same.

To understand Hess's law fully and to see how you can use it, consider a simple example. Suppose you would like to find the enthalpy change for the combustion of graphite (carbon) to carbon monoxide.

The direct determination of this enthalpy change is very difficult, because once carbon monoxide forms it reacts further with oxygen to yield carbon dioxide. If you do the experiment in an excess of oxygen, you obtain only carbon dioxide, and the enthalpy change is the heat of complete combustion of graphite. On the other hand, if you do the experiment in a limited quantity of oxygen, you obtain a mixture of carbon monoxide and carbon dioxide, and the heat of reaction is a value appropriate for a mixture of these products. How can you obtain the enthalpy change for the preparation of pure carbon monoxide from graphite and oxygen?

The answer is to apply Hess's law. To do this, imagine that the combustion of graphite to carbon monoxide takes place in two separate steps:

In the first step, you burn 2 mol of graphite in 2 mol of oxygen to produce 2 mol of carbon dioxide. In the second step, you decompose this carbon dioxide to give 2 mol of carbon monoxide and 1 mol of oxygen. The net result is the combustion of 2 mol of graphite in 1 mol of oxygen to give 2 mol of carbon monoxide. You can obtain this result by adding the two steps, canceling out 2 mol  $\text{CO}_2$  and 1 mol  $\text{O}_2$  on both sides of the equation.

According to Hess's law, the enthalpy change for the overall equation (which is the equation you want) equals the sum of the enthalpy changes for the two steps. Now you need to determine the enthalpy changes for the separate steps.

You can determine the enthalpy change for the first step by simply burning graphite in an excess of oxygen, as described in Example 6.6. The result is  $\Delta H = -393.5 \text{ kJ}$  per mole of  $\text{CO}_2$  formed. For 2 mol  $\text{CO}_2$ , you multiply by 2.

The second step, the decomposition of carbon dioxide, is not an easy experiment. However, the reverse of this decomposition is simply the combustion of carbon monoxide. You could determine the  $\Delta H$  for that combustion by burning carbon monoxide in an excess of oxygen. The experiment is similar to the one for the combustion of graphite to carbon dioxide.

From the properties of thermochemical equations (Section 6.4), you know that the enthalpy change for the reverse reaction is simply  $(-1)$  times the original reaction.

If you now add these two steps and add their enthalpy changes, you obtain the chemical equation and the enthalpy change for the combustion of carbon to carbon monoxide, which is what you wanted.

You see that the combustion of 2 mol of graphite to give 2 mol of carbon monoxide has an enthalpy change of  $-221.0 \text{ kJ}$ . Figure 6.17 gives an enthalpy diagram showing the relationships among the enthalpy changes for this calculation.

This calculation illustrates how you can use Hess's law to obtain the enthalpy change for a reaction that is difficult to determine by direct experiment. Hess's law

**Figure 6.17** ◀

**Enthalpy diagram illustrating Hess's law** The diagram shows two different ways to go from graphite and oxygen (reactants) to carbon monoxide (products). Going by way of reactions 1 and 2 is equivalent to the direct reaction 3.

We have followed common convention in writing S for the formula of sulfur in Equations 1 and 3, although the molecular formula is S<sub>8</sub>. Doing this gives much simpler equations. You might try to do the calculations again, rewriting the equations using S<sub>8</sub> for sulfur. Remember to multiply the value of ΔH in each case by 8.

is more generally useful, however, in that it allows you to calculate the enthalpy change for one reaction from the values for others, whatever their source. Suppose you are given the following data: ◀

How could you use these data to obtain the enthalpy change for the following equation?

You need to multiply Equations 1 and 2 by factors (perhaps reversing one or both equations) so that when you add them together you obtain Equation 3. You can usually guess what you need to do to the first two equations to obtain the third one. Note that Equation 3 has a coefficient of 2 for S(s). This suggests that you should multiply Equation 1 by 2 (and multiply the ΔH by 2). Note also that SO<sub>3</sub>(g) in Equation 3 is on the right-hand side. This suggests that you should reverse Equation 2 (and multiply the ΔH by -1). Here is the calculation:

The next example gives another illustration of how Hess's law can be used to calculate the enthalpy change for a reaction from the enthalpy values for other reactions. In this case, the problem involves three equations from which we obtain a fourth. Although this problem is somewhat more complicated than the one we just did, the basic procedure is the same: Compare the coefficients in the equations. See what factors you need to multiply the equations whose ΔH's you know to obtain the equation you want. Check your results to be sure that the equations (and the ΔH's) add up properly.

### Example 6.7 Applying Hess's Law

#### Gaining Mastery Toolbox

##### Critical Concept 6.7

The ΔH for one reaction can be obtained from the ΔH's of other reactions by applying Hess's law: For a chemical equation that can be written as a sum of two or more steps, the enthalpy change for the overall equation equals the sum of the enthalpy changes for the individual steps.

##### Solution Essentials:

- Hess's law
- Rules for manipulating thermochemical equations
- Thermochemical equation
- Enthalpy of reaction, ΔH
- Heat of reaction, q

What is the enthalpy of reaction, ΔH, for the formation of tungsten carbide, WC, from the elements? (Tungsten carbide is very hard and is used to make cutting tools and rock drills.)

The enthalpy change for this reaction is difficult to measure directly, because the reaction occurs at 1400°C. However, the heats of combustion of the elements and of tungsten carbide can be measured easily:

**Problem Strategy** Note that Equations 1, 2, and 3 involve the reactants and products for the desired reaction (as well as their enthalpy changes). You apply Hess's law to these equations, perhaps reversing an equation or multiplying it by a factor, so that when you add all of them together, you obtain the desired equation.

First, look to see whether any equation needs to be reversed to get a reactant or product on the correct side. If you do reverse an equation, remember to change the sign of its ΔH. Second, to obtain the multiplicative factor for each equation, compare that equation with the desired one. For instance, note that Equation 1 has 2W(s) on the left side, whereas the desired equation has W(s) on the left. Therefore, you divide Equation 1 (and its ΔH) by 2, or multiply by the factor 1/2.

(continued)

**Example 6.7** (continued)

**Solution** Do any equations need to be reversed? Note that you want to end up with W(s) and C(graphite) on the left side and with WC(s) on the right side of the final equation (the formation of WC from its elements). Equation 1 has W(s) on the left, as required after the addition of the equations. Similarly, Equation 2 has C(graphite) on the left, as required. However, Equation 3 has WC(s) on the left, but it should be on the right. Therefore, you reverse Equation 3 (and multiply its  $\Delta H$  by  $-1$ ).

To obtain the multiplicative factor for each equation, you compare Equations 1, 2, and 3', in turn, with the desired equation. We did this earlier (at the end of the Problem Strategy) for Equation 1. Multiplying it by  $\frac{1}{2}$ , you obtain

Compare Equation 2 with the desired equation. Both have C(graphite) on the left side; therefore, you leave Equation 2 as it is.

Now, compare Equation 3' with the desired equation. Equation 3' has 2WC(s) on the right side, whereas the desired equation has WC(s) on the right side. Therefore, you multiply Equation 3' (and its  $\Delta H$ ) by  $\frac{1}{2}$ .

Now add these last three equations and their corresponding  $\Delta H$ 's.

**Answer Check** Check that when you add the three equations, substances that do not appear in the final one cancel correctly. For example, note that  $\frac{3}{2}\text{O}_2(g)$  and  $\text{O}_2(g)$  on the left sides of the equations cancel  $\frac{5}{2}\text{O}_2(g)$  on the right side. Then check that the final equation is the one asked for.

**Exercise 6.10** Manganese metal can be obtained by reaction of manganese dioxide with aluminum.

What is  $\Delta H$  for this reaction? Use the following data:

See Problems 6.77, 6.78, 6.79, and 6.80.

**CONCEPT CHECK 6.4**

The heat of fusion (also called heat of melting),  $\Delta H_{fus}$ , of ice is the enthalpy change for

Similarly, the heat of vaporization,  $\Delta H_{vap}$ , of liquid water is the enthalpy change for

How is the heat of sublimation,  $\Delta H_{sub}$ , the enthalpy change for the reaction

related to  $\Delta H_{fus}$  and  $\Delta H_{vap}$ ?

## 6.8 Standard Enthalpies of Formation

Because Hess's law relates the enthalpy changes of some reactions to the enthalpy changes of others, we only need to tabulate the enthalpy changes of certain types of reactions. We also generally list enthalpy changes only for certain standard thermodynamic conditions (which are not identical to the standard conditions for gases, STP).

The term **standard state** refers to *the standard thermodynamic conditions chosen for substances when listing or comparing thermodynamic data: 1 atm pressure and the specified temperature (usually 25°C)*. ◀ These standard conditions are indicated by a superscript degree sign (°). The enthalpy change for a reaction in which reactants in their standard states yield products in their standard states is denoted  $\Delta H^\circ$  ("delta H degree," but often read as "delta H zero"). The quantity  $\Delta H^\circ$  is called the *standard enthalpy of reaction*.

As we will show, it is sufficient to tabulate just the enthalpy changes for formation reactions—that is, for reactions in which compounds are formed from their elements. To specify the formation reaction precisely, however, we must specify the exact form of each element.

Some elements exist in the same physical state (gas, liquid, or solid) in two or more distinct forms. For example, oxygen in any of the physical states occurs both as dioxygen (commonly called simply oxygen), with  $O_2$  molecules, and as ozone, with  $O_3$  molecules. Dioxygen gas is odorless; ozone gas has a characteristic pungent odor. Solid carbon has two principal crystalline forms: graphite and diamond. Graphite is a soft, black, crystalline substance; diamond is a hard, usually colorless crystal. The elements oxygen and carbon are said to exist in different allotropic forms. An **allotrope** is *one of two or more distinct forms of an element in the same physical state* (Figure 6.18).

The **reference form** of an element for the purpose of specifying the formation reaction is usually *the stablest form (physical state and allotrope) of the element under standard thermodynamic conditions*. The reference form of oxygen at 25°C is  $O_2(g)$ ; the reference form of carbon at 25°C is graphite. ◀

Table 6.2 lists standard enthalpies of formation of substances and ions (a longer table is given in Appendix C). The **standard enthalpy of formation** (also called the **standard heat of formation**) of a substance, denoted  $\Delta H_f^\circ$ , is *the enthalpy change for the formation of one mole of the substance in its standard state from its elements in their reference form and in their standard states*.

To understand this definition, consider the standard enthalpy of formation of liquid water. Note that the stablest forms of hydrogen and oxygen at 1 atm and 25°C are  $H_2(g)$  and  $O_2(g)$ , respectively. These are therefore the reference forms of the elements. You write the formation reaction for 1 mol of liquid water as follows:

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. WCN 02-200-203

The International Union of Pure and Applied Chemistry (IUPAC) recommends that the standard pressure be 1 bar ( $1 \times 10^5$  Pa). Thermodynamic tables are becoming available for 1 bar pressure, and in the future such tables will probably replace those for 1 atm.

Although the reference form is usually the stablest allotrope of an element, the choice is essentially arbitrary as long as one is consistent.

**Figure 6.18** ▶

**Allotropes of sulfur** *Left:* An evaporating dish contains rhombic sulfur, the stable form of the element at room temperature. *Right:* When this sulfur is melted, then cooled, it forms long needles of monoclinic sulfur, another allotrope. At room temperature, monoclinic sulfur will slowly change back to rhombic sulfur. Both forms contain the molecule  $S_8$ , depicted by the model.

\*See Appendix C for additional values.

The standard enthalpy change for this reaction is  $-285.8$  kJ per mole of  $\text{H}_2\text{O}$ . Therefore, the thermochemical equation is

The values of standard enthalpies of formation listed in Table 6.2 and in other tables are determined by direct measurement in some cases and by applying Hess's law in others. Oxides, such as water, can often be determined by direct calorimetric measurement of the combustion reaction. If you look back at Example 6.7, you will see an illustration of how Hess's law can be used to obtain the enthalpy of formation of tungsten carbide, WC.

Note that the standard enthalpy of formation of an element will depend on the form of the element. For example, the  $\Delta H_f^\circ$  for diamond equals the enthalpy change from the stablest form of carbon (graphite) to diamond. The thermochemical equation is

On the other hand, the  $\Delta H_f^\circ$  for graphite equals zero. Note the values of  $\Delta H_f^\circ$  for the elements listed in Table 6.2; the reference forms have zero values.

Now let us see how to use standard enthalpies of formation (listed in Table 6.2) to find the standard enthalpy change for a reaction. We will first look at this problem from the point of view of Hess's law. But when we are finished, we will note a pattern in the result, which will allow us to state a simple mathematical formula for solving this type of problem.

Consider the equation

From Table 6.2, you find the enthalpies of formation for  $\text{CH}_4(g)$ ,  $\text{CCl}_4(l)$ , and  $\text{HCl}(g)$ . You can then write the following thermochemical equations:

You now apply Hess's law. Since you want  $\text{CH}_4$  to appear on the left, and  $\text{CCl}_4$  and  $4\text{HCl}$  on the right, you reverse Equation 1 and add Equation 2 and  $4 \times$  Equation 3.

The setup of this calculation can be greatly simplified once you closely examine what you are doing. Note that the  $\Delta H_f^\circ$  for each compound is multiplied by its coefficient in the chemical equation whose  $\Delta H^\circ$  you are calculating. Moreover, the  $\Delta H_f^\circ$  for each reactant is multiplied by a negative sign. You can symbolize the enthalpy of formation of a substance by writing the formula in parentheses following  $\Delta H_f^\circ$ . Then your calculation can be written as follows:

$$\begin{aligned} \Delta H^\circ &= [\Delta H_f^\circ(\text{CCl}_4) + 4 \Delta H_f^\circ(\text{HCl})] - [\Delta H_f^\circ(\text{CH}_4) + 4 \Delta H_f^\circ(\text{Cl}_2)] \\ &= [(-135.4) + 4(-92.3)] \text{ kJ} - [(-74.9) + 4(0)] \text{ kJ} = -429.7 \text{ kJ} \end{aligned}$$

In general, you can calculate the  $\Delta H^\circ$  for a reaction by the equation

$$\Delta H^\circ = \sum n \Delta H_f^\circ(\text{products}) - \sum m \Delta H_f^\circ(\text{reactants})$$

Here  $\Sigma$  is the mathematical symbol meaning "the sum of," and  $m$  and  $n$  are the coefficients of the substances in the chemical equation.

The next two examples illustrate the calculation of enthalpies of reaction from standard enthalpies of formation.

### Example 6.8 Calculating the Heat of Phase Transition from Standard Enthalpies of Formation

#### Gaining Mastery Toolbox

##### Critical Concept 6.8

The standard enthalpy for a phase change (such as that for vaporization,  $\Delta H_{\text{vap}}^\circ$ ) equals the standard enthalpy of formation,  $\Delta H_f^\circ$ , of the final phase minus the similar quantity for the initial phase.

Use values of  $\Delta H_f^\circ$  to calculate the heat of vaporization,  $\Delta H_{\text{vap}}^\circ$ , of carbon disulfide at  $25^\circ\text{C}$ . The vaporization process is

(continued)

**Example 6.8** (continued)**Solution Essentials:**

- Relation of enthalpy of reaction to enthalpies of formation:  
 $\Delta H^\circ = \sum n \Delta H_f^\circ(\text{products}) - \sum m \Delta H_f^\circ(\text{reactants})$
- Standard enthalpy of formation,  $\Delta H_f^\circ$
- Enthalpy of reaction,  $\Delta H$
- Heat of reaction,  $q$

**Problem Strategy** The vaporization process can be treated like a chemical reaction, with the liquid as the “reactant” and the vapor as the “product.” It is convenient to record the values of  $\Delta H_f^\circ$  under the formulas in the equation, multiplying them by the coefficients in the equation. You calculate  $\Delta H_{\text{vap}}^\circ$  by subtracting values for the “reactant” from values for the “product.”

**Solution** Here is the equation for the vaporization, with values of  $\Delta H_f^\circ$  multiplied by coefficients (here, all 1's).

The calculation is

$$\begin{aligned} \Delta H_{\text{vap}}^\circ &= \sum n \Delta H_f^\circ(\text{products}) - \sum m \Delta H_f^\circ(\text{reactants}) \\ &= \Delta H_f^\circ[\text{CS}_2(g)] - \Delta H_f^\circ[\text{CS}_2(l)] \\ &= (116.9 - 89.7) \text{ kJ} = \mathbf{27.2 \text{ kJ}} \end{aligned}$$

**Answer Check** Review your arithmetic carefully. Note that vaporization requires adding heat, so the enthalpy change should be positive.

**Exercise 6.11** Calculate the heat of vaporization,  $\Delta H_{\text{vap}}^\circ$ , of water, using standard enthalpies of formation (Table 6.2).

See Problems 6.83 and 6.84.

**Example 6.9** Calculating the Enthalpy of Reaction from Standard Enthalpies of Formation**Gaining Mastery Toolbox****Critical Concept 6.9**

The standard enthalpy change for a reaction,  $\Delta H^\circ$ , can be calculated by subtracting the standard enthalpies of formation,  $\Delta H_f^\circ$ , of the reactants from similar quantities of the products.

**Solution Essentials:**

- Relation of enthalpy of reaction to enthalpies of formation:  
 $\Delta H^\circ = \sum n \Delta H_f^\circ(\text{products}) - \sum m \Delta H_f^\circ(\text{reactants})$
- Standard enthalpy of formation,  $\Delta H_f^\circ$
- Enthalpy of reaction,  $\Delta H$
- Heat of reaction,  $q$

Large quantities of ammonia are used to prepare nitric acid. The first step consists of the catalytic oxidation of ammonia to nitric oxide, NO.

What is the standard enthalpy change for this reaction? Use Table 6.2 for data.

**Problem Strategy** You record the values of  $\Delta H_f^\circ$  under the formulas in the equation, multiplying them by the coefficients in the equation. You calculate  $\Delta H^\circ$  by subtracting values for the reactants from values for the products.

**Solution** Here is the equation with the  $\Delta H_f^\circ$ 's recorded beneath it:

The calculation is

$$\begin{aligned} \Delta H^\circ &= \sum n \Delta H_f^\circ(\text{products}) - \sum m \Delta H_f^\circ(\text{reactants}) \\ &= [4 \Delta H_f^\circ(\text{NO}) + 6 \Delta H_f^\circ(\text{H}_2\text{O})] - [4 \Delta H_f^\circ(\text{NH}_3) + 5 \Delta H_f^\circ(\text{O}_2)] \\ &= [4(90.3) + 6(-241.8)] \text{ kJ} - [4(-45.9) + 5(0)] \text{ kJ} \\ &= \mathbf{-906 \text{ kJ}} \end{aligned}$$

**Answer Check** Be very careful of arithmetical signs—they are a likely source of mistakes. Also pay particular attention to the state of each substance. Here, for example, you must use the  $\Delta H_f^\circ$  for  $\text{H}_2\text{O}(g)$ , not for  $\text{H}_2\text{O}(l)$ .

**Exercise 6.12** Calculate the enthalpy change for the following reaction:

Use standard enthalpies of formation.

See Problems 6.85, 6.86, 6.87, and 6.88.

Enthalpies of formation can also be defined for ions. It is not possible to make thermal measurements on individual ions, so we must arbitrarily define the standard enthalpy of formation of one ion as zero. Then values for all other ions can be deduced from calorimetric data. The standard enthalpy of formation of  $\text{H}^+(\text{aq})$  is taken as zero. Values of  $\Delta H_f^\circ$  for some ions are given in Table 6.2.

**Exercise 6.13** Calculate the standard enthalpy change for the reaction of an aqueous solution of barium hydroxide,  $\text{Ba}(\text{OH})_2$ , with an aqueous solution of ammonium nitrate,  $\text{NH}_4\text{NO}_3$ , at  $25^\circ\text{C}$ . (Figure 6.1 illustrated this reaction using solids instead of solutions.) The complete ionic equation is

See Problems 6.89 and 6.90.

## 6.9 Fuels—Foods, Commercial Fuels, and Rocket Fuels

A *fuel* is any substance that is burned or similarly reacted to provide heat and other forms of energy. The earliest use of fuels for heat came with the control of fire, which was achieved perhaps 400,000 years ago. This major advance allowed the human species to migrate from tropical savannas and eventually to inhabit most of the earth. Through cooking, fire also increased the variety of edible food supplies and provided some protection of the food from bacterial decay. During the mid-eighteenth century, the discovery of the steam engine, which converts the chemical energy latent in fuels to mechanical energy, ushered in the Industrial Revolution. Today fuels not only heat our homes and move our cars but are absolutely necessary for every facet of modern technology. For example, fuels generate the electricity required for our modern computing and communications technologies, and they propel the rocket engines that make possible our explorations of outer space. In this section, we will look at foods as fuels; at fossil fuels (which include gas, oil, and coal); at coal gasification and liquefaction; and at rocket fuels.

### Foods as Fuels

Foods fill three needs of the body: they supply substances for the growth and repair of tissue, they supply substances for the synthesis of compounds used in the regulation of body processes, and they supply energy. About 80% of the energy we need is for heat. The rest is used for muscular action, chemical processes, and other body processes. ◀

The body generates energy from food by the same overall process as combustion, so the overall enthalpy change is the same as the heat of combustion, which can be determined in a calorimeter. You can get some idea of the energy available from carbohydrate foods by looking at a typical one, glucose ( $\text{C}_6\text{H}_{12}\text{O}_6$ ). The thermochemical equation for the combustion of glucose is

One gram of glucose yields 15.6 kJ (3.73 kcal) of heat when burned.

A representative fat is glyceryl trimyristate,  $\text{C}_{45}\text{H}_{86}\text{O}_6$ . The equation for its combustion is

One gram of this fat yields 38.5 kJ (9.20 kcal) of heat when burned. The average values quoted for carbohydrates and fats are 4.0 kcal/g and 9.0 kcal/g, respectively. ◀ Note that fats contain more than twice the fuel value per gram as do carbohydrates. Thus, by storing its fuel as fat, the body can store more fuel for a given mass of body tissue.

### Fossil Fuels

All of the fossil fuels in existence today were created millions of years ago when aquatic plants and animals were buried and compressed by layers of sediment at the bottoms of

The human body requires about as much energy in a day as does a 100-watt lightbulb.

In the popular literature of nutrition, the kilocalorie is referred to as the Calorie (capital C). Thus, these values are given as 4.0 Calories and 9.0 Calories.

swamps and seas. Over time this organic matter was converted by bacterial decay and pressure to petroleum (oil), gas, and coal. Figure 6.19 gives the percentages of the total energy consumed in the United States from various sources. Fossil fuels account for over 80% of the total.

Anthracite, or hard coal, the oldest variety of coal, was laid down as long as 250 million years ago and may contain over 80% carbon. Bituminous coal, a younger variety of coal, has between 45% and 65% carbon. Fuel values of coals are rated in Btu's (British thermal units) per pound, which are essentially heats of combustion per pound of coal. A typical value is 13,200 Btu/lb. A Btu equals 1054 J, so 1 Btu/lb equals 2.32 J/g. Therefore, the combustion of coal in oxygen yields about 30.6 kJ/g. You can compare this value with the heat of combustion of pure carbon (graphite).

The value given in the equation is for 1 mol (12.0 g) of carbon. Per gram, you get 32.8 kJ/g, which is comparable with the values obtained for coal.

Natural gas and petroleum together account for nearly two-thirds of the fossil fuels consumed per year. They are very convenient fluid fuels, being easily transportable and having no ash. Purified natural gas is primarily methane,  $\text{CH}_4$ , but it also contains small amounts of ethane,  $\text{C}_2\text{H}_6$ ; propane,  $\text{C}_3\text{H}_8$ ; and butane,  $\text{C}_4\text{H}_{10}$ . We would expect the fuel values of natural gas to be close to that for the heat of combustion of methane:

This value of  $\Delta H^\circ$  is equivalent to 50.1 kJ per gram of fuel.

Petroleum is a very complicated mixture of compounds. Gasoline, which is obtained from petroleum by chemical and physical processes, contains many different hydrocarbons (compounds of carbon and hydrogen). One such hydrocarbon is octane,  $\text{C}_8\text{H}_{18}$ . The combustion of octane evolves 5074 kJ of heat per mole.

This value of  $\Delta H^\circ$  is equivalent to 44.4 kJ/g. These combustion values indicate another reason why the fluid fossil fuels are popular: they release more heat per gram than coal does.

### Coal Gasification and Liquefaction

The major problem with petroleum and natural gas as fuels is their relative short supply. It has been estimated that petroleum supplies will be depleted sometime this century. Natural-gas supplies may last somewhat longer.

Coal supplies, on the other hand, are sufficient to last perhaps several centuries. This abundance has spurred much research into developing commercial methods for converting coal to the more easily handled liquid and gaseous fuels. Most of these methods begin by converting coal to carbon monoxide,  $\text{CO}$ . One way involves the water-gas reaction.

In this reaction, steam is passed over hot coal. Once a mixture of carbon monoxide and hydrogen is obtained, it can be transformed by various reactions into useful products. For example, in the methanation reaction (discussed at length in Chapter 14), this mixture is reacted over a catalyst to give methane.

Different catalysts and different reaction conditions result in liquid fuels. An added advantage of coal gasification and coal liquefaction is that sulfur, normally present

Figure 6.19 ▲

Sources of energy consumed in the United States (2013) Data are from *Monthly Energy Review On-line*, <http://www.eia.gov/mer>

in fossil fuels, can be removed during the process. The burning of sulfur-containing coal is a major source of air pollution and acid rain.

### Rocket Fuels

Rockets are self-contained missiles propelled by the ejection of gases from an orifice. Usually these are hot gases propelled from the rocket by the reaction of a fuel with an oxidizer. Rockets are believed to have originated with the Chinese—perhaps before the thirteenth century, which is when they began to appear in Europe. However, it was not until the twentieth century that rocket propulsion began to be studied seriously, and since World War II rockets have become major weapons. Space exploration with satellites propelled by rocket engines began in 1957 with the Russian satellite *Sputnik I*. Today weather and communications satellites are regularly put into orbit about the earth using rocket engines.

One of the factors determining which fuel and oxidizer to use is the mass of the fuel and oxidizer required. We have already seen that natural gas and gasoline have higher fuel values per gram than does coal. The difference is caused by the higher hydrogen content of natural gas and gasoline. Hydrogen is the element of lowest density, and at the same time it reacts exothermically with oxygen to give water. You might expect hydrogen and oxygen to be an ideal fuel–oxidizer combination. The thermochemical equation for the combustion of hydrogen is

This value of  $\Delta H^\circ$  is equivalent to 120 kJ/g of fuel ( $\text{H}_2$ ) compared with 50 kJ/g of methane. The second and third stages of the *Saturn V* launch vehicle that sent a three-man Apollo crew to the moon used a hydrogen/oxygen system. (The first lunar landing was in 1969.) The launch vehicle contained liquid hydrogen (boiling at  $-253^\circ\text{C}$ ) and liquid oxygen, or LOX (boiling at  $-183^\circ\text{C}$ ).

The first stage of liftoff used kerosene and oxygen, and an unbelievable 550 metric tons ( $550 \times 10^3 \text{ kg}$ ) of kerosene were burned in 2.5 minutes! It is interesting to calculate the average rate of energy production in this 2.5-minute interval. Kerosene is approximately  $\text{C}_{12}\text{H}_{26}$ . The thermochemical equation is

This value of  $\Delta H^\circ$  is equivalent to 44.1 kJ/g. Thus,  $550 \times 10^6 \text{ g}$  of fuel generated  $2.43 \times 10^{10} \text{ kJ}$  in 150 s (2.5 min). Each second, the average energy produced was  $1.62 \times 10^{11} \text{ J}$ . This is equivalent to  $1.62 \times 10^{11} \text{ watts}$ , or 217 million horsepower (1 horsepower equals 745.7 watts, or J/s).

The landing module for the Apollo mission used a fuel made of hydrazine,  $\text{N}_2\text{H}_4$ , and a derivative of hydrazine. The oxidizer was dinitrogen tetroxide,  $\text{N}_2\text{O}_4$ . These substances are normally liquids and are therefore easier to store than liquid hydrogen and oxygen. The reaction of the oxidizer with hydrazine is

Solid propellants are also used as rocket fuels. Indeed, until the twentieth century, rockets used solid propellants composed of gunpowder (a mixture of potassium nitrate, sulfur, and charcoal). Although solid propellants have the disadvantage that once ignited they continue to burn so rockets using them are less controllable than liquid-propellant rockets, they are simple and relatively inexpensive. The *Space Shuttle*, a manned launch vehicle used by NASA (but discontinued in 2011), employed solid-propellant booster rockets for initial liftoff. These rockets used a propellant mixture of ammonium perchlorate,  $\text{NH}_4\text{ClO}_4$ , and aluminum powder bonded together with a polymer. NASA has replaced the Space Shuttle program with its *Space Launch System* (SLS), with the purpose of exploring outer space. The launch vehicle will also employ solid-propellant booster rockets (Figure 6.20).

Figure 6.20 ▲

**The launch of an SLS rocket.** (An artist's rendition.) The rocket boosters use a solid-state propellant.

## A Checklist for Review

### Summary of Facts and Concepts

Energy exists in various forms, including *kinetic energy* and *potential energy*. The SI unit of energy is the *joule* (1 calorie = 4.184 joules). The *internal energy* of a substance is the sum of the kinetic energies and potential energies of the particles making up the substance. According to the *law of conservation of energy*, the total quantity of energy remains constant.

Reactions absorb or evolve definite quantities of heat under given conditions. At constant pressure, this *heat of reaction* is the *enthalpy of reaction*,  $\Delta H$ . The chemical equation plus  $\Delta H$  for molar amounts of reactants is referred to as the *thermochemical equation*. With it, you can calculate

the heat for any amount of substance by *applying stoichiometry to heats of reaction*. One measures the heat of reaction in a *calorimeter*. Direct calorimetric determination of the heat of reaction requires a reaction that goes to completion without other reactions occurring at the same time. Otherwise, the heat or enthalpy of reaction is determined indirectly from other enthalpies of reaction by using *Hess's law of heat summation*. Thermochemical data are conveniently tabulated as *enthalpies of formation*. If you know the values for each substance in an equation, you can easily compute the enthalpy of reaction. As an application of thermochemistry, the last section of the chapter discusses fuels.

### Learning Objectives

### Important Terms

#### 6.1 Energy and Its Units

- Define *energy*, *kinetic energy*, *potential energy*, and *internal energy*.
- Define the SI unit of energy *joule*, as well as the common unit of energy *calorie*.
- Calculate the kinetic energy of a moving object.  
**Example 6.1**
- State the law of conservation of energy.

energy  
kinetic energy  
joule (J)  
calorie (cal)  
potential energy  
internal energy  
law of conservation of energy

#### 6.2 First Law of Thermodynamics; Work and Heat

- Define a thermodynamic system and its surroundings.
- Define *work* and *heat*.
- Define the change of internal energy of a system.
- Express the *first law of thermodynamics* verbally and mathematically.

thermodynamic system (or system)  
surroundings  
work  
heat  
state function  
first law of thermodynamics

#### 6.3 Heat of Reaction; Enthalpy of Reaction

- Define the heat of reaction.
- Distinguish between an exothermic process and an endothermic process.  
Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. WCN 02-200-203
- Describe *pressure-volume work* verbally and mathematically.
- Define enthalpy and enthalpy of reaction.
- Relate the heat of reaction at constant pressure and the enthalpy of reaction.

heat of reaction  
exothermic process  
endothermic process  
pressure-volume work  
enthalpy  
enthalpy of reaction

#### 6.4 Thermochemical Equations

- Define a *thermochemical equation*.
- Write a thermochemical equation given pertinent information. **Example 6.2**
- Learn the two rules for manipulating (reversing and multiplying) thermochemical equations.
- Manipulate a thermochemical equation using these rules. **Example 6.3**

thermochemical equation

**6.5 Applying Stoichiometry to Heats of Reaction**

- Calculate the heat absorbed or evolved from a reaction given its enthalpy of reaction and the mass of a reactant or product. **Example 6.4**

**6.6 Measuring Heats of Reaction**

- Define *heat capacity* and *specific heat*.
- Relate the heat absorbed or evolved to the specific heat, mass, and temperature change.
- Calculate the heat involved in changing the temperature of a material, given its specific heat. **Example 6.5**
- Define *calorimeter*.
- Calculate the enthalpy of reaction from calorimetric data (its temperature change and heat capacity). **Example 6.6**

**heat capacity**  
**specific heat capacity (specific heat)**  
**calorimeter**

**6.7 Hess's Law**

- State Hess's law of heat summation.
- Apply Hess's law to obtain the enthalpy change for one reaction from the enthalpy changes of a number of other reactions. **Example 6.7**

**Hess's law of heat summation**

**6.8 Standard Enthalpies of Formation**

- Define *standard state* and *reference form*.
- Define *standard enthalpy of formation*.
- Calculate the heat of a phase transition using standard enthalpies of formation for the different phases. **Example 6.8**
- Calculate the heat (enthalpy) of reaction from the standard enthalpies of formation of the substances in the reaction. **Example 6.9**

**standard state**  
**allotrope**  
**reference form**  
**standard enthalpy of formation (standard heat of formation)**

**6.9 Fuels—Foods, Commercial Fuels, and Rocket Fuels**

- Define *fuel*.
- Describe the three needs of the body that are fulfilled by foods.
- Give the approximate average values quoted (per gram) for the heat values (heats of combustion) for fats and for carbohydrates.
- List the three major fossil fuels.
- Describe the processes of coal gasification and coal liquefaction.
- Describe some fuel–oxidizer systems used in rockets.

**Key Equations**

$$E_k = \frac{1}{2}mv^2$$

$$1 \text{ cal} = 4.184 \text{ J}$$

$$\Delta U = q + w$$

$$w = -P\Delta V$$

$$H = U + PV$$

$$q = \Delta H \text{ (At fixed pressure and a given temperature)}$$

$$q = C \Delta t$$

$$q = s \times m \times \Delta t$$

$$\Delta H^\circ = \sum n \Delta H_f^\circ(\text{products}) - \sum m \Delta H_f^\circ(\text{reactants})$$

## Questions and Problems

### Self-Assessment and Review Questions

**Key:** These questions test your understanding of the ideas you worked with in the chapter. These problems vary in difficulty and often can be used for the basis of discussion.

6.1 Define *energy*, *kinetic energy*, *potential energy*, and *internal energy*.

6.2 Define the joule in terms of SI base units.

6.3 What is the original definition of the calorie? What is the present definition?

6.4 Describe the interconversions of potential and kinetic energy in a moving pendulum. A moving pendulum eventually comes to rest. Has the energy been lost? If not, what has happened to it?

6.5 Suppose heat flows into a vessel containing a gas. As the heat flows into the gas, what happens to the gas molecules? What happens to the internal energy of the gas?

6.6 Define an *exothermic* reaction and an *endothermic* reaction. Give an example of each.

6.7 The internal energy of a substance is a state function. What does this mean?

6.8 Under what condition is the enthalpy change equal to the heat of reaction?

6.9 How does the enthalpy change for an endothermic reaction occurring at constant pressure?

6.10 Why is it important to give the states of the reactants and products when giving an equation for  $\Delta H$ ?

6.11 If an equation for a reaction is doubled and then reversed, how is the value of  $\Delta H$  changed?

6.12 Consider the reaction of methane,  $\text{CH}_4$ , with oxygen,  $\text{O}_2$ , discussed in Section 6.5. How would you set up the calculation if the problem had been to compute the heat if 10.0 g  $\text{H}_2\text{O}$  were produced (instead of 10.0 g  $\text{CH}_4$  reacted)?

6.13 Define the heat capacity of a substance. Define the specific heat of a substance.

6.14 Describe a simple calorimeter. What measurements are needed to determine the heat of reaction?

6.15 What property of enthalpy provides the basis of Hess's law? Explain.

6.16 You discover that you cannot carry out a particular reaction for which you would like the enthalpy change. Does this mean that you will be unable to obtain this enthalpy change? Explain.

6.17 What is meant by the thermodynamic standard state?

6.18 What is meant by the reference form of an element? What is the standard enthalpy of formation of an element in its reference form?

6.19 What is meant by the standard enthalpy of formation of a substance?

6.20 Write the chemical equation for the formation reaction of  $\text{H}_2\text{S}(g)$ .

6.21 Is the following reaction the appropriate one to use in determining the enthalpy of formation of methane,  $\text{CH}_4(g)$ ? Why or why not?

6.22 What is a fuel? What are the fossil fuels?

6.23 Give chemical equations for the conversion of carbon in coal to methane,  $\text{CH}_4$ .

6.24 List some rocket fuels and corresponding oxidizers. Give thermochemical equations for the exothermic reactions of these fuels with the oxidizers.

6.25 The equation for the combustion of 2 mol of butane can be written

Which of the following produces the *least* heat?

a Burning 1 mol of butane.

b Reacting 1 mol of oxygen with excess butane.

c Burning enough butane to produce 1 mol of carbon dioxide.

d Burning enough butane to produce 1 mol of water.

e All of the above reactions (a, b, c, and d) produce the same amount of heat.

6.26 A 5.0-g sample of water starting at  $60.0^\circ\text{C}$  loses 418 J of energy in the form of heat. What is the *final* temperature of the water after this heat loss?

a  $20.^\circ\text{C}$

b  $40.^\circ\text{C}$

c  $50.^\circ\text{C}$

d  $60.^\circ\text{C}$

e  $80.^\circ\text{C}$

6.27 Hypothetical elements  $\text{A}_2$  and  $\text{B}_2$  react according to the following equation, forming the compound AB.

If solutions  $\text{A}_2(aq)$  and  $\text{B}_2(aq)$ , starting at the same temperature, are mixed in a coffee-cup calorimeter, the reaction that occurs is

a exothermic, and the temperature of the resulting solution rises.

b endothermic, and the temperature of the resulting solution rises.

c endothermic, and the temperature of the resulting solution falls.

d exothermic, and the temperature of the resulting solution falls.

e exothermic or endothermic, depending on the original and final temperatures.

6.28 Consider the following specific heats of metals.

Metal	Specific Heat
copper	0.385 J/(g $\cdot$ °C)
magnesium	1.02 J/(g $\cdot$ °C)
mercury	0.138 J/(g $\cdot$ °C)
silver	0.237 J/(g $\cdot$ °C)

Four 25-g samples, one of each metal, and four insulated containers with identical water volumes, all start out at room temperature. Now suppose you add exactly the same quantity of heat to each metal sample. Then you place the hot metal samples in different containers of water (that all have the same volume of water). Which of the answers below is true?

a The water with the copper will be the hottest.

b The water with the magnesium will be the hottest.

c The water with the mercury will be the hottest.

d The water with the silver will be the hottest.

e The temperature of the water will be the same in all the cups.

## Concept Explorations

**Key:** Concept explorations are comprehensive problems that provide a framework that will enable you to explore and learn many of the critical concepts and ideas in each chapter. If you master the concepts associated with these explorations, you will have a better understanding of many important chemistry ideas and will be more successful in solving all types of chemistry problems. These problems are well suited for group work and for use as in-class activities.

### 6.29 Thermal Interactions

**Part 1:** In an insulated container, you mix 200. g of water at 80°C with 100. g of water at 20°C. After mixing, the temperature of the water is 60°C.

- How much did the temperature of the hot water change? How much did the temperature of the cold water change? Compare the magnitudes (positive values) of these changes.
- During the mixing, how did the heat transfer occur: from hot water to cold, or from cold water to hot?
- What quantity of heat was transferred from one sample to the other?
- How does the quantity of heat transferred to or from the hot-water sample compare with the quantity of heat transferred to or from the cold-water sample?
- Knowing these relative quantities of heat, why is the temperature change of the cold water greater than the magnitude of the temperature change of the hot water.
- A sample of hot water is mixed with a sample of cold water that has twice its mass. Predict the temperature change of each of the samples.
- You mix two samples of water, and one increases by 20°C, while the other drops by 60°C. Which of the samples has less mass? How do the masses of the two water samples compare?
- A 7-g sample of hot water is mixed with a 3-g sample of cold water. How do the temperature changes of the two water samples compare?

**Part 2:** A sample of water is heated from 10°C to 50°C. Can you calculate the amount of heat added to the water sample that caused this temperature change? If not, what information do you need to perform this calculation?

**Part 3:** Two samples of water are heated from 20°C to 60°C. One of the samples requires twice as much heat to bring about this temperature change as the other. How do the masses of the two water samples compare? Explain your reasoning.

### 6.30 Enthalpy

- A 100.-g sample of water is placed in an insulated container and allowed to come to room temperature at 21°C. To heat the water sample to 41°C, how much heat must you add to it?
- Consider the hypothetical reaction,

- being run in an insulated container that contains 100. g of solution. If the temperature of the solution changes from 21°C to 31°C, how much heat does the chemical reaction produce? How does this answer compare with that in part a? (You can assume that this solution is so dilute that it has the same heat capacity as pure water.)
- If you wanted the temperature of 100. g of this solution to increase from 21°C to 51°C, how much heat would you have to add to it? (Try to answer this question without using a formula.)
- If you had added 0.02 mol of X and 0.01 mol of Y to form the solution in part b, how many moles of X and Y would you need to bring about the temperature change described in part c.
- Judging on the basis of your answers so far, what is the enthalpy of the reaction  $2X(aq) + Y(l) \longrightarrow X_2Y(aq)$ ?

## Conceptual Problems

**Key:** These problems are designed to check your understanding of the concepts associated with some of the main topics presented in each chapter. A strong conceptual understanding of chemistry is the foundation for both applying chemical knowledge and solving chemical problems. These problems vary in level of difficulty and often can be used as a basis for group discussion.

**6.31** Chemical reactions are run in each of the beakers depicted below (labeled A, B, and C). The magnitude and direction of heat and work for each reaction are represented as arrows, with the length of an arrow depicting the relative magnitude of the heat or work.

For the reaction in each beaker, answer the following and explain your reasoning:

- Is the reaction endothermic or exothermic?
- What is the sign (+ or -) of the work?
- What is the sign (+ or -) of the enthalpy of each reaction?
- Is there an increase or decrease in internal energy?
- What is the temperature of the reaction mixture immediately after the reaction when compared to room temperature?

**6.32** Shown below is a diagram depicting the enthalpy change of a chemical reaction run at constant pressure.

- a Is the reaction exothermic or endothermic?
- b What is the sign of  $\Delta H$ ?
- c What is the sign of  $q$ ?
- d If the reaction does no work, what is the sign of  $\Delta E$  for this process?

**6.33** A small car is traveling at twice the speed of a larger car, which has twice the mass of the smaller car. Which car has the greater kinetic energy? (Or do they both have the same kinetic energy?)

**6.34** The equation for the combustion of butane,  $C_4H_{10}$ , is

$$C_4H_{10}(g) + \frac{13}{2}O_2(g) \longrightarrow 4CO_2(g) + 5H_2O(g)$$

Which one of the following generates the least heat? Why?

- a Burning one mole of butane
- b Reacting one mole of oxygen with excess butane
- c Producing one mole of carbon dioxide by burning butane
- d Producing one mole of water by burning butane

**6.35** A 250-g sample of water at  $20.0^\circ C$  is placed in a freezer that is held at a constant temperature of  $-20.0^\circ C$ . Considering the water as the “system,” answer the following questions:

- a What is the sign of  $q_{sys}$  for the water after it is placed in the freezer?
- b After a few hours, what will be the state of the water?
- c How will the initial enthalpy for the water compare with the final enthalpy of the water after it has spent several hours in the freezer?
- d What will the temperature of the water be after several hours in the freezer?

**6.36** A 20.0-g block of iron at  $50.0^\circ C$  and a 20.0 g block of aluminum at  $45^\circ C$  are placed in contact with each other. Assume that heat is only transferred between the two blocks.

- a Draw an arrow indicating the heat flow between the blocks.
- b What is the sign of  $q_{sys}$  for the aluminum when the blocks first come into contact?
- c What will you observe when  $q_{sys}$  for the iron is zero?
- d Estimate the temperature of the Al and Fe blocks when  $q_{sys}$  of the iron equals  $q_{sys}$  of the aluminum.

**6.37** What is the enthalpy change for the preparation of one mole of liquid water from the elements, given the following equations?

**6.38** A block of aluminum and a block of iron, both having the same mass, are removed from a freezer and placed outside on a warm day. When the same quantity of heat has flowed into each block, which block will be warmer? Assume that neither block has yet reached the outside temperature. (See Table 6.1 for the specific heats of the metals.)

**6.39** You have two samples of different metals, metal A and metal B, each having the same mass. You heat both metals to  $95^\circ C$  and then place each one into separate beakers containing the same quantity of water at  $25^\circ C$ .

- a You measure the temperatures of the water in the two beakers when each metal has cooled by  $10^\circ C$  and find that the temperature of the water with metal A is higher than the temperature of the water with metal B. Which metal has the greater specific heat? Explain.
- b After waiting a period of time, the temperature of the water in each beaker rises to a maximum value. In which beaker does the water temperature rise to the higher value, the one with metal A or the one with metal B? Explain.

**6.40** Consider the reactions of silver metal,  $Ag(s)$ , with each of the halogens: fluorine,  $F_2(g)$ , chlorine,  $Cl_2(g)$ , and bromine,  $Br_2(l)$ . What chapter data could you use to decide which reaction is most exothermic? Which reaction is that?

**6.41** Tetraphosphorus trisulfide,  $P_4S_3$ , burns in excess oxygen to give tetraphosphorus decoxide,  $P_4O_{10}$ , and sulfur dioxide,  $SO_2$ . Suppose you have measured the enthalpy change for this reaction. How could you use it to obtain the enthalpy of formation of  $P_4S_3$ ? What other data do you need?

**6.42** A soluble salt,  $MX_2$ , is added to water in a beaker. The equation for the dissolving of the salt is:

- a Immediately after the salt dissolves, is the solution warmer or colder?
- b Indicate the direction of heat flow, in or out of the beaker, while the salt dissolves.
- c After the salt dissolves and the water returns to room temperature, what is the value of  $q$  for the system?

## Practice Problems

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. WCN 02-200-203

**Key:** These problems are for practice in applying problem-solving skills. They are divided by topic, and some are keyed to exercises (see the ends of the exercises). The problems are arranged in matching pairs; the odd-numbered problem of each pair is listed first, and its answer is given in the back of the book.

### Energy and Its Units

**6.43** Methane,  $CH_4$ , is a major component of marsh gas. When 0.5000 mol methane burns to produce carbon dioxide and liquid water,  $-445.1$  kJ of heat is released. What is this heat in kilocalories?

**6.44** Hydrogen sulfide,  $H_2S$ , is produced during decomposition of organic matter. When 0.5000 mol  $H_2S$  burns to

produce  $SO_2(g)$  and  $H_2O(l)$ ,  $-281.0$  kJ of heat is released. What is this heat in kilocalories?

**6.45** A car whose mass is  $5.30 \times 10^3$  lb is traveling at a speed of 57 miles per hour. What is the kinetic energy of the car in joules? in calories? See Table 1.4 for conversion factors.

**6.46** A bullet weighing 235 grains is moving at a speed of  $2.52 \times 10^3$  ft/s. Calculate the kinetic energy of the bullet in joules and in calories. One grain equals 0.0648 g.

**6.47** Chlorine dioxide,  $ClO_2$ , is a reddish yellow gas used in bleaching paper pulp. The average speed of a  $ClO_2$  molecule at  $25^\circ C$  is 306 m/s. What is the kinetic energy (in joules) of a  $ClO_2$  molecule moving at this speed?

**6.48** Nitrous oxide,  $\text{N}_2\text{O}$ , has been used as a dental anesthetic. The average speed of an  $\text{N}_2\text{O}$  molecule at  $25^\circ\text{C}$  is 379 m/s. Calculate the kinetic energy (in joules) of an  $\text{N}_2\text{O}$  molecule traveling at this speed.

### First Law of Thermodynamics

**6.49** A gas is cooled and loses 82 J of heat. The gas contracts as it cools, and work done on the system equal to 29 J is exchanged with the surroundings. What are  $q$ ,  $w$ , and  $\Delta U$ ?

**6.50** An ideal gas expands isothermally (at constant temperature). The internal energy of an ideal gas remains constant during an isothermal change. If  $q$  is  $-76$  J, what are  $\Delta U$  and  $w$ ?

### Heat of Reaction

**6.51** The process of dissolving ammonium nitrate,  $\text{NH}_4\text{NO}_3$ , in water is an endothermic process. What is the sign of  $q$ ? If you were to add some ammonium nitrate to water in a flask, would you expect the flask to feel warm or cool?

**6.52** The decomposition of ozone,  $\text{O}_3$ , to oxygen,  $\text{O}_2$ , is an exothermic reaction. What is the sign of  $q$ ? If you were to touch a flask in which ozone is decomposing to oxygen, would you expect the flask to feel warm or cool?

**6.53** Nitric acid, a source of many nitrogen compounds, is produced from nitrogen dioxide. An old process for making nitrogen dioxide employed nitrogen and oxygen.

The reaction absorbs 66.2 kJ of heat per 2 mol  $\text{NO}_2$  produced. Is the reaction endothermic or exothermic? What is the value of  $q$ ?

**6.54** Hydrogen cyanide is used in the manufacture of clear plastics such as Lucite and Plexiglas. It is prepared from ammonia and natural gas ( $\text{CH}_4$ ).

The reaction evolves 469 kJ of heat per mol of HCN formed. Is the reaction endothermic or exothermic? What is the value of  $q$  when 2 mol HCN forms?

**6.55** What is  $\Delta U$  when 1.00 mol of liquid water vaporizes at  $100^\circ\text{C}$ ? The heat of vaporization,  $\Delta H_{\text{vap}}^\circ$ , of water at  $100^\circ\text{C}$  is 40.66 kJ/mol.

**6.56** What is  $\Delta U$  for the following reaction at  $25^\circ\text{C}$ ?

### Thermochemical Equations

**6.57** When 1 mol of iron metal reacts with hydrochloric acid at constant temperature and pressure to produce hydrogen gas and aqueous iron(II) chloride, 89.1 kJ of heat evolves. Write a thermochemical equation for this reaction.

**6.58** When 2 mol of potassium chlorate crystals decompose to potassium chloride crystals and oxygen gas at constant temperature and pressure, 78.0 kJ of heat is given off. Write a thermochemical equation for this reaction.

**6.59** When white phosphorus burns in air, it produces phosphorus(V) oxide.

What is  $\Delta H$  for the following equation?

**6.60** Carbon disulfide burns in air, producing carbon dioxide and sulfur dioxide.

What is  $\Delta H$  for the following equation?

**6.61** Phosphoric acid,  $\text{H}_3\text{PO}_4$ , can be prepared by the reaction of phosphorus(V) oxide,  $\text{P}_4\text{O}_{10}$ , with water.

What is  $\Delta H$  for the reaction involving 1 mol of  $\text{P}_4\text{O}_{10}$ ?

**6.62** With a platinum catalyst, ammonia will burn in oxygen to give nitric oxide, NO.

$$\Delta H = -906 \text{ kJ}$$

What is the enthalpy change for the following reaction?

### Stoichiometry of Reaction Heats

**6.63** Colorless nitric oxide, NO, combines with oxygen to form nitrogen dioxide,  $\text{NO}_2$ , a brown gas.

What is the enthalpy change per gram of nitric oxide?

**6.64** Hydrogen,  $\text{H}_2$ , is used as a rocket fuel. The hydrogen is burned in oxygen to produce water vapor.

What is the enthalpy change per kilogram of hydrogen?

**6.65** Ammonia burns in the presence of a copper catalyst to form nitrogen gas.

$$\Delta H = -1267 \text{ kJ}$$

What is the enthalpy change to burn 48.1 g of ammonia?

**6.66** Hydrogen sulfide,  $\text{H}_2\text{S}$ , is a foul-smelling gas. It burns to form sulfur dioxide.

Calculate the enthalpy change to burn 27.4 g of hydrogen sulfide.

**6.67** Propane,  $\text{C}_3\text{H}_8$ , is a common fuel gas. Use the following to calculate the grams of propane you would need to provide 369 kJ of heat.

**6.68** Ethanol,  $\text{C}_2\text{H}_5\text{OH}$ , is mixed with gasoline and sold as gasohol. Use the following to calculate the grams of ethanol needed to provide 429 kJ of heat.

### Heat Capacity and Calorimetry

**6.69** You wish to heat water to make coffee. How much heat (in joules) must be used to raise the temperature of 0.180 kg of tap water (enough for one cup of coffee) from  $30^\circ\text{C}$  to  $96^\circ\text{C}$  (near the ideal brewing temperature)? Assume the specific heat is that of pure water,  $4.18 \text{ J}/(\text{g} \cdot ^\circ\text{C})$ .

**6.70** An iron skillet weighing 1.63 kg is heated on a stove to  $178^\circ\text{C}$ . Suppose the skillet is cooled to room temperature,  $21^\circ\text{C}$ . How much heat energy (in joules) must be removed to affect this cooling? The specific heat of iron is  $0.449 \text{ J}/(\text{g} \cdot ^\circ\text{C})$ .

**6.71** When steam condenses to liquid water, 2.26 kJ of heat is released per gram. The heat from 168 g of steam is used to heat a room containing  $6.44 \times 10^4 \text{ g}$  of air ( $20 \text{ ft} \times 12 \text{ ft} \times 8 \text{ ft}$ ). The specific heat of air at normal pressure is  $1.015 \text{ J}/(\text{g} \cdot ^\circ\text{C})$ . What is the change in air temperature, assuming the heat from the steam is all absorbed by air?

**6.72** When ice at  $0^\circ\text{C}$  melts to liquid water at  $0^\circ\text{C}$ , it absorbs 0.334 kJ of heat per gram. Suppose the heat needed to melt 38.0 g of ice is absorbed from the water contained in a glass. If this water has a mass of 0.210 kg and a temperature of  $21.0^\circ\text{C}$ , what is the final temperature of the water? (Note that you will also have 38.0 g of water at  $0^\circ\text{C}$  from the ice.)

**6.73** When 15.3 g of sodium nitrate,  $\text{NaNO}_3$ , was dissolved in water in a constant-pressure calorimeter, the temperature fell from  $25.00^\circ\text{C}$  to  $21.56^\circ\text{C}$ . If the heat capacity of the solution and the calorimeter is  $1071 \text{ J}/^\circ\text{C}$ , what is the enthalpy change when 1 mol of sodium nitrate dissolves in water? The solution process is

**6.74** When 23.6 g of calcium chloride,  $\text{CaCl}_2$ , was dissolved in water in a constant-pressure calorimeter, the temperature rose from  $25.0^\circ\text{C}$  to  $38.7^\circ\text{C}$ . If the heat capacity of the solution and the calorimeter is  $1258 \text{ J}/^\circ\text{C}$ , what is

the enthalpy change when 0.710 mol of calcium chloride dissolves in water? The solution process is

**6.75** A sample of ethanol,  $\text{C}_2\text{H}_5\text{OH}$ , weighing 2.84 g was burned in an excess of oxygen in a bomb calorimeter. The temperature of the calorimeter rose from  $25.00^\circ\text{C}$  to  $33.73^\circ\text{C}$ . If the heat capacity of the calorimeter and contents was  $9.63 \text{ kJ}/^\circ\text{C}$ , what is the value of  $q$  for burning 1.00 mol of ethanol at constant volume and  $25.00^\circ\text{C}$ ? The reaction is

Is  $q$  equal to  $\Delta U$  or  $\Delta H$ ?

**6.76** A sample of benzene,  $\text{C}_6\text{H}_6$ , weighing 3.51 g was burned in an excess of oxygen in a bomb calorimeter. The temperature of the calorimeter rose from  $25.00^\circ\text{C}$  to  $37.18^\circ\text{C}$ . If the heat capacity of the calorimeter and contents was  $12.05 \text{ kJ}/^\circ\text{C}$ , what is the value of  $q$  for burning 1.00 mol of benzene at constant volume and  $25.00^\circ\text{C}$ ? The reaction is

Is  $q$  equal to  $\Delta U$  or  $\Delta H$ ?

### Hess's Law

**6.77** Hydrazine,  $\text{N}_2\text{H}_4$ , is a colorless liquid used as a rocket fuel. What is the enthalpy change for the process in which hydrazine is formed from its elements?

Use the following reactions and enthalpy changes:

**6.78** Hydrogen peroxide,  $\text{H}_2\text{O}_2$ , is a colorless liquid whose solutions are used as a bleach and an antiseptic.  $\text{H}_2\text{O}_2$  can be prepared in a process whose overall change is

Calculate the enthalpy change using the following data:

**6.79** Ammonia will burn in the presence of a platinum catalyst to produce nitric oxide, NO.

What is the heat of reaction at constant pressure? Use the following thermochemical equations:

**6.80** Hydrogen cyanide is a highly poisonous, volatile liquid. It can be prepared by the reaction

What is the heat of reaction at constant pressure? Use the following thermochemical equations:

**6.81** Compounds with carbon-carbon double bonds, such as ethylene,  $\text{C}_2\text{H}_4$ , add hydrogen in a reaction called hydrogenation.

Calculate the enthalpy change for this reaction, using the following combustion data:

**6.82** Acetic acid,  $\text{CH}_3\text{COOH}$ , is contained in vinegar. Suppose acetic acid was formed from its elements, according to the following equation:

Find the enthalpy change,  $\Delta H$ , for this reaction, using the following data:

### Standard Enthalpies of Formation

**6.83** The cooling effect of alcohol on the skin is due to its evaporation. Calculate the heat of vaporization of ethanol (ethyl alcohol),  $\text{C}_2\text{H}_5\text{OH}$ .

The standard enthalpy of formation of  $\text{C}_2\text{H}_5\text{OH}(\text{l})$  is  $-277.7 \text{ kJ/mol}$  and that of  $\text{C}_2\text{H}_5\text{OH}(\text{g})$  is  $-235.1 \text{ kJ/mol}$ .

**6.84** Carbon tetrachloride,  $\text{CCl}_4$ , is a liquid used as an industrial solvent and in the preparation of fluorocarbons. What is the heat of vaporization of carbon tetrachloride?

Use standard enthalpies of formation (Table 6.2).

**6.85** Hydrogen sulfide gas is a poisonous gas with the odor of rotten eggs. It occurs in natural gas and is produced dur-

ing the decay of organic matter, which contains sulfur. The gas burns in oxygen as follows:

Calculate the standard enthalpy change for this reaction using standard enthalpies of formation.

**6.86** Carbon disulfide is a colorless liquid. When pure, it is nearly odorless, but the commercial product smells vile. Carbon disulfide is used in the manufacture of rayon and cellophane. The liquid burns as follows:

Calculate the standard enthalpy change for this reaction using standard enthalpies of formation.

**6.87** Iron is obtained from iron ore by reduction with carbon monoxide. The overall reaction is

Calculate the standard enthalpy change for this equation. See Appendix C for data.

**6.88** The first step in the preparation of lead from its ore (galena,  $\text{PbS}$ ) consists of roasting the ore.

Calculate the standard enthalpy change for this reaction, using enthalpies of formation (see Appendix C).

**6.89** Hydrogen chloride gas dissolves in water to form hydrochloric acid (an ionic solution).

Find  $\Delta H^\circ$  for the above reaction. The data are given in Table 6.2.

**6.90** Carbon dioxide from the atmosphere “weathers,” or dissolves, limestone ( $\text{CaCO}_3$ ) by the reaction

Obtain  $\Delta H^\circ$  for this reaction. See Table 6.2 for the data.

**6.91** The Group 2A carbonates decompose when heated. For example,

Use enthalpies of formation (see Appendix C) and calculate the heat required to decompose 10.0 g of magnesium carbonate.

**6.92** The Group 2A carbonates decompose when heated. For example,

Use enthalpies of formation (see Appendix C) and calculate the heat required to decompose 6.50 g of barium carbonate.

## General Problems

**Key:** These problems provide more practice but are not divided by topic or keyed to exercises. Each section ends with essay questions, each of which is color coded to refer to the *A Chemist Looks at Daily Life* (orange) chapter essay on which it is based. Odd-numbered problems and the even-numbered problems that follow are similar; answers to

all odd-numbered problems except the essay questions are given in the back of the book.

**6.93** The energy,  $E$ , needed to move an object a distance  $d$  by applying a force  $F$  is  $E = F \times d$ . What must be the SI unit of force if this equation is to be consistent with the SI unit of energy for  $E$ ?

**6.94** The potential energy of an object in the gravitational field of the earth is  $E_p = mgh$ . What must be the SI unit of  $g$  if this equation is to be consistent with the SI unit of energy for  $E_p$ ?

**6.95** Liquid hydrogen peroxide has been used as a propellant for rockets. Hydrogen peroxide decomposes into oxygen and water, giving off heat energy equal to 686 Btu per pound of propellant. What is this energy in joules per gram of hydrogen peroxide? (1 Btu = 252 cal; see also Table 1.4.)

**6.96** Hydrogen is an ideal fuel in many respects; for example, the product of its combustion, water, is nonpolluting. The heat given off in burning hydrogen to gaseous water is  $5.16 \times 10^4$  Btu per pound. What is this heat energy in joules per gram? (1 Btu = 252 cal; see also Table 1.4.)

**6.97** Niagara Falls has a height of 167 ft (American Falls). What is the potential energy in joules of 1.00 lb of water at the top of the falls if we take water at the bottom to have a potential energy of zero? What would be the speed of this water at the bottom of the falls if we neglect friction during the descent of the water?

Warren Jacobi/Corbis

**6.98** Any object, be it a space satellite or a molecule, must attain an initial upward velocity of at least 11.2 km/s in order to escape the gravitational attraction of the earth. What would be the kinetic energy in joules of a satellite weighing 2458 lb that has the speed equal to this escape velocity of 11.2 km/s?

NASA

**6.99** When calcium carbonate,  $\text{CaCO}_3$  (the major constituent of limestone and seashells), is heated, it decomposes to calcium oxide (quicklime).

How much heat is required to decompose 21.3 g of calcium carbonate?

**6.100** Calcium oxide (quicklime) reacts with water to produce calcium hydroxide (slaked lime).

The heat released by this reaction is sufficient to ignite paper. How much heat is released when 28.6 g of calcium oxide reacts?

**6.101** Formic acid,  $\text{HCHO}_2$ , was first discovered in ants (*formica* is Latin for “ant”). In an experiment, 5.48 g of formic acid was burned at constant pressure.

If 30.3 kJ of heat evolved, what is  $\Delta H$  per mole of formic acid?

**6.102** Acetic acid,  $\text{HC}_2\text{H}_3\text{O}_2$ , is the sour constituent of vinegar (*acetum* is Latin for “vinegar”). In an experiment, 3.58 g of acetic acid was burned.

If 52.0 kJ of heat evolved, what is  $\Delta H$  per mole of acetic acid?

**6.103** Suppose you mix 19.8 g of water at  $80.0^\circ\text{C}$  with 54.7 g of water at  $29.0^\circ\text{C}$  in an insulated cup. What is the maximum temperature of the water after mixing?

**6.104** Suppose you mix 23.6 g of water at  $66.2^\circ\text{C}$  with 45.4 g of water at  $35.7^\circ\text{C}$  in an insulated cup. What is the maximum temperature of the solution after mixing?

**6.105** A piece of lead of mass 121.6 g was heated by an electrical coil. From the resistance of the coil, the current, and the time the current flowed, it was calculated that 235 J of heat was added to the lead. The temperature of the lead rose from  $20.4^\circ\text{C}$  to  $35.5^\circ\text{C}$ . What is the specific heat of the lead?

**6.106** The specific heat of copper metal was determined by putting a piece of the metal weighing 35.4 g in hot water. The quantity of heat absorbed by the metal was calculated to be 47.0 J from the temperature drop of the water. What was the specific heat of the metal if the temperature of the metal rose  $3.45^\circ\text{C}$ ?

**6.107** A 44.3 g sample of water at  $100.00^\circ\text{C}$  was placed in an insulated cup. Then 25.4 g of zinc metal at  $29.80^\circ\text{C}$  was added to the water. The temperature of the water dropped to  $96.50^\circ\text{C}$ . What is the specific heat of zinc?

**6.108** A 19.6-g sample of a metal was heated to  $61.67^\circ\text{C}$ . When the metal was placed into 26.7 g of water in a calorimeter, the temperature of the water increased from  $25.00^\circ\text{C}$  to  $30.61^\circ\text{C}$ . What is the specific heat of the metal?

**6.109** A 21.3-mL sample of 0.977 M NaOH is mixed with 29.5 mL of 0.918 M HCl in a coffee-cup calorimeter (see Section 6.6 of your text for a description of a coffee-cup calorimeter). The enthalpy of the reaction, written with the lowest whole-number coefficients, is  $-55.8 \text{ kJ}$ . Both solutions are at  $19.6^\circ\text{C}$  prior to mixing and reacting. What is the final temperature of the reaction mixture? When solving this problem, assume that no heat is lost from the calorimeter to the surroundings, the density of all solutions is 1.00 g/mL, the specific heat of all solutions is the same as that of water, and volumes are additive.

**6.110** A 29.1-mL sample of 1.05 M KOH is mixed with 20.9 mL of 1.07 M HBr in a coffee-cup calorimeter (see Section 6.6 of your text for a description of a coffee-cup

calorimeter). The enthalpy of the reaction, written with the lowest whole-number coefficients, is  $-55.8$  kJ. Both solutions are at  $21.8^\circ\text{C}$  prior to mixing and reacting. What is the final temperature of the reaction mixture? When solving this problem, assume that no heat is lost from the calorimeter to the surroundings, the density of all solutions is  $1.00$  g/mL, and volumes are additive.

**6.111** In a calorimetric experiment,  $6.48$  g of lithium hydroxide,  $\text{LiOH}$ , was dissolved in water. The temperature of the calorimeter rose from  $25.00^\circ\text{C}$  to  $36.66^\circ\text{C}$ . What is  $\Delta H$  for the solution process?

The heat capacity of the calorimeter and its contents is  $547$  J/°C.

**6.112** When  $21.45$  g of potassium nitrate,  $\text{KNO}_3$ , was dissolved in water in a calorimeter, the temperature fell from  $25.00^\circ\text{C}$  to  $14.14^\circ\text{C}$ . What is the  $\Delta H$  for the solution process?

The heat capacity of the calorimeter and its contents is  $682$  J/°C.

**6.113** A  $10.00$ -g sample of acetic acid,  $\text{HC}_2\text{H}_3\text{O}_2$ , was burned in a bomb calorimeter in an excess of oxygen.

The temperature of the calorimeter rose from  $25.00^\circ\text{C}$  to  $35.84^\circ\text{C}$ . If the heat capacity of the calorimeter and its contents is  $13.43$  kJ/°C, what is the enthalpy change for the reaction?

**6.114** The sugar arabinose,  $\text{C}_5\text{H}_{10}\text{O}_5$ , is burned completely in oxygen in a calorimeter.

Burning a  $0.548$ -g sample caused the temperature to rise from  $20.00^\circ\text{C}$  to  $20.54^\circ\text{C}$ . The heat capacity of the calorimeter and its contents is  $15.8$  kJ/°C. Calculate  $\Delta H$  for the combustion reaction per mole of arabinose.

**6.115** Hydrogen sulfide,  $\text{H}_2\text{S}$ , is a poisonous gas with the odor of rotten eggs. The reaction for the formation of  $\text{H}_2\text{S}$  from the elements is

Use Hess's law to obtain the enthalpy change for this reaction from the following enthalpy changes:

**6.116** Ethylene glycol,  $\text{HOCH}_2\text{CH}_2\text{OH}$ , is used as anti-freeze. It is produced from ethylene oxide,  $\text{C}_2\text{H}_4\text{O}$ , by the reaction

Use Hess's law to obtain the enthalpy change for this reaction from the following enthalpy changes:

**6.117** Hydrogen,  $\text{H}_2$ , is prepared by *steam reforming*, in which hydrocarbons are reacted with steam. For  $\text{CH}_4$ ,

Calculate the enthalpy change  $\Delta H^\circ$  for this reaction, using standard enthalpies of formation.

**6.118** Hydrogen is prepared from natural gas (mainly methane,  $\text{CH}_4$ ) by partial oxidation.

Calculate the enthalpy change  $\Delta H^\circ$  for this reaction, using standard enthalpies of formation.

**6.119** Calcium oxide,  $\text{CaO}$ , is prepared by heating calcium carbonate (from limestone and seashells).

Calculate the standard enthalpy of reaction, using enthalpies of formation. The  $\Delta H_f^\circ$  of  $\text{CaO}(s)$  is  $-635$  kJ/mol. Other values are given in Table 6.2.

**6.120** Sodium carbonate,  $\text{Na}_2\text{CO}_3$ , is used to manufacture glass. It is obtained from sodium hydrogen carbonate,  $\text{NaHCO}_3$ , by heating.

Calculate the standard enthalpy of reaction, using enthalpies of formation (Table 6.2).

**6.121** Calculate the heat released when  $2.395$  L  $\text{O}_2$  with a density of  $1.11$  g/L at  $25^\circ\text{C}$  reacts with an excess of hydrogen to form liquid water at  $25^\circ\text{C}$ .

**6.122** Calculate the heat released when  $5.000$  L  $\text{Cl}_2$  with a density of  $2.46$  g/L at  $25^\circ\text{C}$  reacts with an excess of sodium metal to form solid sodium chloride at  $25^\circ\text{C}$ .

**6.123** Sucrose,  $\text{C}_{12}\text{H}_{22}\text{O}_{11}$ , is common table sugar. The enthalpy change at  $25^\circ\text{C}$  and  $1$  atm for the complete burning of  $1$  mol of sucrose in oxygen to give  $\text{CO}_2(g)$  and  $\text{H}_2\text{O}(l)$  is  $-5641$  kJ. From this and from data given in Table 6.2, calculate the standard enthalpy of formation of sucrose.

**6.124** Acetone,  $\text{CH}_3\text{COCH}_3$ , is a liquid solvent. The enthalpy change at  $25^\circ\text{C}$  and  $1$  atm for the complete burning of  $1$  mol of acetone in oxygen to give  $\text{CO}_2(g)$  and  $\text{H}_2\text{O}(l)$  is  $-1791$  kJ. From this and from data given in Table 6.2, calculate the standard enthalpy of formation of acetone.

**6.125** Ammonium nitrate is an oxidizing agent and can give rise to explosive mixtures. A mixture of  $2.00$  mol of powdered aluminum and  $3.00$  mol of ammonium nitrate crystals reacts exothermically, yielding nitrogen gas, water vapor, and aluminum oxide. How many grams of the mixture are required to provide  $245$  kJ of heat? See Appendix C for data.

**6.126** The thermite reaction is a very exothermic reaction; it has been used to produce liquid iron for welding. A mixture of  $2$  mol of powdered aluminum metal and  $1$  mol of iron(III) oxide yields liquid iron and solid aluminum oxide. How many grams of the mixture are needed to produce  $277$  kJ of heat? See Appendix C for data.

■ **6.127** Describe the physical characteristics of white phosphorus. Is it found in any modern matches? Why or why not?

■ **6.128** What is the phosphorus compound used in "strike anywhere" matches. What is the chemical equation for the burning of this compound in air?

## Strategy Problems

**Key:** As noted earlier, all of the practice and general problems are matched pairs. This section is a selection of problems that are not in matched-pair format. These challenging problems require that you employ many of the concepts and strategies that were developed in the chapter. In some cases, you will have to integrate several concepts and operational skills in order to solve the problem successfully.

**6.129** How fast (in meters per second) must a spherical iron ball with a diameter of 4.00 cm be traveling in order to have a kinetic energy of 94.7 J? The density of iron is 7.87 g/cm<sup>3</sup>.

**6.130** The maximum mass allowed for a bowling ball in ten-pin bowling is 16 lb. The average speed of the ball when released during a game is between about 17 to 19 miles per hour (mph). Imagine that a 16.0-lb bowling ball is flung up an incline at 18.0 mph. The ball rolls up the incline, reaching a certain height  $h$  above where it started before rolling backward down the slope. What is the maximum height  $h$  (in meters) attained by the bowling ball? Neglect any loss of energy through friction with the incline or with air.

**6.131** An experimenter puts 3.00 mol H<sub>2</sub> gas and 1.00 mol O<sub>2</sub> gas, both at 1.00 atm and 25°C, in a cylinder with a piston (the setup is similar to that in Figure 6.9 but with the weight replaced by the weight of the atmosphere). Suppose the gases are then ignited so that they react to form liquid water, H<sub>2</sub>O(*l*). When the reaction is complete (at 1.00 atm and 25°C), what is the work done by an external atmosphere of 1.00 atm on this system. (You can ignore the volume of liquid water.) What is the net change of internal energy from this reaction? Note that 285.8 kJ of heat evolves when 1.00 mol liquid water forms from the gaseous elements at 1.00 atm and 25°C.

**6.132** A researcher places an aqueous solution containing 16.8 g NaHCO<sub>3</sub> and another aqueous solution containing 18.2 g HCl into a stout container that she closes with a sturdy lid. The reaction that occurs is

She determines that the reaction mixture evolves 3.04 kJ of heat. What is the work done by the system (the reaction mixture) for these amounts of reactants? What is the change of internal energy,  $\Delta U$ , for this reaction per mole of NaHCO<sub>3</sub>?

**6.133** Dry ice is solid carbon dioxide; it vaporizes at room temperature and normal pressures to the gas. Suppose you put 21.5 g of dry ice in a vessel fitted with a piston (similar to the one in Figure 6.9 but with the weight replaced by the atmosphere), and it vaporizes completely to the gas, pushing the piston upward until its pressure and temperature equal those of the surrounding atmosphere at 24.0°C and 751 mmHg. Calculate the work done by the gas in expanding against the atmosphere. Neglect the volume of the solid carbon dioxide, which is very small in comparison to the volume of the gas phase.

**6.134** Potassium superoxide, KO<sub>2</sub>, is used in some rebreathing gas masks (in which the exhaled breath is recycled in a closed space). Water vapor in the exhaled air reacts with potassium superoxide to produce oxygen gas:

In an experiment at 25°C and 1.00 atm in which water vapor reacts with a quantity of potassium superoxide, it was found that 2.70 kJ of heat was absorbed. The oxygen gas produced was then collected at 23.0°C and 789 mmHg. What volume (in liters) of oxygen was collected?

**6.135** Sulfur forms a number of allotropes; two important ones are rhombic and monoclinic (see Figure 6.18). Suppose you start with a 10.0-g sample of rhombic sulfur at 25.0°C and 1.00 atm and heat the sample until it melts at 113°C. The liquid is then quickly cooled to 25.0°C and 1.000 atm at which it freezes to form crystalline needles of monoclinic sulfur. After a time, the monoclinic crystals form rhombic sulfur at 25.0°C and 1.000 atm. What is the total change of enthalpy,  $\Delta H^\circ$ , for this process in going from rhombic sulfur to liquid sulfur to monoclinic sulfur and then to rhombic sulfur?

**6.136** Sulfur dioxide gas reacts with oxygen, O<sub>2</sub>(*g*), to produce SO<sub>3</sub>(*g*). This reaction releases 99.0 kJ of heat (at constant pressure) for each mole of sulfur dioxide that reacts. Write the thermochemical equation for the reaction of 2 mol of sulfur dioxide, and then also for the decomposition of 3 mol of sulfur trioxide gas into oxygen gas and sulfur dioxide gas. Do you need any other information to answer either question?

**6.137** When solid iron burns in oxygen gas (at constant pressure) to produce Fe<sub>2</sub>O<sub>3</sub>(*s*), 1651 kJ of heat is released for every 4 mol of iron burned. How much heat is released when 10.3 g Fe<sub>2</sub>O<sub>3</sub>(*s*) is produced (at constant pressure)? What additional information would you need to calculate the heat released to produce this much Fe<sub>2</sub>O<sub>3</sub>(*s*) if you burned iron in ozone gas, O<sub>3</sub>(*g*), instead of O<sub>2</sub>(*g*)?

**6.138** Calculate the grams of oxygen gas required to produce 7.60 kJ of heat when hydrogen gas burns at constant pressure to give liquid water, given the following:

Liquid water has a heat of vaporization of 44.0 kJ per mole at 25°C.

**6.139** Hydrogen is burned in oxygen to release heat (see equation below). How many grams of hydrogen gas must be burned to release enough heat to warm a 50.0-g block of iron from 21°C to 225°C?

Iron has a specific heat of 0.449 J/(g · °C).

**6.140** Sodium metal reacts with water to produce hydrogen gas in an exothermic process.

The reaction was carried out at 25.0°C and 760.0 mmHg, and the hydrogen gas generated was then collected over water at 23.0°C and 785 mmHg, yielding 23.1 L of gas. Calculate the heat evolved; use data from Appendix C.

**6.141** A mixture of hydrogen gas and oxygen gas at 25.0°C and 1.00 atm with a total mass of 2.500 g was burned to yield liquid water and any excess reactant. If this reaction generated 28.6 kJ of heat, what was the composition of the initial gas mixture? Is there any ambiguity in the answer? If so, describe.

**6.142** Water gas is a mixture of equal molar amounts of  $\text{H}_2$  and  $\text{CO}$  gases produced by passing steam through hot coke (C):

Water gas was originally burned as a fuel gas, though it is now used to produce hydrogen. How much heat would you obtain by completely burning 1.00 L of water gas at  $25.0^\circ\text{C}$  and 1.00 atm? The products are liquid water and gaseous carbon dioxide.

**6.143** You heat 1.000 quart of water from  $25.0^\circ\text{C}$  to its normal boiling point by burning a quantity of methane gas,  $\text{CH}_4$ . What volume of methane at  $23.0^\circ\text{C}$  and 745 mmHg would you require to heat this quantity of water, assuming that the methane is completely burned? The products are liquid water and gaseous carbon dioxide.

**6.144** A piece of iron was heated to  $95.4^\circ\text{C}$  and dropped into a constant-pressure calorimeter containing 284 g of water at  $32.2^\circ\text{C}$ . The final temperature of the water and iron was  $51.9^\circ\text{C}$ . Assuming that the calorimeter itself absorbs a negligible amount of heat, what was the mass (in grams) of the piece of iron? The specific heat of iron is  $0.449 \text{ J}/(\text{g}\cdot^\circ\text{C})$ , and the specific heat of water is  $4.18 \text{ J}/(\text{g}\cdot^\circ\text{C})$ .

**6.145** The enthalpy of combustion,  $\Delta H$ , for benzoic acid,  $\text{C}_6\text{H}_5\text{COOH}$ , is  $-3226 \text{ kJ/mol}$ . When a sample of benzoic acid was burned in a calorimeter (at constant pressure), the temperature of the calorimeter and contents rose from  $23.44^\circ\text{C}$  to  $27.65^\circ\text{C}$ . The heat capacity of the calorimeter

and contents was  $12.41 \text{ kJ}/^\circ\text{C}$ . What mass of benzoic acid was burned?

**6.146** Given the following (hypothetical) thermochemical equations:

Calculate  $\Delta H$ , in kJ, for the equation

**6.147** The head of a “strike anywhere” match contains tetraphosphorus trisulfide,  $\text{P}_4\text{S}_3$ . In an experiment, a student burned this compound in an excess of oxygen and found that it evolved 3651 kJ of heat per mole of  $\text{P}_4\text{S}_3$  at a constant pressure of 1 atm. She wrote the following thermochemical equation:

Calculate the standard enthalpy of formation of  $\text{P}_4\text{S}_3$ , using this student's result and the following standard enthalpies of formation:  $\text{P}_4\text{O}_{10}(s)$ ,  $-3009.9 \text{ kJ/mol}$ ;  $\text{SO}_2(g)$ ,  $-296.8 \text{ kJ/mol}$ . How does this value compare with the value given in Appendix C?

**6.148** Toluene,  $\text{C}_6\text{H}_5\text{CH}_3$ , has an enthalpy of combustion of  $-3908 \text{ kJ/mol}$ . Using data from Appendix C, calculate the enthalpy of formation of toluene.

## Capstone Problems

**Key:** The problems under this heading combine skills, strategies, and concepts learned in previous chapters with those introduced in the current one.

**6.149** What will be the final temperature of a mixture made from 25.0 g of water at  $15.0^\circ\text{C}$ , 45.0 g of water at  $50.0^\circ\text{C}$ , and 15.0 g of water at  $37.0^\circ\text{C}$ ?

**6.150** What will be the final temperature of a mixture made from equal masses of the following: water at  $25.0^\circ\text{C}$ , ethanol at  $35.5^\circ\text{C}$ , and iron at  $95^\circ\text{C}$ ?

**6.151** Graphite is burned in oxygen to give carbon monoxide and carbon dioxide. If the product mixture is 33%  $\text{CO}$  and 67%  $\text{CO}_2$  by mass, what is the heat from the combustion of 1.00 g of graphite?

**6.152** A sample of natural gas is 80.0%  $\text{CH}_4$  and 20.0%  $\text{C}_2\text{H}_6$  by mass. What is the heat from the combustion of 1.00 g of this mixture? Assume the products are  $\text{CO}_2(g)$  and  $\text{H}_2\text{O}(l)$ .

**6.153** A sample containing 2.00 mol of graphite reacts completely with a limited quantity of oxygen at  $25^\circ\text{C}$  and 1.0 atm pressure, producing 481 kJ of heat and a mixture of  $\text{CO}$  and  $\text{CO}_2$ . Calculate the masses of  $\text{CO}$  and  $\text{CO}_2$  produced.

**6.154** A 10.0-g sample of a mixture of  $\text{CH}_4$  and  $\text{C}_2\text{H}_4$  reacts with oxygen at  $25^\circ\text{C}$  and 1 atm to produce  $\text{CO}_2(g)$  and  $\text{H}_2\text{O}(l)$ . If the reaction produces 520 kJ of heat, what is the mass percentage of  $\text{CH}_4$  in the mixture?

**6.155** How much heat is released when a mixture containing 10.0 g  $\text{NH}_3$  and 20.0 g  $\text{O}_2$  reacts by the following equation?

**6.156** How much heat is released when a mixture containing 10.0 g  $\text{CS}_2$  and 10.0 g  $\text{Cl}_2$  reacts by the following equation?

**6.157** Consider the Haber process:

The density of ammonia at  $25^\circ\text{C}$  and 1.00 atm is 0.696 g/L. The density of nitrogen,  $\text{N}_2$ , is 1.145 g/L, and the molar heat capacity is  $29.12 \text{ J}/(\text{mol}\cdot^\circ\text{C})$ . (a) How much heat is evolved in the production of 1.00 L of ammonia at  $25^\circ\text{C}$  and 1.00 atm? (b) What percentage of this heat is required to heat the nitrogen required for this reaction (0.500 L) from  $25^\circ\text{C}$  to  $400^\circ\text{C}$ , the temperature at which the Haber process is run?

**6.158** An industrial process for manufacturing sulfuric acid,  $\text{H}_2\text{SO}_4$ , uses hydrogen sulfide,  $\text{H}_2\text{S}$ , from the purification of natural gas. In the first step of this process, the hydrogen sulfide is burned to obtain sulfur dioxide,  $\text{SO}_2$ .

The density of sulfur dioxide at 25°C and 1.00 atm is 2.62 g/L, and the molar heat capacity is 30.2 J/(mol·°C). (a) How much heat would be evolved in producing 1.00 L of SO<sub>2</sub> at 25°C and 1.00 atm? (b) Suppose heat from this reaction is used to heat 1.00 L of the SO<sub>2</sub> from 25°C to 500°C for its use in the next step of the process. What percentage of the heat evolved is required for this?

**6.159** The carbon dioxide exhaled in the breath of astronauts is often removed from the spacecraft by reaction with lithium hydroxide.

Estimate the grams of lithium hydroxide required per astronaut per day. Assume that each astronaut requires  $2.50 \times 10^3$  kcal of energy per day. Further assume that this energy can be equated to the heat of combustion of a quantity of glucose, C<sub>6</sub>H<sub>12</sub>O<sub>6</sub>, to CO<sub>2</sub>(g) and H<sub>2</sub>O(l). From the amount of glucose required to give  $2.50 \times 10^3$  kcal of heat, calculate the amount of CO<sub>2</sub> produced and hence the amount of LiOH required. The  $\Delta H_f^\circ$  for glucose(s) is -1273 kJ/mol.

**6.160** A rebreathing gas mask contains potassium superoxide, KO<sub>2</sub>, which reacts with moisture in the breath to give oxygen.

Estimate the grams of potassium superoxide required to supply a person's oxygen needs for one hour. Assume a person requires  $1.00 \times 10^2$  kcal of energy for this time period. Further assume that this energy can be equated to the heat of combustion of a quantity of glucose, C<sub>6</sub>H<sub>12</sub>O<sub>6</sub>, to CO<sub>2</sub>(g) and H<sub>2</sub>O(l). From the amount of glucose required to give  $1.00 \times 10^2$  kcal of heat, calculate the amount of oxygen consumed and hence the amount of KO<sub>2</sub> required. The  $\Delta H_f^\circ$  for glucose(s) is -1273 kJ/mol.

**6.161** Power plants are driven by the energy supplied by the combustion of complex fossil fuels. Although more-efficient systems are always being conceptualized, engineers usually base the energy availability on a fuel's low heating value (LHV) when evaluating fuels. This is the energy supplied by a fuel when the water produced is allowed to escape from the exhaust stack as a vapor. The primary reason for this relates to the practical lifetime of a plant's expensive infrastructure; internal condensation of water

generally reduces the power plant's lifetime. This is particularly true when using sulfur-laden fuels (e.g., inexpensive coals) where acid-producing SO<sub>x</sub> gases would go into solution and drip back into the plant and cause significant corrosion problems over time. If water is allowed to condense in the combustion process, the energy supplied by the fuel is referred to as the high heating value (HHV).

The table below provides HHVs for 3 hydrocarbons and the absolute differences between the HHVs and LHVs for the fuels.

Hydrocarbon	High Heating Value (HHV) (BTU/lb)	HHV-LHV (BTU/lb)
CH <sub>4</sub>	23857	2358
C <sub>2</sub> H <sub>6</sub>	22301	1888
C <sub>4</sub> H <sub>10</sub>	21284	1628

**a** For each hydrocarbon, graph the HHV (y-axis) against the molar mass of the hydrocarbon (x-axis). Fit the data with a power-based ( $y = a x^c$ ) trend line and include the equation on the graph. Use the resulting information to estimate the HHV for C<sub>3</sub>H<sub>8</sub>.

**b** For each hydrocarbon, graph the HHV-LHV differences (y-axis) against the molar mass of the hydrocarbon (x-axis). Fit the data with a power-based ( $y = a x^c$ ) trend line and include the equation on the graph. Use the resulting information to estimate the HHV-LHV difference for C<sub>3</sub>H<sub>8</sub>.

**c** Using the information obtained in (a) and (b), estimate the enthalpies of reaction (in kJ/mol) for the following reactions:

**d** Using the results from (c), estimate the amount of heat energy released (in kJ) when 1700 kg of C<sub>3</sub>H<sub>8</sub>(g) is combusted when only water vapor is the product.

**e** Compare the estimated result in (d) to that which would be calculated using the accepted thermochemical heats of formation tabulated in Appendix C by calculating a percentage difference between the two results.

# Quantum Theory of the Atom

Colored flames from several elements: sodium (yellow), strontium (red), and boron (green).

© Cengage Learning/Charles D. Winters

## CONTENTS AND CONCEPTS

### Light Waves, Photons, and the Bohr Theory

To understand the formation of chemical bonds, you need to know something about the electronic structure of atoms. Because light gives us information about this structure, we begin by

discussing the nature of light. Then we look at the Bohr theory of the simplest atom, hydrogen.

**7.1** The Wave Nature of Light

**7.2** Quantum Effects and Photons

**7.3** The Bohr Theory of the Hydrogen Atom

### Quantum Mechanics and Quantum Numbers

The Bohr theory firmly establishes the concept of energy levels but fails to account for the details of atomic structure. Here we discuss some basic notions of quantum mechanics, which is

the theory currently applied to extremely small particles, such as electrons in atoms.

**7.4** Quantum Mechanics

**7.5** Quantum Numbers and Atomic Orbitals

According to Rutherford's model (Section 2.2), an atom consists of a nucleus many times smaller than the atom itself, with electrons occupying the remaining space. How are the electrons distributed in this space? Or, we might ask, what are the electrons doing in the atom?

The answer was to come from an unexpected area: the study of colored flames. When metallic compounds burn in a flame, they emit bright colors (Figure 7.1). The spectacular colors of fireworks are due to the burning of metal compounds. Lithium and strontium compounds give a deep red color; barium compounds, a green color; and copper compounds, a bluish green color.

Although the red flames of lithium and strontium appear similar, the light from each can be resolved (separated) by means of a prism into distinctly different colors. This resolution easily distinguishes the two elements. A prism disperses the colors of white light just as small rain-

drops spread the colors of sunlight into a rainbow or spectrum. But the light from a flame, when passed through a prism, reveals something other than a rainbow. Instead of the continuous range of color from red to yellow to violet, the spectrum from a strontium flame, for example, shows a cluster of red lines and blue lines against a black background. The spectrum of lithium is different, showing a red line, a yellow line, and two blue lines against a black background. (See Figure 7.2.)

Each element, in fact, has a characteristic line spectrum because of the emission of light from atoms in the hot gas. The spectra can be used to identify elements. How is it that each atom emits particular colors of light? What does a line spectrum tell us about the structure of an atom? If you know something about the structures of atoms, can you explain the formation of ions and molecules? We will answer these questions in this and the next few chapters.

Figure 7.1 ▲

**Flame tests of Groups IA and IIA elements** A wire loop containing a sample of a metallic compound is placed in a flame. *Left to right:* flames of lithium (red), sodium (yellow), strontium (red), and calcium (orange).

Figure 7.2 ►

**Emission (line) spectra of some elements** The lines correspond to visible light emitted by atoms. (Wavelengths of lines are given in nanometers.)

## ► Light Waves, Photons, and the Bohr Theory

In Chapter 2, we looked at the *basic structure* of atoms and we introduced the concept of a chemical bond. To understand the formation of a chemical bond between atoms, however, you need to know something about the *electronic structure* of atoms. The present theory of the electronic structure of atoms started with an explanation of the colored light produced in hot gases and flames. Before we can discuss this, we need to describe the nature of light.

### 7.1 The Wave Nature of Light

If you drop a stone into one end of a quiet pond, the impact of the stone with the water starts an up-and-down motion of the water surface. This up-and-down motion travels outward from where the stone hit; it is a familiar example of a wave. A *wave* is a continuously repeating change or oscillation in matter or in a physical field. Light is also a wave. It consists of oscillations in electric and magnetic fields that can travel through space. Visible light, x rays, and radio waves are all forms of *electromagnetic radiation*.

You characterize a wave by its wavelength and frequency. The **wavelength**, denoted by the Greek letter  $\lambda$  (lambda), is *the distance between any two adjacent identical points of a wave*. Thus, the wavelength is the distance between two adjacent peaks or troughs of a wave. Figure 7.3 shows a cross section of a water wave at a given moment, with the wavelength ( $\lambda$ ) identified. Radio waves have wavelengths from approximately 100 mm to several hundred meters. Visible light has much shorter wavelengths, about  $10^{-6}$  m. Wavelengths of visible light are often given in nanometers ( $1 \text{ nm} = 10^{-9} \text{ m}$ ). For example, light of wavelength  $5.55 \times 10^{-7} \text{ m}$ , the greenish yellow light to which the human eye is most sensitive, equals 555 nm.

The **frequency** of a wave is *the number of wavelengths of that wave that pass a fixed point in one unit of time* (usually one second). For example, imagine you are anchored in a small boat on a pond when a stone is dropped into the water. Waves travel outward from this point and move past your boat. The number of wavelengths that pass you in one second is the frequency of that wave. Frequency is denoted by the Greek letter  $\nu$  (nu, pronounced “new”). The unit of frequency is  $/\text{s}$ , or  $\text{s}^{-1}$ , also called the *hertz* (Hz).

The wavelength and frequency of a wave are related to each other. Figure 7.4 shows two waves, each traveling from left to right at the same speed; that is, each wave moves the same total length in 1 s. The top wave, however, has a wavelength twice that of the bottom wave. In 1 s, two complete wavelengths of the top wave move left to right from the origin. It has a frequency of  $2/\text{s}$ , or 2 Hz. In the same time, four complete wavelengths of the bottom wave move left to right from the origin. It has a frequency of  $4/\text{s}$ , or 4 Hz. Note that for two waves traveling with a given speed, wavelength and frequency are inversely related: the greater the wavelength, the lower the frequency, and vice versa. In general, with a wave of frequency  $\nu$  and wavelength  $\lambda$ , there are  $\nu$  wavelengths, each of length  $\lambda$ , that pass a fixed point every second. The product  $\nu\lambda$  is the total length of the wave that has passed

**Figure 7.3** ▲

**Water wave (ripple)** The wavelength ( $\lambda$ ) is the distance between any two adjacent identical points of a wave, such as two adjacent peaks or two adjacent troughs.

**Figure 7.4** ▲

**Relation between wavelength and frequency** Both waves are traveling at the same speed. The top wave has a wavelength twice that of the bottom wave. The bottom wave, however, has twice the frequency of the top wave.

To understand how fast the speed of light is, it might help to realize that it takes only 2.6 s for radar waves (which travel at the speed of light) to leave Earth, bounce off the moon, and return—a total distance of 478,000 miles.

the point in 1s. This length of wave per second is the speed of the wave. For light of speed  $c$ ,

$$c = \nu\lambda$$

The speed of light waves in a vacuum is a constant and is independent of wavelength or frequency. This speed is  $3.00 \times 10^8$  m/s, which is the value for  $c$  that we use in the following examples. ◀

### Example 7.1 Obtaining the Wavelength of Light from Its Frequency

#### Gaining Mastery Toolbox

##### Critical Concept 7.1

A wave is characterized by its wavelength,  $\lambda$ , and its frequency,  $\nu$ , which are related by the speed of the wave (which for light waves is denoted by the symbol  $c$ ). You need to be able to manipulate this relationship to solve for wavelength in terms of frequency.

##### Solution Essentials:

- Equation relating frequency and wavelength:  $c = \nu\lambda$

What is the wavelength of the yellow sodium emission, which has a frequency of  $5.09 \times 10^{14}$ /s?

**Problem Strategy** Note that frequency and wavelength are related (their product equals the speed of light). Write this as an equation, and then rearrange it to give the wavelength on the left and the frequency and speed of light on the right.

**Solution** The frequency and wavelength are related by the formula  $c = \nu\lambda$ . You rearrange this formula to give

$$\lambda = \frac{c}{\nu}$$

in which  $c$  is the speed of light ( $3.00 \times 10^8$  m/s). Substituting yields

$$\lambda = \frac{3.00 \times 10^8 \text{ m/s}}{5.09 \times 10^{14} / \text{s}} = 5.89 \times 10^{-7} \text{ m, or } \mathbf{589 \text{ nm}}$$

**Answer Check** Make sure you use the same units for  $c$  and  $\nu$  (we used SI units in the solution). Check that the units cancel on the right to give the units of wavelength. As a check on your arithmetic, note that the wavelength for the answer should be in the visible range (400 nm to 750 nm).

**Exercise 7.1** The frequency of the strong red line in the spectrum of potassium is  $3.91 \times 10^{14}$ /s. What is the wavelength of this light in nanometers?

See Problems 7.35 and 7.36.

### Example 7.2 Obtaining the Frequency of Light from Its Wavelength

#### Gaining Mastery Toolbox

##### Critical Concept 7.2

A wave is characterized by its wavelength,  $\lambda$ , and its frequency,  $\nu$ , which are related by the speed of the wave (which for light waves is denoted by the symbol  $c$ ). You need to be able to manipulate this relationship to solve for frequency in terms of wavelength.

##### Solution Essentials:

- Equation relating frequency and wavelength:  $c = \nu\lambda$

In 1854, Kirchhoff found that each element has a unique spectrum. Later, Bunsen and Kirchhoff developed the prism spectroscope and used it to confirm their discovery of two new elements, cesium (in 1860) and rubidium (in 1861).

What is the frequency of violet light with a wavelength of 408 nm?

**Problem Strategy** Rearrange the equation relating frequency and wavelength so that the frequency is on the left and the wavelength and speed of light are on the right.

**Solution** You rearrange the equation relating frequency and wavelength to give

$$\nu = \frac{c}{\lambda}$$

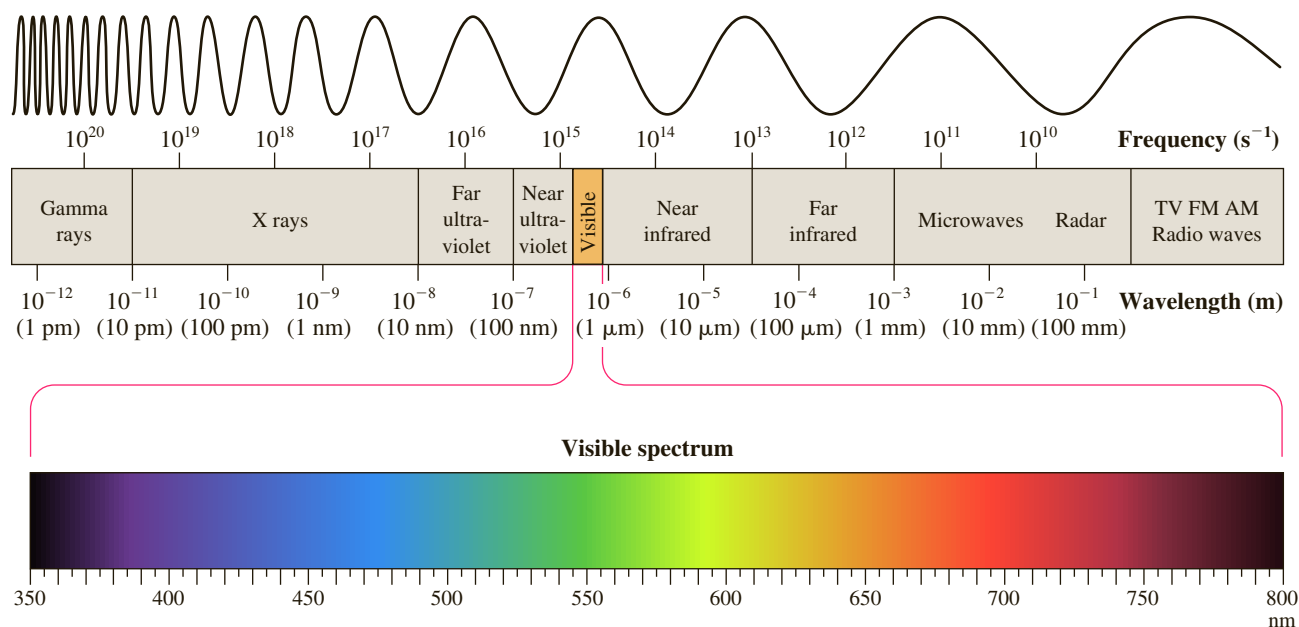

Substituting for  $\lambda$  ( $408 \text{ nm} = 408 \times 10^{-9} \text{ m}$ ) gives

$$\nu = \frac{3.00 \times 10^8 \text{ m/s}}{408 \times 10^{-9} \text{ m}} = \mathbf{7.35 \times 10^{14} / \text{s}}$$

**Answer Check** Use the same units for wavelength and speed of light; then check that the units cancel after substituting to give the units of frequency. We have used SI units here.

**Exercise 7.2** The element cesium was discovered in 1860 by Robert Bunsen and Gustav Kirchhoff, who found two bright blue lines in the spectrum of a substance isolated from a mineral water. One of the spectral lines of cesium has a wavelength of 456 nm. What is its frequency? ◀

See Problems 7.37 and 7.38.

**Figure 7.5** ▲

**The electromagnetic spectrum** Divisions between regions are not defined precisely.

The range of frequencies or wavelengths of electromagnetic radiation is called the **electromagnetic spectrum**, shown in Figure 7.5. Visible light extends from the violet end of the spectrum, which has a wavelength of about 400 nm, to the red end, with a wavelength of less than 800 nm. Beyond these extremes, electromagnetic radiation is not visible to the human eye. Infrared radiation has wavelengths greater than 800 nm (greater than the wavelength of red light), and ultraviolet radiation has wavelengths less than 400 nm (less than the wavelength of violet light).

### CONCEPT CHECK 7.1

Laser light of a specific frequency falls on a crystal that converts a portion of this light into light with double the original frequency. How is the wavelength of this frequency-doubled light related to the wavelength of the original laser light? Suppose the original laser light was red. In which region of the spectrum would the frequency-doubled light be? (If this is in the visible region, what color is the light?)

## 7.2 Quantum Effects and Photons

Isaac Newton, who studied the properties of light in the seventeenth century, believed that light consisted of a beam of particles. In 1801, however, British physicist Thomas Young showed that light, like waves, could be diffracted. *Diffraction* is a property of waves in which the waves spread out when they encounter an obstruction or small hole about the size of the wavelength. You can observe diffraction by viewing a light source through a hole—for example, a streetlight through a mesh curtain. The image of the streetlight is blurred by diffraction.

By the early part of the twentieth century, the wave theory of light appeared to be well entrenched. But in 1905 the German-born physicist Albert Einstein (1879–1955; emigrated to the United States in 1933) discovered that he could explain a phenomenon known as the *photoelectric effect* by postulating that light had both wave and particle properties. Einstein based this idea on the work of the German physicist Max Planck (1858–1947).

Max Planck was professor of physics at the University of Berlin when he did this research. He received the Nobel Prize in physics for it in 1918.

Radiation emitted from the human body and warm objects is mostly infrared, which is detected by burglar alarms, military night-vision scopes, and similar equipment.

### Planck's Quantization of Energy

In 1900 Max Planck found a theoretical formula that exactly describes the intensity of light of various frequencies emitted by a hot solid at different temperatures. ◀ Earlier, others had shown experimentally that the light of maximum intensity from a hot solid varies in a definite way with temperature. A solid glows red at 750°C, then white as the temperature increases to 1200°C. At the lower temperature, chiefly red light is emitted. As the temperature increases, more yellow and blue light become mixed with the red, giving white light. ◀

According to Planck, the atoms of the solid oscillate, or vibrate, with a definite frequency  $\nu$ , depending on the solid. But in order to reproduce the results of experiments on glowing solids, he found it necessary to accept a strange idea. An atom could have only certain energies of vibration,  $E$ , those allowed by the formula

$$E = nh\nu, \quad n = 1, 2, 3, \dots$$

where  $h$  is a constant, now called **Planck's constant**, a physical constant relating energy and frequency, having the value  $6.63 \times 10^{-34} \text{ J}\cdot\text{s}$ . The value of  $n$  must be 1 or 2 or some other whole number. Thus, the only energies a vibrating atom can have are  $h\nu$ ,  $2h\nu$ ,  $3h\nu$ , and so forth.

The numbers symbolized by  $n$  are called *quantum numbers*. The vibrational energies of the atoms are said to be *quantized*; that is, the possible energies are limited to certain values.

The quantization of energy seems contradicted by everyday experience. Consider the potential energy of an object, such as a tennis ball. Its potential energy depends on its height above the surface of the earth: the greater the upward height, the greater the potential energy. (Recall the discussion of potential energy in Section 6.1.) We have no problem in placing the tennis ball at any height, so it can have any energy. Imagine, however, that you could only place the tennis ball on the steps of a stairway. In that case, you could only put the tennis ball on one of the steps, so the potential energy of the tennis ball could have only certain values; its energy would be quantized. Of course, this restriction of the tennis ball is artificial; in fact, a tennis ball can have a range of energies, not just particular values. As we will see, quantum effects depend on the mass of the object: the smaller the mass, the more likely you will see quantum effects. Atoms, and particularly electrons, have small enough masses to exhibit quantization of energy; tennis balls do not.

### Photoelectric Effect

Planck himself was uneasy with the quantization assumption and tried unsuccessfully to eliminate it from his theory. Albert Einstein, on the other hand, boldly extended Planck's work to include the structure of light itself. Einstein reasoned that if a vibrating atom changed energy, say from  $3h\nu$  to  $2h\nu$ , it would decrease in energy by  $h\nu$ , and this energy would be emitted as a bit (or quantum) of light energy. He therefore postulated that light consists of quanta (now called **photons**), or *particles of electromagnetic energy, with energy  $E$  proportional to the observed frequency of the light*: ◀

$$E = h\nu$$

In 1905 Einstein used this photon concept to explain the photoelectric effect.

The **photoelectric effect** is the ejection of electrons from the surface of a metal or from another material when light shines on it (see Figure 7.6). Electrons are ejected, however, only when the frequency of light exceeds a certain *threshold value* characteristic of the particular metal. For example, although violet light will cause potassium metal to eject electrons, no amount of red light (which has a lower frequency) has any effect.

To explain this dependence of the photoelectric effect on the frequency, Einstein assumed that an electron is ejected from a metal when it is struck by a single

Albert Einstein obtained his Ph.D. in 1905. In the same year he published five groundbreaking research papers: one on the photoelectric effect (for which he received the Nobel Prize in physics in 1921); two on special relativity; a paper on the determination of molecular size; and one on Brownian motion (which led to experiments that tested kinetic-molecular theory and ended remaining doubts about the existence of atoms and molecules).

photon. Therefore, this photon must have at least enough energy to remove the electron from the attractive forces of the metal. No matter how many photons strike the metal, if no single one has sufficient energy, an electron cannot be ejected. A photon of red light has insufficient energy to remove an electron from potassium. But a photon corresponding to the threshold frequency has just enough energy, and at higher frequencies it has more than enough energy. When the photon hits the metal, its energy  $h\nu$  is taken up by the electron. The photon ceases to exist as a particle; it is said to be *absorbed*.

The minimum energy that a photon can have and still eject an electron from a material in the photoelectric effect is characteristic of the material; this energy is called its photoelectric *work function*. The work function is frequently expressed in electron volts, eV. (An electron volt is the energy imparted to an electron when it is accelerated by an electric potential of one volt; 1 eV equals  $1.602 \times 10^{-19}$  J.) For example, the work function of potassium metal is 2.30 eV. If a photon has energy greater than the work function, the excess energy appears as kinetic energy of the ejected electron.

The wave and particle pictures of light should be regarded as complementary views of the same physical entity. This is called the *wave-particle duality* of light. The equation  $E = h\nu$  displays this duality;  $E$  is the energy of a light particle or photon, and  $\nu$  is the frequency of the associated wave. Neither the wave nor the particle view alone is a complete description of light.

Figure 7.6 ▲

**The photoelectric effect** Light shines on a metal surface, knocking out electrons. The metal surface is contained in an evacuated tube, which allows the ejected electrons to be accelerated to a positively charged plate. As long as light of sufficient frequency shines on the metal, free electrons are produced and a current flows through the tube. (The current is measured by an ammeter.) When the light is turned off, the current stops flowing.

### Example 7.3 Calculating the Energy of a Photon

#### Gaining Mastery Toolbox

##### Critical Concept 7.3

The energy of a photon,  $E$ , is related to Planck's constant,  $h$ , times the frequency of the corresponding light wave,  $\nu$ .

##### Solution Essentials:

- Equation relating the photon energy to frequency:  $E = h\nu$
- Equation relating frequency and wavelength:  $c = \nu\lambda$

The red spectral line of lithium occurs at 671 nm ( $6.71 \times 10^{-7}$  m). Calculate the energy of one photon of this light.

**Problem Strategy** Note that the energy of a photon is related to its corresponding frequency. Therefore, you will first need to obtain this frequency from the wavelength of the spectral line.

**Solution** The frequency of this light is

$$\nu = \frac{c}{\lambda} = \frac{3.00 \times 10^8 \text{ m/s}}{6.71 \times 10^{-7} \text{ m}} = 4.47 \times 10^{14} / \text{s}$$

Hence, the energy of one photon is

$$E = h\nu = 6.63 \times 10^{-34} \text{ J} \cdot \text{s} \times 4.47 \times 10^{14} / \text{s} = 2.96 \times 10^{-19} \text{ J}$$

**Answer Check** Be sure to use the same system of units for the wavelength, the speed of light, and Planck's constant. Check that units cancel to give the proper units for energy in the final answer.

**Exercise 7.3** The following are representative wavelengths in the infrared, ultraviolet, and x-ray regions of the electromagnetic spectrum, respectively:  $1.0 \times 10^{-6}$  m,  $1.0 \times 10^{-8}$  m, and  $1.0 \times 10^{-10}$  m. What is the energy of a photon of each radiation? Which has the greatest amount of energy per photon? Which has the least?

See Problems 7.43, 7.44, 7.45, and 7.46.

**Figure 7.7** ▲

**Niels Bohr (1885–1962)** After Bohr developed his quantum theory of the hydrogen atom, he used his ideas to explain the periodic behavior of the elements. Later, when the new quantum mechanics was discovered by Schrödinger and Heisenberg, Bohr spent much of his time developing its philosophical basis. He received the Nobel Prize in physics in 1922.

### 7.3 The Bohr Theory of the Hydrogen Atom

According to Rutherford's nuclear model, the atom consists of a nucleus with most of the mass of the atom and a positive charge, around which move enough electrons to make the atom electrically neutral. But this model, offered in 1911, posed a dilemma. Using the then-current theory, one could show that an electrically charged particle (such as an electron) that revolves around a center would continuously lose energy as electromagnetic radiation. As an electron in an atom lost energy, it would spiral into the nucleus (in about  $10^{-10}$  s, according to available theory). The stability of the atom could not be explained.

A solution to this theoretical dilemma was found in 1913 by Niels Bohr (1885–1962), a Danish physicist, who at the time was working with Rutherford (see Figure 7.7). Using the work of Planck and Einstein, Bohr applied a new theory to the simplest atom, hydrogen. Before we look at Bohr's theory, we need to consider the line spectra of atoms, which we looked at briefly in the chapter opening.

#### Atomic Line Spectra

As described in the previous section, a heated solid emits light. A heated tungsten filament in an ordinary lightbulb is a typical example. With a prism we can spread out the light from a bulb to give a **continuous spectrum**—that is, *a spectrum containing light of all wavelengths*, like that of a rainbow (see Figure 7.8). The light emitted by a heated gas, however, yields different results. Rather than a continuous spectrum, with all colors of the rainbow, we obtain a **line spectrum**—*a spectrum showing only certain colors or specific wavelengths of light*. When the light from a hydrogen gas discharge tube (in which an electrical discharge heats hydrogen gas) is separated into its components by a prism, it gives a spectrum of lines, each line corresponding to light of a given wavelength. The light produced in the discharge tube is emitted by hydrogen atoms. Figure 7.2 shows the line spectrum of the hydrogen atom, as well as line spectra of other atoms.

The line spectrum of the hydrogen atom is especially simple. In the visible region, it consists of only four lines (a red, a blue-green, a blue, and a violet), although others appear in the infrared and ultraviolet regions. In 1885 J. J. Balmer showed that the wavelengths  $\lambda$  in the visible spectrum of hydrogen could be reproduced by a simple formula:

$$\frac{1}{\lambda} = 1.097 \times 10^7 / \text{m} \left( \frac{1}{2^2} - \frac{1}{n^2} \right)$$

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. WCH 02-200-203

**Figure 7.8** ►

**Dispersion of white light by a prism**  
White light, entering at the left, strikes a prism, which disperses the light into a continuous spectrum of wavelengths.

Here  $n$  is some whole number (integer) greater than 2. By substituting  $n = 3$ , for example, and calculating  $1/\lambda$  and then  $\lambda$ , one finds  $\lambda = 6.56 \times 10^{-7}$  m, or 656 nm, a wavelength corresponding to red light. The wavelengths of the other lines in the hydrogen atom visible spectrum are obtained by successively substituting  $n = 4$ ,  $n = 5$ , and  $n = 6$ .

### Bohr's Postulates

Bohr set down the following postulates to account for (1) the stability of the hydrogen atom (that the atom exists and its electron does not continuously radiate energy and spiral into the nucleus) and (2) the line spectrum of the atom.

**1. Energy-level Postulate** An electron can have only *specific energy values in an atom*, which are called its **energy levels**. Therefore, the atom itself can have only specific total energy values.

Bohr borrowed the idea of quantization of energy from Planck. Bohr, however, devised a rule for this quantization that could be applied to the motion of an electron in an atom. From this he derived the following formula for the energy levels of the electron in the hydrogen atom:

$$E = -\frac{R_H}{n^2} \quad n = 1, 2, 3, \dots \infty \quad (\text{for H atom})$$

where  $R_H$  is the *Rydberg constant* (expressed in energy units) with the value  $2.179 \times 10^{-18}$  J. Different values of the possible energies of the electron are obtained by putting in different values of  $n$ , which can have only the integral values 1, 2, 3, and so forth (up to infinity,  $\infty$ ). Here  $n$  is called the *principal quantum number*. The diagram in Figure 7.9 shows the energy levels of the electron in the H atom. ▶

**2. Transitions Between Energy Levels** An electron in an atom can change energy only by going from one energy level to another energy level. By so doing, the electron undergoes a *transition*.

By using only these two postulates, Bohr was able to explain Balmer's formula for the wavelengths in the spectrum of the hydrogen atom. According to Bohr, the emission of light from an atom occurs as follows. An electron in a higher energy level (initial energy level,  $E_i$ ) undergoes a transition to a lower energy level (final energy level,  $E_f$ ) (see Figure 7.9). In this process, the electron loses energy, which is emitted as a photon. Balmer's formula follows by this reasoning: The energy lost by the hydrogen atom is  $\Delta E = E_f - E_i$ . If we write  $n_i$  for the principal quantum number of the initial energy level, and  $n_f$  for the principal quantum number of the final energy level, then from Postulate 1,

$$E_i = -\frac{R_H}{n_i^2} \quad \text{and} \quad E_f = -\frac{R_H}{n_f^2}$$

so

$$\Delta E = \left(-\frac{R_H}{n_f^2}\right) - \left(-\frac{R_H}{n_i^2}\right) = -R_H \left(\frac{1}{n_f^2} - \frac{1}{n_i^2}\right)$$

For example, if the electron undergoes a transition from  $n_i = 4$  to  $n_f = 2$ ,

$$\Delta E = -2.179 \times 10^{-18} \text{ J} \left(\frac{1}{2^2} - \frac{1}{4^2}\right) = -4.086 \times 10^{-19} \text{ J}$$

The sign of the energy change is negative. This means that energy equal to  $4.086 \times 10^{-19}$  J is lost by the atom in the form of a photon.

The energies have negative values because the energy of the separated nucleus and electron is taken to be zero. As the nucleus and electron come together to form a stable state of the atom, energy is released and the energy becomes less than zero, or negative.

**Figure 7.9** ▶

#### Energy-level diagram for the electron in the hydrogen atom

Energy is plotted on the vertical axis (in fractional multiples of  $R_H$ ). The arrow represents an electron transition (discussed in Postulate 2) from level  $n = 4$  to level  $n = 2$ . Light of wavelength 486 nm (blue-green) is emitted. (See Example 7.4 for the calculation of this wavelength.)

**Figure 7.10** ▲

**Transitions of the electron in the hydrogen atom** The diagram shows the Lyman, Balmer, and Paschen series of transitions that occur for  $n_f = 1, 2,$  and  $3,$  respectively.

In general, the energy of the emitted photon,  $h\nu$ , equals the positive energy lost by the atom ( $-\Delta E$ ):

$$\text{Energy of emitted photon} = h\nu = -\Delta E = -(E_f - E_i)$$

That is,

$$h\nu = R_H \left( \frac{1}{n_f^2} - \frac{1}{n_i^2} \right)$$

Recalling that  $\nu = c/\lambda$ , you can rewrite this as

$$\frac{1}{\lambda} = \frac{R_H}{hc} \left( \frac{1}{n_f^2} - \frac{1}{n_i^2} \right)$$

By substituting  $R_H = 2.179 \times 10^{-18} \text{ J}$ ,  $h = 6.626 \times 10^{-34} \text{ J}\cdot\text{s}$ , and  $c = 2.998 \times 10^8 \text{ m/s}$ , you find that  $R_H/hc = 1.097 \times 10^7/\text{m}$ , which is the constant given in the Balmer formula. In Balmer's formula, the quantum number  $n_f$  is 2. This means that Balmer's formula gives wavelengths that occur when electrons in H atoms undergo transitions from energy levels  $n_i > 2$  to level  $n_f = 2$ . If you change  $n_f$  to other integers, you obtain different series of lines (or wavelengths) for the spectrum of the H atom (see Figure 7.10).

### Example 7.4 Determining the Wavelength or Frequency of a Hydrogen Atom Transition

#### Gaining Mastery Toolbox

##### Critical Concept 7.4

The energy levels of the hydrogen atom,  $E$ , are related to the inverse of the square of the principal quantum number,  $n$ . The wavelength or frequency of a transition depends on the difference in energies of the levels involved.

##### Solution Essentials:

- Energy levels of the H atom:  
 $E = -R_H/n^2$
- Equation relating frequency and wavelength:  $c = \nu\lambda$

What is the wavelength of light emitted when the electron in a hydrogen atom undergoes a transition from energy level  $n = 4$  to level  $n = 2$ ?

**Problem Strategy** Remember that the wavelength or frequency of a transition depends on the difference in energies of the levels involved. For an H atom, the energy levels are  $E = -R_H/n^2$ . You calculate the difference in energy for the two levels *to obtain the energy of the photon*. Then, calculate the frequency and wavelength of the emitted light. (Although you could do this problem by “plugging into” the previously derived equation for  $1/\lambda$ , the method followed here requires you to remember only a minimum number of key formulas.)

**Solution** From the formula for the energy levels, you know that

$$E_i = \frac{-R_H}{4^2} = \frac{-R_H}{16} \quad \text{and} \quad E_f = \frac{-R_H}{2^2} = \frac{-R_H}{4}$$

You subtract the lower value from the higher value, to get a positive result. (The energy of the photon is positive. If your result is negative, it means you calculated  $E_f - E_i$ , rather than  $E_i - E_f$ . Simply reverse the subtraction to obtain a positive result.) Because this result equals the energy of the photon, you equate it to  $h\nu$ :

$$\left( \frac{-R_H}{16} \right) - \left( \frac{-R_H}{4} \right) = \frac{-4R_H + 16R_H}{64} = \frac{-R_H + 4R_H}{16} = \frac{3R_H}{16} = h\nu$$

The frequency of the light emitted is

$$\nu = \frac{3R_H}{16h} = \frac{3}{16} \times \frac{2.179 \times 10^{-18} \text{ J}}{6.626 \times 10^{-34} \text{ J}\cdot\text{s}} = 6.17 \times 10^{14}/\text{s}$$

(continued)

**Example 7.4** (continued)

Since  $\lambda = c/\nu$ ,

$$\lambda = \frac{3.00 \times 10^8 \text{ m/s}}{6.17 \times 10^{14} / \text{s}} = 4.86 \times 10^{-7} \text{ m, or } \mathbf{486 \text{ nm}}$$

The color is blue-green (see Figure 7.9).

**Answer Check** Balmer lines (lines ending with  $n = 2$ ) are in the visible region of the spectrum. Wavelengths of visible light are in the range of 400 nm to about 800 nm. Note that the answer lies in this range.

**Exercise 7.4** Calculate the wavelength of light emitted from the hydrogen atom when the electron undergoes a transition from level  $n = 3$  to level  $n = 1$ .

See Problems 7.49, 7.50, 7.51, and 7.52.

According to Bohr's theory, the *emission* of light from an atom occurs when an electron undergoes a transition from an upper energy level to a lower one. To complete the explanation, we need to describe how the electron gets into the upper level prior to emission. Normally, the electron in a hydrogen atom exists in its lowest, or  $n = 1$ , level. To get into a higher energy level, the electron must gain energy, or be *excited*. One way this can happen is through the collision of two hydrogen atoms. During this collision, some of the kinetic energy of one atom can be gained by the electron of another atom, thereby boosting, or exciting, the electron from the  $n = 1$  level to a higher energy level. The excitation of atoms and the subsequent emission of light are most likely to occur in a hot gas, where atoms have large kinetic energies.

Bohr's theory explains not only the emission but also the *absorption* of light. When an electron in the hydrogen atom undergoes a transition from  $n = 3$  to  $n = 2$ , a photon of red light (wavelength 656 nm) is emitted. When red light of wavelength 656 nm shines on a hydrogen atom in the  $n = 2$  level, a photon can be absorbed. If the photon is absorbed, the energy is gained by the electron, which undergoes a transition to the  $n = 3$  level. (This is the reverse of the emission process we just discussed.) Materials that have a color, such as dyed textiles and painted walls, appear colored because of the absorption of light. For example, when white light falls on a substance that absorbs red light, the color components that are not absorbed, the yellow and blue light, are reflected. The substance appears blue-green.

Postulates 1 and 2 hold for atoms other than hydrogen, except that the energy levels cannot be obtained by a simple formula. However, if you know the wavelength of the emitted light, you can relate it to  $\nu$  and then to the difference in energy levels of the atom. The energy levels of atoms have been experimentally determined in this way.

**Exercise 7.5** What is the difference in energy levels of the sodium atom if emitted light has a wavelength of 589 nm?

See Problems 7.55 and 7.56.

**CONCEPT CHECK 7.2**

An atom has a line spectrum consisting of a red line and a blue line. Assume that each line corresponds to a transition between two adjacent energy levels. Sketch an energy-level diagram with three energy levels that might explain this line spectrum, indicating the transitions on this diagram. Consider the transition from the highest energy level on this diagram to the lowest energy level. How would you describe the color or region of the spectrum corresponding to this transition?

## Materials

A CHEMIST Looks at . . .

## Lasers and CD and DVD Players

Lasers are sources of intense, highly directed beams of *monochromatic* light—light of very narrow wavelength range. The word *laser* is an acronym meaning light amplification by stimulated emission of radiation. Many different kinds of lasers now exist, but the general principle of a laser can be understood by looking at the ruby laser, the first type constructed (in 1960).

Ruby is aluminum oxide containing a small concentration of chromium(III) ions,  $\text{Cr}^{3+}$ , in place of some aluminum ions. The electron transitions in a ruby laser are those of  $\text{Cr}^{3+}$  ions. Figure 7.11 shows an energy-level diagram of this ion in ruby. When you shine light of wavelength 545 nm on a ruby crystal, the light is absorbed and  $\text{Cr}^{3+}$  undergoes a transition from level 1 to level 3. Most of the ions in level 3 then undergo *radiationless transitions* to level 2. (In these transitions, the ions lose energy as heat to the crystal, rather than by emitting photons.) When an intense green light at 545 nm is flashed on a ruby crystal,  $\text{Cr}^{3+}$  ions of the ruby end up in level 2. Like all excited states, level 2 spontaneously emits photons, going to the ground state. But whereas most excited states quickly (within  $10^{-8}$  s) emit photons, level 2 has a much longer lifetime (a fraction of a millisecond), resulting in a buildup of excited  $\text{Cr}^{3+}$  ions in this level. If these accumulated excited ions can be triggered to emit all at once, or nearly so, an intense emission of monochromatic light at 694 nm will occur.

The process of *stimulated emission* is ideal for this triggering. When a photon corresponding to 694 nm encounters a  $\text{Cr}^{3+}$  ion in level 2, it stimulates the ion to undergo the transition from level 2 to level 1. The ion emits a photon corresponding to exactly the same wavelength as the original photon. In place of just one photon, there are now two photons, the original one and the one obtained by stimulated emission. The net effect is to increase the intensity of the light at this wavelength. Thus, a weak light at 694 nm can be amplified by stimulated emission of the excited ruby.

Figure 7.12 shows a sketch of a ruby laser. A flash lamp emits green light (at 545 nm) that is absorbed by the ruby, building up a concentration of  $\text{Cr}^{3+}$  in level 2. A few of these excited ions spontaneously emit photons corresponding to 694 nm (red light), and these photons then stimulate other ions to emit, which in turn stimulate more ions to emit, and so forth, resulting in a pulse of laser light at 694 nm.

Figure 7.11 ▲

**Energy levels of the chromium(III) ion in ruby** The energy levels have been numbered by increasing energy from 1 to 3. (Level 3 is broadened in the solid state.) When chromium(III) ions absorb the 545-nm portion of the light from a flash lamp, electrons in the ions first undergo transitions to level 3 and then radiationless transitions to level 2. (The energy is lost as heat.) Electrons accumulate in level 2 until more exist in level 2 than in level 1. Then a photon from a spontaneous emission from level 2 to level 1 can stimulate the emission from other atoms in level 2. These photons move back and forth between reflective surfaces, stimulating additional emissions and forming a laser pulse at 694 nm.

Laser light is *coherent*. This means that the waves forming the beam are all in phase; that is, the waves have their maxima and minima at the same points in space and time. The property of coherence of a laser beam is used in CDs (compact discs) and DVDs. Music, video, or other information is encoded on the discs in the form of pits, or indentations, on a spiral track, starting at the center of the disc. Figure 7.13 shows how a CD works; DVDs work similarly but with shorter wavelengths of laser light. When the disc is played, a small laser beam scans the track and is reflected back to a detector. Light reflected from an indentation is out of phase with light from the laser and interferes with it. Because of this interference, the reflected beam is diminished in intensity and gives a diminished detector

(continued)

## A CHEMIST Looks at . . . Lasers and CD and DVD Players *(continued)*

signal. Fluctuations in the signal are then converted to sound, video, or other information. The difference between CDs and DVDs is in the wavelength of laser light used. A shorter wavelength allows the indentations on a disc to be smaller so that more information can be placed on a disc of the same size. A CD disc uses laser light at 780 nm (in the near infrared), whereas a DVD disc uses light at 650 nm (red). A Blu-ray disc uses laser light at 405 nm, which is in the violet (although commonly called a “blue” laser).

**Figure 7.12** ▲

**A ruby laser** A flash lamp encircles a ruby rod. Light of 545 nm (green) from the flash “pumps” electrons from level 1 to level 3, then level 2, from which stimulated emission forms a laser pulse at 694 nm (red). The stimulated emission bounces back and forth between reflective surfaces at the ends of the ruby rod, building up a coherent laser beam. One end has a partially reflective surface to allow the laser beam to exit from the ruby.

**1** Music or other information is encoded in the form of pits on a compact disc.

**2** Lenses direct laser light to the disc, which reflects it back. Light reflected from a pit is out of phase with light from the laser, and these two waves interfere, reducing the intensity of the wave.

**3** As the disc moves around, light is reflected from either the main surface at full intensity (on) or from a pit at reduced intensity (off).

**4** A light-sensitive detector converts this reflected light to a digital signal (a series of on and off pulses). A converter changes this signal to one acceptable to audio, video, or other media.

## ► Quantum Mechanics and Quantum Numbers

A photon has a rest mass of zero but a relativistic mass  $m$  as a result of its motion. Einstein's equation  $E = mc^2$  relates this relativistic mass to the energy of the photon, which also equals  $h\nu$ . Therefore,  $mc^2 = h\nu$ , or  $mc = h\nu/c = h/\lambda$ .

Bohr's theory firmly established the concept of atomic energy levels. It was unsuccessful, however, in accounting for the details of atomic structure and in predicting energy levels for atoms other than hydrogen. Further understanding of atomic structure required other theoretical developments.

### 7.4 Quantum Mechanics

Current ideas about atomic structure depend on the principles of *quantum mechanics*, a theory that applies to submicroscopic (that is, extremely small) particles of matter, such as electrons. The development of this theory was stimulated by the discovery of the de Broglie relation.

#### de Broglie Relation

According to Einstein, light has not only wave properties, which we characterize by frequency and wavelength, but also particle properties. For example, a particle of light, the photon, has a definite energy  $E = h\nu$ . One can also show that the photon has momentum. (The momentum of a particle is the product of its mass and speed.) This momentum,  $mc$ , is related to the wavelength of the light:  $mc = h/\lambda$  or  $\lambda = h/mc$ . ◀

In 1923 the French physicist Louis de Broglie reasoned that if light (considered as a wave) exhibits particle aspects, then perhaps particles of matter show characteristics of waves under the proper circumstances. He therefore postulated that a particle of matter of mass  $m$  and speed  $v$  has an associated wavelength, by analogy with light:

$$\lambda = \frac{h}{mv}$$

The equation  $\lambda = h/mv$  is called the **de Broglie relation**.

If matter has wave properties, why are they not commonly observed? Calculation using the de Broglie relation shows that a baseball (0.145 kg) moving at about 60 mi/hr (27 m/s) has a wavelength of about  $10^{-34}$  m, a value so incredibly small that such waves cannot be detected. On the other hand, electrons moving at only moderate speeds have wavelengths of a few hundred picometers ( $1 \text{ pm} = 10^{-12} \text{ m}$ ). Under the proper circumstances, the wave character of electrons and even molecules (such as C<sub>60</sub>) have been observed.

The wave property of electrons was first demonstrated in 1927 by C. Davisson and L. H. Germer in the United States and by George Paget Thomson (son of J. J. Thomson) in Britain. They showed that a beam of electrons, just like X rays, can be diffracted by a crystal. The German physicist Ernst Ruska used this wave property to construct the first *electron microscope* in 1933; he shared the 1986 Nobel Prize in physics for this work. A modern instrument is shown in Figure 7.14. The *resolving power*, or ability to distinguish detail, of a microscope that uses waves depends on their wavelength. To resolve detail the size of several hundred picometers, we need a wavelength on that order. X rays have wavelengths in this range but are difficult to focus. Electrons, on the other hand, are readily focused with electric and magnetic fields. Figure 7.15 shows a photograph taken with an electron microscope, displaying the detail that is possible with this instrument.

**Example 7.5** Calculating the Wavelength of a Moving Particle**Gaining Mastery Toolbox****Critical Concept 7.5**

A particle has an associated wavelength,  $\lambda$ , that depends inversely on the mass,  $m$ , and speed of the particle,  $v$ .

**Solution Essentials:**

- DeBroglie relation:  
 $\lambda = h/mv$

a. Calculate the wavelength (in meters) of the wave associated with a 1.00-kg mass moving at 1.00 km/hr. b. What is the wavelength (in picometers) associated with an electron, whose mass is  $9.11 \times 10^{-31}$  kg, traveling at a speed of  $4.19 \times 10^6$  m/s? (This speed can be attained by an electron accelerated between two charged plates differing by 50.0 volts; voltages in the kilovolt range are used in electron microscopes.)

**Problem Strategy** The questions ask for the wavelength associated with a moving mass, which is given by de Broglie's relation,  $\lambda = h/mv$ . Be careful to use consistent units in substituting into this equation. If you use SI units, then in *Part a* you will need to convert km/hr to m/s. In *Part b*, you will need to convert the answer in meters to picometers.

**Solution**

a. A speed  $v$  of 1.00 km/hr equals

$$1.00 \frac{\text{km}}{\text{hr}} \times \frac{1 \text{ hr}}{3600 \text{ s}} \times \frac{10^3 \text{ m}}{1 \text{ km}} = 0.278 \text{ m/s}$$

Substituting quantities (all expressed in SI units for consistency), you get

$$\lambda = \frac{h}{mv} = \frac{6.63 \times 10^{-34} \text{ J} \cdot \text{s}}{1.00 \text{ kg} \times 0.278 \text{ m/s}} = \mathbf{2.38 \times 10^{-33} \text{ m}}$$

$$\text{b. } \lambda = \frac{h}{mv} = \frac{6.63 \times 10^{-34} \text{ J} \cdot \text{s}}{9.11 \times 10^{-31} \text{ kg} \times 4.19 \times 10^6 \text{ m/s}} = 1.74 \times 10^{-10} \text{ m} = \mathbf{174 \text{ pm}}$$

**Answer Check** Make sure that you are using the correct equation for the de Broglie relation; units should cancel to give units of length (for wavelength). Check that the final units are those asked for in the problem statement.

**Exercise 7.6** Calculate the wavelength (in picometers) associated with an electron traveling at a speed of  $2.19 \times 10^6$  m/s.

See Problems 7.57 and 7.58.

**CONCEPT CHECK 7.3**

A proton is approximately 2000 times heavier than an electron. How would the speeds of these particles compare if their corresponding wavelengths were about equal?

**Wave Functions**

De Broglie's relation applies quantitatively only to particles in a force-free environment. It cannot be applied directly to an electron in an atom, where the electron is subject to the attractive force of the nucleus. But in 1926 Erwin Schrödinger, guided by de Broglie's work, devised a theory that could be used to find the wave properties of electrons in atoms and molecules. *The branch of physics that mathematically describes the wave properties of submicroscopic particles* is called **quantum mechanics** or **wave mechanics**. ▶

Without going into the mathematics of quantum mechanics here, we will discuss some of the most important conclusions of the theory. In particular, quantum mechanics alters the way we think about the motion of particles. Our usual concept of motion comes from what we see in the everyday world. We might, for instance, visually follow a ball that has been thrown. The path of the ball is given by its position and velocity (or momentum) at various times. We are therefore conditioned

Schrödinger received the Nobel Prize in physics in 1933 for his wave formulation of quantum mechanics. Werner Heisenberg won the Nobel Prize the previous year for his matrix-algebra formulation of quantum mechanics. The two formulations yield identical results.

to think in terms of a continuous path for moving objects. In Bohr's theory, the electron was thought of as moving about, or orbiting, the nucleus in the way the earth orbits the sun. Quantum mechanics vastly changes this view of motion. We can no longer think of an electron as having a precise orbit in an atom. To describe such an orbit, we would have to know the exact position of the electron at various times and exactly how long it would take it to travel to a nearby position in the orbit. That is, at any moment we would have to know not only the precise position but also the precise momentum (mass times speed) of the electron.

In 1927 Werner Heisenberg showed from quantum mechanics that it is impossible to know simultaneously, with absolute precision, both the position and the momentum of a particle such as an electron. Heisenberg's **uncertainty principle** is a relation that states that the product of the uncertainty in position and the uncertainty in momentum of a particle can be no smaller than Planck's constant divided by  $4\pi$ . Thus, letting  $\Delta x$  be the uncertainty in the  $x$  coordinate of the particle and letting  $\Delta p_x$  be the uncertainty in the momentum in the  $x$  direction, we have

$$(\Delta x)(\Delta p_x) \geq \frac{h}{4\pi}$$

There are similar relations in the  $y$  and  $z$  directions. The uncertainty principle says that the more precisely you know the position (the smaller  $\Delta x$ ,  $\Delta y$ , and  $\Delta z$ ), the less well you know the momentum of the particle (the larger  $\Delta p_x$ ,  $\Delta p_y$ , and  $\Delta p_z$ ). In other words, if you know very well where a particle is, you cannot know where it is going!

The uncertainty principle is significant only for particles of very small mass such as electrons. You can see this by noting that the momentum equals mass times velocity, so  $p_x = mv_x$ . The preceding relation becomes

$$(\Delta x)(\Delta v_x) \geq \frac{h}{4\pi m}$$

For dust particles and baseballs, where  $m$  is relatively large, the term on the right becomes nearly zero, and the uncertainties of position and velocity are quite small. The path of a baseball has meaning. For electrons, however, the uncertainties in position and momentum are normally quite large relative to atomic scale dimensions. We cannot describe the electron in an atom as moving in a definite orbit.

Although quantum mechanics does not allow us to describe the electron in the hydrogen atom as moving in an orbit, it does allow us to make *statistical* statements about where we would find the electron if we were to look for it. For example, we can obtain the *probability* of finding an electron at a certain point in a hydrogen atom. Although we cannot say that an electron will definitely be at a particular position at a given time, we can say that the electron is likely (or not likely) to be at this position.

Information about a particle in a given energy level (such as an electron in an atom) is contained in a mathematical expression called a *wave function*, denoted by the Greek letter psi,  $\psi$ . The wave function is obtained by solving an equation of quantum mechanics (Schrödinger's equation). Its square,  $\psi^2$ , gives the probability of finding the particle within a region of space.

The wave function and its square,  $\psi^2$ , have values for all locations about a nucleus. Figure 7.16 shows values of  $\psi^2$  for the electron in the lowest energy level of the hydrogen atom along a line starting from the nucleus. Note that  $\psi^2$  is large near the nucleus ( $r = 0$ ), indicating that the electron is most likely to be found in this region. The value of  $\psi^2$  decreases rapidly as the distance from the nucleus increases, but  $\psi^2$  never goes to exactly zero, although the probability does become extremely small at large distances from the nucleus. This means that an atom does not have a definite boundary, unlike in the Bohr model of the atom.

Figure 7.17 shows another view of this electron probability. The graph plots the probability of finding the electron in different spherical shells at particular distances from the nucleus, rather than the probability at a point. Even though the

**Figure 7.16** ▲

**Plot of  $\psi^2$  for the lowest energy level of the hydrogen atom** The square of the wave function is plotted versus the distance,  $r$ , from the nucleus.

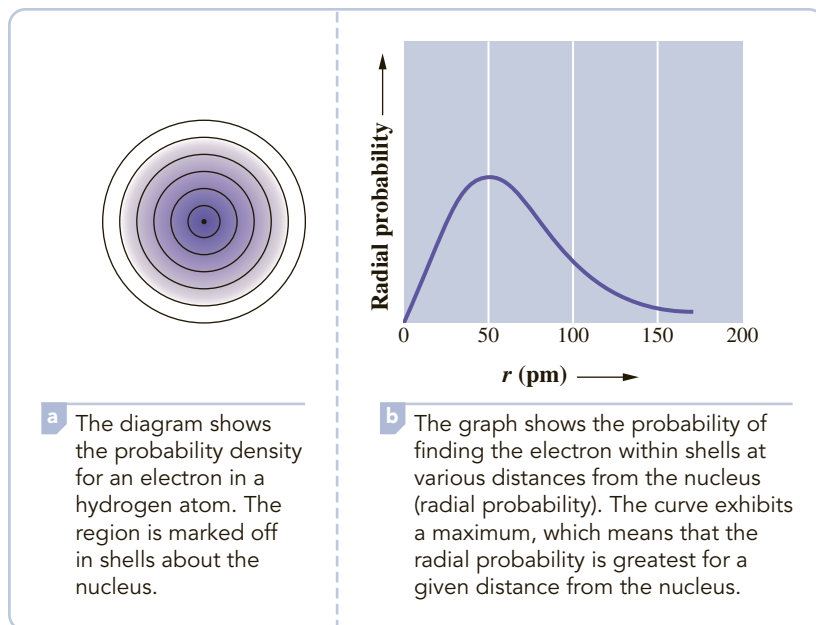

Figure 7.17 ◀

Probability of finding an electron in a spherical shell about the nucleus

probability of finding the electron at a point near the nucleus is high, the volume of any shell there is small. Therefore, the probability of finding the electron *within a shell* is greatest at some distance from the nucleus. This distance just happens to equal the radius that Bohr calculated for an electron orbit in his model.

## 7.5 Quantum Numbers and Atomic Orbitals

According to quantum mechanics, each electron in an atom is described by four different quantum numbers, three of which ( $n$ ,  $l$ , and  $m_l$ ) specify the wave function that gives the probability of finding the electron at various points in space. ▶ A wave function for an electron in an atom is called an **atomic orbital**. An atomic orbital is pictured qualitatively by describing the region of space where there is high probability of finding the electrons. The atomic orbital so pictured has a definite shape. A fourth quantum number ( $m_s$ ) refers to a magnetic property of electrons called *spin*. We first look at quantum numbers, then at atomic orbitals.

Three different quantum numbers are needed because there are three dimensions to space.

### Quantum Numbers

The allowed values and general meaning of each of the four quantum numbers of an electron in an atom are as follows:

**1. Principal Quantum Number ( $n$ )** This quantum number is the one on which the energy of an electron in an atom principally depends; it can have any positive value: 1, 2, 3, and so on. The energy of an electron in an atom depends principally on  $n$ . The smaller  $n$  is, the lower the energy. In the case of the hydrogen atom or single-electron atomic ions, such as  $\text{Li}^{2+}$  and  $\text{He}^+$ ,  $n$  is the only quantum number determining the energy (which is given by Bohr's formula, discussed in Section 7.3). For other atoms, the energy also depends to a slight extent on the  $l$  quantum number.

The size of an orbital also depends on  $n$ . The larger the value of  $n$  is, the larger the orbital. Orbitals of the same quantum state  $n$  are said to belong to the same *shell*. Shells are sometimes designated by the following letters:

Letter	K	L	M	N . . .
$n$	1	2	3	4 . . .

**2. Angular Momentum Quantum Number ( $l$ ) (Also Called Azimuthal Quantum Number)** This quantum number distinguishes orbitals of given  $n$  having different shapes; it can have any integer value from 0 to  $n - 1$ . Within each shell of quantum number  $n$ , there

## Instrumental Methods

# Scanning Tunneling Microscopy

The 1986 Nobel Prize in physics went to three physicists for their work in developing microscopes for viewing extremely small objects. Half of the prize went to Ernst Ruska for the development of the electron microscope, described earlier. The other half was awarded to Gerd Binnig and Heinrich Rohrer, at IBM's research laboratory in Zurich, Switzerland, for their invention of the *scanning tunneling microscope* in 1981. This instrument makes possible the viewing of atoms and molecules on a solid surface (Figure 7.18).

The scanning tunneling microscope is based on the concept of quantum mechanical *tunneling*, which in turn depends on the probability interpretation of quantum mechanics. Consider a hydrogen atom, which consists of an electron about a proton (call it A), and imagine another proton (called B) some distance from the first. In classical terms, if we were to move the electron from the region of proton A to the region of proton B, energy would have to be supplied to remove the electron from the attractive field of proton A. Quantum mechanics, however, gives us a different picture. The probability of the electron in the hydrogen atom being at a location far from proton A, say near proton B, is very small but not zero. In effect, this means that the electron, which nominally belongs to proton A, may find itself near proton B without extra energy having been supplied. The electron is said to have *tunneled* from one atom to another.

The scanning tunneling microscope consists of a tungsten metal needle with an extremely fine point (the probe) placed close to the sample to be viewed (Figure 7.19). If the probe is close enough to the sample, electrons can tunnel from the probe to the sample. The probability for this can be increased by having a small voltage applied between the probe and sample. Electrons tunneling from the probe to the sample give rise to a measurable electric current. The magnitude of the current depends on the distance between the probe and the sample (as well as on the *wave function* of the atom in the sample). By adjusting this distance, the current can be maintained at a fixed value. As the probe scans the sample, it moves toward or away from the sample to maintain a fixed current; in effect, the probe follows the contours of the sample. (The probe is attached to the end of a *piezoelectric rod*, which undergoes very small changes in length when small voltages are applied to it.)

Researchers routinely use the scanning tunneling microscope to study the arrangement of atoms and molecules on surfaces. Lately, scientists have also used the microscope probe to move atoms about a surface in an effort to

■ See Problems 7.93 and 7.94.

are  $n$  different kinds of orbitals, each with a distinctive shape denoted by an  $l$  quantum number. For example, if an electron has a principal quantum number of 3, the possible values for  $l$  are 0, 1, and 2. Thus, within the  $M$  shell ( $n = 3$ ), there are three kinds of orbitals, each having a different shape for the region where the electron is most likely to be found. These orbital shapes will be discussed later in this section.

Although the energy of an orbital is principally determined by the  $n$  quantum number, the energy also depends somewhat on the  $l$  quantum number (except for the H atom). For a given  $n$ , the energy of an orbital increases with  $l$ .

Orbitals of the same  $n$  but different  $l$  are said to belong to different *subshells* of a given shell. The different subshells are usually denoted by letters as follows:

<b>Letter</b>	<i>s</i>	<i>p</i>	<i>d</i>	<i>f</i>	<i>g</i> . . .
<b><i>l</i></b>	0	1	2	3	4 . . .

To denote a subshell within a particular shell, we write the value of the  $n$  quantum number for the shell, followed by the letter designation for the subshell. For example,  $2p$  denotes a subshell with quantum numbers  $n = 2$  and  $l = 1$ . ►

**3. Magnetic Quantum Number ( $m_l$ )** *This quantum number distinguishes orbitals of given  $n$  and  $l$ —that is, of given energy and shape but having a different orientation in space; the allowed values are the integers from  $-l$  to  $+l$ . For  $l = 0$  ( $s$  subshell), the allowed  $m_l$  quantum number is 0 only; there is only one orbital in the  $s$  subshell. For  $l = 1$  ( $p$  subshell),  $m_l = -1, 0,$  and  $+1$ ; there are three different orbitals in the  $p$  subshell. The orbitals have the same shape but different orientations in space. In addition, all orbitals of a given subshell have the same energy. Note that there are  $2l + 1$  orbitals in each subshell of quantum number  $l$ .*

**4. Spin Quantum Number ( $m_s$ )** *This quantum number refers to the two possible orientations of the spin axis of an electron; possible values are  $+\frac{1}{2}$  and  $-\frac{1}{2}$ . An electron acts as though it were spinning on its axis like the earth. Such an electron spin would give rise to a circulating electric charge that would generate a magnetic field. In this way, an electron behaves like a small bar magnet, with a north and a south pole.* ►

The rather odd choice of letter symbols for  $l$  quantum numbers survives from old spectroscopic terminology (describing the lines in a spectrum as sharp, principal, diffuse, and fundamental).

Electron spin will be discussed further in Section 8.1.

**Table 7.1** Permissible Values of Quantum Numbers for Atomic Orbitals

$n$	$l$	$m_l^*$	Subshell Notation	Number of Orbitals in the Subshell
1	0	0	1s	1
2	0	0	2s	1
2	1	-1, 0, +1	2p	3
3	0	0	3s	1
3	1	-1, 0, +1	3p	3
3	2	-2, -1, 0, +1, +2	3d	5
4	0	0	4s	1
4	1	-1, 0, +1	4p	3
4	2	-2, -1, 0, +1, +2	4d	5
4	3	-3, -2, -1, 0, +1, +2, +3	4f	7

\*Any one of the  $m_l$  quantum numbers may be associated with the  $n$  and  $l$  quantum numbers on the same line.

**Figure 7.21** ▲

**Orbital energies of the hydrogen atom** The lines for each subshell indicate the number of different orbitals of that subshell. (Note break in the energy scale.)

Table 7.1 lists the permissible quantum numbers for all orbitals through the  $n = 4$  shell. These values follow from the rules just given. Energies for the orbitals are shown in Figure 7.21 for the hydrogen atom. Note that all orbitals with the same principal quantum number  $n$  have the same energy. For atoms with more than one electron, however, only orbitals in the same subshell (denoted by a given  $n$  and  $l$ ) have the same energy. We will have more to say about orbital energies in Chapter 8.

### Example 7.6 Applying the Rules for Quantum Numbers

#### Gaining Mastery Toolbox

##### Critical Concept 7.6

An electron in an atom is described by four quantum numbers: the principal quantum number ( $n$ ), the angular momentum quantum number ( $l$ ), the magnetic quantum number ( $m_l$ ), and the spin quantum number ( $m_s$ ). You need to know the allowed values of each quantum number.

##### Solution Essentials:

Allowed values of the quantum numbers of an atom:  $n$ ,  $l$ ,  $m_l$ , and  $m_s$ .

State whether each of the following sets of quantum numbers is permissible for an electron in an atom. If a set is not permissible, explain why.

- $n = 1, l = 1, m_l = 0, m_s = +\frac{1}{2}$
- $n = 3, l = 1, m_l = -2, m_s = -\frac{1}{2}$
- $n = 2, l = 1, m_l = 0, m_s = +\frac{1}{2}$
- $n = 2, l = 0, m_l = 0, m_s = 1$

**Problem Strategy** Apply the rules for quantum numbers in order, first to  $n$ , then to  $l$  and  $m_l$ , and finally to  $m_s$ . A set of quantum numbers is impermissible if it disobeys any rule.

#### Solution

- Not permissible.** The  $l$  quantum number is equal to  $n$ ; it must be less than  $n$ .
- Not permissible.** The magnitude of the  $m_l$  quantum number (that is, the  $m_l$  value, ignoring its sign) must not be greater than  $l$ .
- Permissible.**
- Not permissible.** The  $m_s$  quantum number can be only  $+\frac{1}{2}$  or  $-\frac{1}{2}$ .

**Answer Check** Check that  $n$  is a positive integer (it cannot be zero). Also, check that  $l$  is a positive integer (but zero is allowed) and that  $m_l$  is an integer whose magnitude (its value except for sign) is equal to or less than  $l$ . The  $m_s$  quantum number can be only  $+\frac{1}{2}$  or  $-\frac{1}{2}$ .

**Exercise 7.7** Explain why each of the following sets of quantum numbers is not permissible for an orbital.

- $n = 0, l = 1, m_l = 0, m_s = +\frac{1}{2}$
- $n = 2, l = 3, m_l = 0, m_s = -\frac{1}{2}$
- $n = 3, l = 2, m_l = +3, m_s = +\frac{1}{2}$
- $n = 3, l = 2, m_l = +2, m_s = 0$

See Problems 7.69 and 7.70.

## Atomic Orbital Shapes

An  $s$  orbital has a spherical shape, though specific details of the probability distribution depend on the value of  $n$ . Figure 7.22 shows cross-sectional representations of the probability distributions of a  $1s$  and a  $2s$  orbital. The color shading is darker where the electron is more likely to be found. In the case of a  $1s$  orbital, the electron is most likely to be found near the nucleus. The shading becomes lighter as the distance from the nucleus increases, indicating that the electron is less likely to be found there.

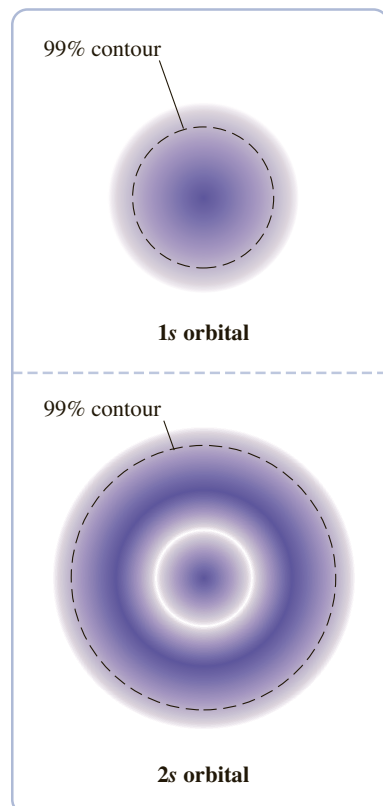

The orbital does not abruptly end at some particular distance from the nucleus. An atom, therefore, has an indefinite extension, or “size.” We can gauge the “size” of the orbital by means of the *99% contour*. The electron has a 99% probability of being found within the space of the 99% contour (the sphere indicated by the dashed line in the diagram).

A  $2s$  orbital differs in detail from a  $1s$  orbital. The electron in a  $2s$  orbital is likely to be found in two regions, one near the nucleus and the other in a spherical shell about the nucleus. (The electron is most likely to be here.) The 99% contour shows that the  $2s$  orbital is larger than the  $1s$  orbital.

A cross-sectional diagram cannot portray the three-dimensional aspect of the  $1s$  and  $2s$  atomic orbitals. Figure 7.23 shows cutaway diagrams, which better illustrate this three-dimensionality.

There are three  $p$  orbitals in each  $p$  subshell. All  $p$  orbitals have the same basic shape (two lobes arranged along a straight line with the nucleus between the lobes) but differ in their orientations in space. Because the three orbitals are set at right angles to each other, we can show each one as oriented along a different coordinate axis (Figure 7.24). We denote these orbitals as  $2p_x$ ,  $2p_y$ , and  $2p_z$ . A  $2p_x$  orbital has its greatest electron probability along the  $x$ -axis, a  $2p_y$  orbital along the  $y$ -axis, and a  $2p_z$  orbital along the  $z$ -axis. Other  $p$  orbitals, such as  $3p$ , have this same general shape, with differences in detail depending on  $n$ . We will discuss  $s$  and  $p$  orbital shapes again in Chapter 10 in reference to chemical bonding.

There are five  $d$  orbitals, which have more complicated shapes than do  $s$  and  $p$  orbitals. These are represented in Figure 7.25.

**Figure 7.22** ◀

**Cross-sectional representations of the probability distributions of  $s$  orbitals** In a  $1s$  orbital, the probability distribution is largest near the nucleus. In a  $2s$  orbital, it is greatest in a spherical shell about the nucleus. Note the relative “size” of the orbitals, indicated by the 99% contours.

The **five  $3d$  orbitals** These are labeled by subscripts, as in  $d_{xy}$ , that describe their mathematical characteristics and indicate their orientation.

## ✓ A Checklist for Review

### Summary of Facts and Concepts

One way to study the electronic structure of the atom is to analyze the electromagnetic radiation that is emitted from an atom. Electromagnetic radiation is characterized by its *wavelength*  $\lambda$  and frequency  $\nu$ , and these quantities are related to the speed of light  $c$  ( $c = \nu\lambda$ ).

Einstein showed that light consists of particles (*photons*), each of energy  $E = h\nu$ , where  $h$  is Planck's constant. According to Bohr, electrons in an atom have *energy levels*, and when an electron in a higher energy level drops (or undergoes a transition) to a lower energy level, a photon is emitted. The energy of the photon equals the difference in energy between the two levels.

Electrons and other particles of matter have both particle and wave properties. For a particle of mass  $m$  and

speed  $v$ , the wavelength is related to momentum  $mv$  by the *de Broglie relation*:  $\lambda = h/mv$ . The wave properties of a particle are described by a *wave function*, from which we can get the probability of finding the particle in different regions of space.

Each electron in an atom is characterized by four different quantum numbers. The distribution of an electron in space—its *atomic orbital*—is characterized by three of these quantum numbers: the principal quantum number, the angular momentum quantum number, and the magnetic quantum number. The fourth quantum number (spin quantum number) describes the magnetism of the electron.

### Learning Objectives

### Important Terms

#### 7.1 The Wave Nature of Light

- Define the *wavelength* and *frequency* of a wave.
- Relate the wavelength, frequency, and speed of light. **Examples 7.1 and 7.2**
- Describe the different regions of the electromagnetic spectrum.

**wavelength ( $\lambda$ )**  
**frequency ( $\nu$ )**  
**electromagnetic spectrum**

#### 7.2 Quantum Effects and Photons

- State Planck's quantization of vibrational energy.
- Define *Planck's constant* and *photon*.
- Describe the photoelectric effect.
- Calculate the energy of a photon from its frequency or wavelength. **Example 7.3**

**Planck's constant**  
**photons**  
**photoelectric effect**

#### 7.3 The Bohr Theory of the Hydrogen Atom

- State the postulates of Bohr's theory of the hydrogen atom.
- Relate the energy of a photon to the associated energy levels of an atom.
- Determine the wavelength or frequency of a hydrogen atom transition. **Example 7.4**
- Describe the difference between *emission* and *absorption* of light by an atom.

**continuous spectrum**  
**line spectrum**  
**energy levels**

#### 7.4 Quantum Mechanics

- State the de Broglie relation.
- Calculate the wavelength of a moving particle. **Example 7.5**
- Define *quantum mechanics*.
- State Heisenberg's uncertainty principle.
- Relate the wave function for an electron to the probability of finding it at a location in space.

**de Broglie relation**  
**quantum (wave) mechanics**  
**uncertainty principle**

## 7.5 Quantum Numbers and Atomic Orbitals

- Define *atomic orbital*.
- Define each of the quantum numbers for an atomic orbital.
- State the rules for the allowed values for each quantum number.
- Apply the rules for quantum numbers. **Example 7.6**
- Describe the shapes of *s*, *p*, and *d* orbitals.

**atomic orbital****principal quantum number (*n*)****angular momentum quantum number (*l*)****magnetic quantum number (*m<sub>l</sub>*)****spin quantum number (*m<sub>s</sub>*)**

## Key Equations

$$c = \nu\lambda$$

$$E = h\nu$$

$$E = -\frac{R_H}{n^2} \quad n = 1, 2, 3, \dots \infty \quad (\text{for H atom})$$

$$\text{Energy of emitted photon} = h\nu = -(E_f - E_i)$$

$$\lambda = \frac{h}{m\nu}$$

## Questions and Problems

## Self-Assessment and Review Questions

**Key:** These questions test your understanding of the ideas you worked with in the chapter. These problems vary in difficulty and often can be used for the basis of discussion.

**7.1** Give a brief wave description of light. What are two characteristics of light waves?

**7.2** What is the mathematical relationship among the different characteristics of light waves? State the meaning of each of the terms in the equation.

**7.3** Briefly describe the portions of the electromagnetic spectrum, starting with shortest wavelengths and going to longer wavelengths.

**7.4** Planck originated the idea that energies can be quantized. What does the term *quantized* mean? What was Planck trying to explain when he was led to the concept of quantization of energy? Give the formula he arrived at and explain each of the terms in the formula.

**7.5** In your own words, explain the photoelectric effect. How does the photon concept explain this effect?

**7.6** Describe the wave-particle picture of light.

**7.7** Give the equation that relates particle properties of light. Explain the meaning of each symbol in the equation.

**7.8** Physical theory at the time Rutherford proposed his nuclear model of the atom was not able to explain how this model could give a stable atom. Explain the nature of this difficulty.

**7.9** Explain the main features of Bohr's theory. Do these features solve the difficulty alluded to in Question 7.8?

**7.10** Explain the process of emission of light by an atom.

**7.11** Explain the process of absorption of light by an atom.

**7.12** What is the evidence for electron waves? Give a practical application.

**7.13** What kind of information does a wave function give about an electron in an atom?

**7.14** The atom is sometimes said to be similar to a miniature planetary system, with electrons orbiting the nucleus. What does the uncertainty principle have to say about this view of the atom?

**7.15** Bohr described the hydrogen atom as an electron orbiting a hydrogen nucleus. Although certain aspects of his theory are still valid, his theory agreed quantitatively with experiment only in the case of the hydrogen atom. In what way does quantum mechanics change Bohr's original picture of the hydrogen atom?

**7.16** Give the possible values of a. the principal quantum number, b. the angular momentum quantum number, c. the magnetic quantum number, and d. the spin quantum number.

**7.17** What is the notation for the subshell in which  $n = 4$  and  $l = 3$ ? How many orbitals are in this subshell?

**7.18** What is the general shape of an *s* orbital? of a *p* orbital?

**7.19** Which of the following statements about a hydrogen atom is *false*?

- An electron in the  $n = 1$  level of the hydrogen atom is in its ground state.
- On average, an electron in the  $n = 3$  level is farther from the nucleus than an electron in the  $n = 2$  state.
- The wavelength of light emitted when the electron goes from the  $n = 3$  level to the  $n = 1$  level is the same as the wavelength of light absorbed when the electron goes from the  $n = 1$  level to  $n = 3$  level.
- An electron in the  $n = 1$  level is higher in energy than an electron in the  $n = 4$  level.
- Light of greater frequency is required for a transition from the  $n = 1$  level to  $n = 3$  level than is required for a transition from the  $n = 2$  level to  $n = 3$  level.

- 7.20 Which of the following statements is (are) true?
- The product of wavelength and frequency of light is a constant.
  - As the energy of electromagnetic radiation increases, its frequency decreases.
  - As the wavelength of light increases, its frequency increases.
- I only
  - II only
  - III only
  - I and III only
  - II and III only
- 7.21 Of the following possible transitions of an electron in a hydrogen atom, which emits light of the highest energy?
- Transition from the  $n = 1$  to the  $n = 3$  level
  - Transition from the  $n = 1$  to the  $n = 2$  level

- Transition from the  $n = 3$  to the  $n = 1$  level
- Transition from the  $n = 2$  to the  $n = 1$  level
- Transition from the  $n = 5$  to the  $n = 4$  level

7.22 What wavelength of electromagnetic radiation corresponds to a frequency of  $3.46 \times 10^{13} \text{ s}^{-1}$ ?

- $8.66 \times 10^{-6} \text{ m}$
- $1.15 \times 10^5 \text{ m}$
- $7.65 \times 10^{-29} \text{ m}$
- $9.10 \times 10^{-6} \text{ m}$
- $8.99 \times 10^{-6} \text{ m}$

## Concept Explorations

**Key:** Concept explorations are comprehensive problems that provide a framework that will enable you to explore and learn many of the critical concepts and ideas in each chapter. If you master the concepts associated with these explorations, you will have a better understanding of many important chemistry ideas and will be more successful in solving all types of chemistry problems. These problems are well suited for group work and for use as in-class activities.

### 7.23 Light, Energy, and the Hydrogen Atom

- Which has the greater wavelength, blue light or red light?
- How do the frequencies of blue light and red light compare?
- How does the energy of blue light compare with that of red light?
- Does blue light have a greater speed than red light?
- How does the energy of three photons from a blue light source compare with the energy of one photon of blue light from the same source? How does the energy of two photons corresponding to a wavelength of 451 nm (blue light) compare with the energy of three photons corresponding to a wavelength of 704 nm (red light)?
- A hydrogen atom with an electron in its ground state interacts with a photon of light with a wavelength of  $1.22 \times 10^{-6} \text{ m}$ . Could the electron make a transition from the ground state to a higher energy level? If it does make a transition, indicate which one. If no transition can occur, explain.
- If you have one mole of hydrogen atoms with their electrons in the  $n = 1$  level, what is the minimum number of photons you would need to interact with

these atoms in order to have all of their electrons promoted to the  $n = 3$  level? What wavelength of light would you need to perform this experiment?

### 7.24 Investigating Energy Levels

Consider the hypothetical atom X that has one electron like the H atom but has different energy levels. The energies of an electron in an X atom are described by the equation

$$E = -\frac{R_{\text{H}}}{n^3}$$

where  $R_{\text{H}}$  is the same as for hydrogen ( $2.179 \times 10^{-18} \text{ J}$ ). Answer the following questions, *without calculating energy values*.

- How would the ground-state energy levels of X and H compare?
- Would the energy of an electron in the  $n = 2$  level of H be higher or lower than that of an electron in the  $n = 2$  level of X? Explain your answer.
- How do the spacings of the energy levels of X and H compare?
- Which would involve the emission of a higher frequency of light, the transition of an electron in an H atom from the  $n = 5$  to the  $n = 3$  level or a similar transition in an X atom?
- Which atom, X or H, would require more energy to completely remove its electron?
- A photon corresponding to a particular frequency of blue light produces a transition from the  $n = 2$  to the  $n = 5$  level of a hydrogen atom. Could this photon produce the same transition ( $n = 2$  to  $n = 5$ ) in an atom of X? Explain.

## Conceptual Problems

**Key:** These problems are designed to check your understanding of the concepts associated with some of the main topics presented in each chapter. A strong conceptual understanding of chemistry is the foundation for both applying chemical knowledge and solving chemical problems. These problems vary in level of difficulty and often can be used as a basis for group discussion.

7.25 Consider two beams of the same yellow light. Imagine that one beam has its wavelength doubled; the other has its frequency doubled. Which of these two beams is then in the ultraviolet region?

7.26 Some infrared radiation has a wavelength that is 1000 times larger than that of a certain visible light. This visible light has a frequency that is 1000 times smaller than that

## 238b

## Quantum Theory of the Atom

of some X radiation. How many times more energy is there in a photon of this X radiation than there is in a photon of the infrared radiation?

**7.27** One photon of green light has less than twice the energy of two photons of red light. Consider two hypothetical experiments. In one experiment, potassium metal is exposed to one photon of green light; in another experiment, potassium metal is exposed to two photons of red light. In one of these experiments, no electrons are ejected by the photoelectric effect (no matter how many times this experiment is repeated). In the other experiment, at least one electron was observed to be ejected. What is the maximum number of electrons that could be ejected during this other experiment, one or two?

**7.28** An atom in its ground state absorbs a photon (photon 1), then quickly emits another photon (photon 2). One of these photons corresponds to ultraviolet radiation, whereas the other one corresponds to red light. Explain what is happening. Which electromagnetic radiation, ultraviolet or red light, is associated with the emitted photon (photon 2)?

**7.29** Three emission lines involving three energy levels in an atom occur at wavelengths  $x$ ,  $1.5x$ , and  $3.0x$  nanometers. Which wavelength corresponds to the transition from the highest to the lowest of the three energy levels?

**7.30** An atom emits yellow light when an electron makes the transition from the  $n = 5$  to the  $n = 1$  level. In separate experiments, suppose you bombarded the  $n = 1$  level of this atom with red light, yellow light (obtained from the previous emission), and blue light. In which experiment or experiments would the electron be promoted to the  $n = 5$  level?

**7.31** Which of the following particles has the longest wavelength?

- a an electron traveling at  $x$  meters per second
- b a proton traveling at  $x$  meters per second
- c a proton traveling at  $2x$  meters per second

**7.32** Imagine a world in which the rule for the  $l$  quantum number is that values start with 1 and go up to  $n$ . The rules for the  $n$  and  $m_l$  quantum numbers are unchanged from those of our world. Write the quantum numbers for the first two shells (i.e.,  $n = 1$  and  $n = 2$ ).

**7.33** Given the following energy level diagram for an atom that contains an electron in the  $n = 3$  level, answer the following questions.

- a Which transition of the electron will emit light of the lowest frequency?
- b Using only those levels depicted in the diagram, which transition of the electron would require the highest-frequency light?
- c If the transition from the  $n = 3$  level to the  $n = 1$  level emits green light, what color light is absorbed when an electron makes the transition from the  $n = 1$  to  $n = 3$  level?

**7.34** The following shapes each represent an orbital of an atom in a hypothetical universe. The small circle is the location of the nucleus in each orbital.

- a If you placed an electron in each orbital, which one would be higher in energy?
- b When an electron makes a transition from the orbital represented on the right to the orbital on the left, would you expect energy to be absorbed or released?
- c Draw a sketch of an orbital of the same type that would be higher in energy than either of the two pictured orbitals.

## Practice Problems

**Key:** These problems are for practice in applying problem-solving skills. They are divided by topic, and some are keyed to exercises (see the ends of the exercises). The problems are arranged in matching pairs; the odd-numbered problem of each pair is listed first, and its answer is given in the back of the book.

### Electromagnetic Waves

**7.35** Radio waves in the AM region have frequencies in the range 530 to 1700 kilocycles per second (530 to 1700 kHz). Calculate the wavelength corresponding to a radio wave of frequency  $1.460 \times 10^6/s$  (that is, 1460 kHz).

**7.36** Microwaves have frequencies in the range  $10^9$  to  $10^{12}/s$  (cycles per second), equivalent to between 1 gigahertz and

1 terahertz. What is the wavelength of microwave radiation whose frequency is  $1.395 \times 10^{10}/s$ ?

**7.37** Light with a wavelength of 478 nm lies in the blue region of the visible spectrum. Calculate the frequency of this light.

**7.38** Calculate the frequency associated with light of wavelength 434 nm. (This corresponds to one of the wavelengths of light emitted by the hydrogen atom.)

**7.39** At its closest approach, Mercury is 77.3 million km from Earth. How long would it take to send a radio message from a space probe of Mercury to Earth when the planets are at this closest distance?

**7.40** The space probe *Pioneer 11* was launched April 5, 1973, and reached Jupiter in December 1974, traveling

a distance of 998 million km. How long did it take an electromagnetic signal to travel to Earth from *Pioneer 11* when it was near Jupiter?

**7.41** The meter was defined in 1963 as the length equal to 1,650,763.73 wavelengths of the orange-red radiation emitted by the krypton-86 atom (the meter has since been redefined). What is the wavelength of this transition? What is the frequency?

**7.42** The second is defined as the time it takes for 9,192,631,770 wavelengths of a certain transition of the cesium-133 atom to pass a fixed point. What is the frequency of this electromagnetic radiation? What is the wavelength?

### Photons

**7.43** What is the energy of a photon corresponding to radio waves of frequency  $1.490 \times 10^6/s$ ?

**7.44** What is the energy of a photon corresponding to microwave radiation of frequency  $1.258 \times 10^{10}/s$ ?

**7.45** The green line in the atomic spectrum of thallium has a wavelength of 535 nm. Calculate the energy of a photon of this light.

**7.46** Molybdenum compounds give a yellowish-green flame test. The atomic emission responsible for this color has a wavelength of 551 nm. Obtain the energy of a single photon of this wavelength.

**7.47** A particular transition of the rubidium atom emits light whose frequency is  $3.84 \times 10^{14}$  Hz. (Hz is the abbreviation for *hertz*, which is equivalent to the unit/s, or  $s^{-1}$ .) Is this light in the visible spectrum? If so, what is the color of the light? (See Figure 7.5.)

**7.48** Selenium atoms have a particular transition that emits light of frequency  $1.53 \times 10^{15}$  Hz. (Hz is the abbreviation for *hertz*, which is equivalent to the unit/s, or  $s^{-1}$ .) Is this light in the visible spectrum? If so, what is the color of the light? (See Figure 7.5.)

### Bohr Theory

**7.49** An electron in a hydrogen atom in the level  $n = 5$  undergoes a transition to level  $n = 3$ . What is the frequency of the emitted radiation?

**7.50** Calculate the frequency of electromagnetic radiation emitted by the hydrogen atom in the electron transition from  $n = 6$  to  $n = 3$ .

**7.51** The first line of the Lyman series of the hydrogen atom emission results from a transition from the  $n = 2$  level to the  $n = 1$  level. What is the wavelength of the emitted photon? Using Figure 7.5, describe the region of the electromagnetic spectrum in which this emission lies.

**7.52** What is the wavelength of the electromagnetic radiation emitted from a hydrogen atom when the electron undergoes the transition  $n = 4$  to  $n = 1$ ? In what region of the spectrum does this line occur? (See Figure 7.5.)

**7.53** Calculate the shortest wavelength of the electromagnetic radiation emitted by the hydrogen atom in undergoing a transition from the  $n = 4$  level.

**7.54** Calculate the longest wavelength of the electromagnetic radiation emitted by the hydrogen atom in undergoing a transition from the  $n = 6$  level.

**7.55** What is the difference in energy between the two levels responsible for the violet emission line of the calcium atom at 422.7 nm?

**7.56** What is the difference in energy between the two levels responsible for a red emission line of the strontium atom at 640.8 nm?

### de Broglie Waves

*Note:* Masses of the electron, proton, and neutron are listed on the inside back cover of this book.

**7.57** What is the wavelength of a neutron traveling at a speed of 4.54 km/s? (Neutrons of these speeds are obtained from a nuclear pile.)

**7.58** What is the wavelength of a proton traveling at a speed of 6.21 km/s? What would be the region of the spectrum for electromagnetic radiation of this wavelength?

**7.59** At what speed must an electron travel to have a wavelength of 10.0 pm?

**7.60** At what speed must a neutron travel to have a wavelength of 10.6 pm?

**7.61** What is the de Broglie wavelength of a 149-g baseball traveling at 23.0 m/s (51.4 mph)? Is the wavelength much smaller or much larger than the diameter of an atom (on the order of 100 pm)?

**7.62** What is the de Broglie wavelength of an oxygen molecule,  $O_2$ , traveling at 535 m/s? Is the wavelength much smaller or much larger than the diameter of an atom (on the order of 100 pm)?

### Atomic Orbitals

**7.63** If the  $n$  quantum number of an atomic orbital is 4, what are the possible values of  $l$ ? If the  $l$  quantum number is 3, what are the possible values of  $m_l$ ?

**7.64** The  $n$  quantum number of an atomic orbital is 5. What are the possible values of  $l$ ? What are the possible values of  $m_l$  if the  $l$  quantum number is 4?

**7.65** How many subshells are there in the  $M$  shell? How many orbitals are there in the  $d$  subshell?

**7.66** How many subshells are there in the  $N$  shell? How many orbitals are there in the  $f$  subshell?

**7.67** Give the notation (using letter designations for  $l$ ) for the subshells denoted by the following quantum numbers.

- a**  $n = 6, l = 2$       **b**  $n = 5, l = 4$   
**c**  $n = 4, l = 3$       **d**  $n = 6, l = 1$

**7.68** Give the notation (using letter designations for  $l$ ) for the subshells denoted by the following quantum numbers.

- a**  $n = 3, l = 1$   
**b**  $n = 4, l = 2$   
**c**  $n = 4, l = 0$   
**d**  $n = 5, l = 3$

**7.69** Explain why each of the following sets of quantum numbers would not be permissible for an electron, according to the rules for quantum numbers.

- a**  $n = 1, l = 0, m_l = 0, m_s = +1$   
**b**  $n = 1, l = 3, m_l = +3, m_s = +\frac{1}{2}$   
**c**  $n = 3, l = 2, m_l = +3, m_s = -\frac{1}{2}$   
**d**  $n = 0, l = 1, m_l = 0, m_s = +\frac{1}{2}$   
**e**  $n = 2, l = 1, m_l = -1, m_s = +\frac{3}{2}$

**7.70** State which of the following sets of quantum numbers would be possible and which impossible for an electron in an atom.

- a**  $n = 2, l = 0, m_l = 0, m_s = +\frac{1}{2}$   
**b**  $n = 1, l = 1, m_l = 0, m_s = +\frac{1}{2}$   
**c**  $n = 0, l = 0, m_l = 0, m_s = -\frac{1}{2}$   
**d**  $n = 2, l = 1, m_l = -1, m_s = +\frac{1}{2}$   
**e**  $n = 2, l = 1, m_l = -2, m_s = +\frac{1}{2}$

## General Problems

**Key:** These problems provide more practice but are not divided by topic or keyed to exercises. Each section ends with essay questions, each of which is color coded to refer to the *A Chemist Looks at Materials* (blue) and *Instrumental Methods* (brown) chapter essay on which it is based. Odd-numbered problems and the even-numbered problems that follow are similar; answers to all odd-numbered problems except the essay questions are given in the back of the book.

**7.71** The blue line of the strontium atom emission has a wavelength of 461 nm. What is the frequency of this light? What is the energy of a photon of this light?

**7.72** The barium atom has an emission with wavelength 554 nm (green). Calculate the frequency of this light and the energy of a photon of this light.

**7.73** The energy of a photon is  $2.70 \times 10^{-19}$  J. What is the wavelength of the corresponding light? What is the color of this light?

**7.74** The energy of a photon is  $3.05 \times 10^{-19}$  J. What is the wavelength of the corresponding light? What is the color of this light?

**7.75** The photoelectric work function of a metal is the minimum energy needed to eject an electron by irradiating the metal with light. For calcium, this work function equals  $4.34 \times 10^{-19}$  J. What is the minimum frequency of light for the photoelectric effect in calcium?

**7.76** The photoelectric work function for magnesium is  $5.90 \times 10^{-19}$  J. Calculate the minimum frequency of light required to eject electrons from magnesium.

**7.77** Light of wavelength 345 nm shines on a piece of calcium metal. What is the speed of the ejected electron? (Light energy greater than that of the work function of calcium ends up as kinetic energy of the ejected electron. See Problem 7.75 for the definition of work function and its value for calcium.)

**7.78** Light of wavelength 285 nm shines on a piece of magnesium metal. What is the speed of the ejected electron? (Light energy greater than that of the work function of magnesium ends up as kinetic energy of the ejected electron. See Problem 7.76 for the definition of work function and its value for magnesium.)

**7.79** Calculate the wavelength of the Balmer line of the hydrogen spectrum in which the initial  $n$  quantum number is 5 and the final  $n$  quantum number is 2.

**7.80** Calculate the wavelength of the Balmer line of the hydrogen spectrum in which the initial  $n$  quantum number is 3 and the final  $n$  quantum number is 2.

**7.81** One of the lines in the Balmer series of the hydrogen atom emission spectrum is at 397 nm. It results from a transition from an upper energy level to  $n = 2$ . What is the principal quantum number of the upper level?

**7.82** A line of the Lyman series of the hydrogen atom spectrum has the wavelength  $9.50 \times 10^{-8}$  m. It results from a transition from an upper energy level to  $n = 1$ . What is the principal quantum number of the upper level?

**7.83** A hydrogen-like ion has a nucleus of charge  $+Ze$  and a single electron outside this nucleus. The energy levels of these ions are  $-Z^2R_H/n^2$  (where  $Z =$  atomic number). Calculate the wavelength of the transition from  $n = 3$  to  $n = 2$  for  $\text{He}^+$ , a hydrogen-like ion. In what region of the spectrum does this emission occur?

**7.84** What is the wavelength of the transition from  $n = 4$  to  $n = 2$  for  $\text{Li}^{2+}$ ? In what region of the spectrum does this emission occur?  $\text{Li}^{2+}$  is a hydrogen-like ion. Such an ion has a nucleus of charge  $+Ze$  and a single electron outside this nucleus. The energy levels of the ion are  $-Z^2R_H/n^2$ , where  $Z$  is the atomic number.

**7.85** An electron microscope employs a beam of electrons to obtain an image of an object. What energy must be imparted to each electron of the beam to obtain a wavelength of 10.0 pm? Obtain the energy in electron volts (eV) ( $1 \text{ eV} = 1.602 \times 10^{-19} \text{ J}$ ).

**7.86** Neutrons are used to obtain images of the hydrogen atoms in molecules. What energy must be imparted to each neutron in a neutron beam to obtain a wavelength of 10.0 pm? Obtain the energy in electron volts (eV) ( $1 \text{ eV} = 1.602 \times 10^{-19} \text{ J}$ ).

**7.87** What is the number of different orbitals in each of the following subshells?

- a** 3d    **b** 4f    **c** 4p    **d** 5s

**7.88** What is the number of different orbitals in each of the following subshells?

- a** 5f    **b** 5g    **c** 6s    **d** 5p

**7.89** List the possible subshells for the  $n = 6$  shell.

**7.90** List the possible subshells for the  $n = 8$  shell.

**7.91** The word *laser* is an acronym meaning *light amplification by stimulated emission of radiation*. What is the stimulated emission of radiation?

- 7.92 Explain how lasers are used to “read” a compact disc.
- 7.93 Explain the concept of quantum mechanical tunneling.

- 7.94 Explain how the probe in a scanning tunneling microscope scans a sample on the surface of a metal.

## Strategy Problems

**Key:** As noted earlier, all of the practice and general problems are matched pairs. This section is a selection of problems that are not in matched-pair format. These challenging problems require that you employ many of the concepts and strategies that were developed in the chapter. In some cases, you will have to integrate several concepts and operational skills in order to solve the problem successfully.

**Note:** See back cover for physical constants and conversion factors.

**7.95** What wavelength of electromagnetic radiation corresponds to a frequency of  $7.76 \times 10^9 \text{ s}^{-1}$ ? Note that Planck’s constant is  $6.63 \times 10^{-34} \text{ J} \cdot \text{s}$ , and the speed of light is  $3.00 \times 10^8 \text{ m/s}$ .

**7.96** AM radio stations broadcast at frequencies between 530 kHz and 1700 kHz. ( $1 \text{ kHz} = 10^3 \text{ s}^{-1}$ .) For a station broadcasting at  $1.69 \times 10^3 \text{ kHz}$ , what is the energy of this radio wave? Note that Planck’s constant is  $6.63 \times 10^{-34} \text{ J} \cdot \text{s}$ , and the speed of light is  $3.00 \times 10^8 \text{ m/s}$ .

**7.97** A particular microwave oven delivers 750 watts. (A watt is a unit of power, which is the joules of energy delivered, or used, per second.) If the oven uses microwave radiation of wavelength 12.6 cm, how many photons of this radiation are required to heat 1.00 g of water  $1.00^\circ\text{C}$ , assuming that all of the photons are absorbed?

**7.98** A ruby laser puts out a pulse of red light at a wavelength of 694 nm. (The ruby laser is described in the essay on p. 226.) If a pulse delivers  $1.05 \times 10^5$  watts of power for  $280 \mu\text{s}$ , how many photons are there in this pulse? ( $1 \text{ watt} = 1 \text{ J/s}$ .)

**7.99** The retina of the eye contains two types of light-sensitive cells: rods (responsible for night vision) and cones (responsible for color vision). Rod cells are about a hundred times more sensitive to light than cone cells and are able to detect a single photon. Suppose a group of rod cells are radiated with a pulse of light having an energy equal to  $1.60 \times 10^{-16} \text{ J}$ . If the wavelength of this light was 498 nm (the wavelength at which rod cells are most sensitive), how many photons are in this light pulse?

**7.100** Ozone in the stratosphere absorbs ultraviolet light of wavelengths shorter than 320 nm, thus filtering out the most energetic radiation from sunlight. During this absorption, an ozone molecule absorbs a photon, which breaks an oxygen–oxygen bond, yielding an oxygen molecule and an oxygen atom:

(Here,  $h\nu$  denotes a photon.) Suppose a flask of ozone is irradiated with a pulse of UV light of wavelength 275 nm. Assuming that each photon of this pulse that is absorbed breaks up one ozone molecule, calculate the energy absorbed per mole of  $\text{O}_2$  produced, giving the answer in kJ/mol.

**7.101** The photoelectric *work function* of a metal is the minimum energy required to eject an electron by shining

light on the metal. The work function of calcium is  $4.60 \times 10^{-19} \text{ J}$ . What is the longest wavelength of light (in nanometers) that can cause an electron to be ejected from calcium metal.

**7.102** The photoelectric work function of potassium is 2.29 eV. A photon of energy greater than this ejects the electron with the excess as kinetic energy. Suppose light of wavelength 455 nm ejects an electron from the surface of potassium. What is the speed of the ejected electron?

**7.103** The surface of a metal was illuminated with light whose wavelength is 327 nm. Upon illumination, the metal ejected an electron with a speed of  $3.46 \times 10^5 \text{ m/s}$ . What is the photoelectric work function of the metal (in eV)? Assuming that the metal is an element, use values given in the *CRC Handbook of Chemistry and Physics* to discover the element.

**7.104** Calculate the shortest wavelength of *visible* light (in nanometers) seen in the spectrum of the hydrogen atom. What are the principal quantum numbers for the levels in this transition? Does Figure 7.11 include all visible lines?

**7.105** Light of wavelength  $1.03 \times 10^{-7} \text{ m}$  is emitted when an electron in an excited level of a hydrogen atom undergoes a transition to the  $n = 1$  level. What is the region of the spectrum of this light? What is the principal quantum number of the excited level?

**7.106** A hydrogen atom in the ground state absorbs a photon whose wavelength is 95.0 nm. The resulting excited atom then emits a photon of 1282 nm. What are the regions of the electromagnetic spectrum for the radiations involved in these transitions? What is the principal quantum number of the final state resulting from the emission from the excited atom?

**7.107** Hydrogen-like ions are atomic ions consisting of just one electron about a nucleus. The energy levels of such an ion are given by a formula similar to that of the hydrogen atom except that the Rydberg constant for a hydrogen-like ion of atomic number  $Z$  has a value of  $2.179 \times 10^{-18} Z^2$ . What is the shortest wavelength transition in the  $\text{Li}^{2+}$  ion?

**7.108** It requires 799 kJ of energy to break one mole of carbon–oxygen double bonds in carbon dioxide. What wavelength of light does this correspond to per bond? Is there any transition in the hydrogen atom that has at least this quantity of energy in one photon?

**7.109** The root-mean-square speed of an oxygen molecule,  $\text{O}_2$ , at  $21^\circ\text{C}$  is 479 m/s. Calculate the de Broglie wavelength for an  $\text{O}_2$  molecule traveling at this speed. How does this wavelength compare with the approximate length of this molecule, which is about 242 pm? (For this comparison, state the wavelength as a percentage of the molecular length.)

**7.110** An electron is accelerated through a potential difference of 15.6 kilovolts (giving the electron a kinetic energy of 15.6 keV). What is the associated wavelength of the electron in angstroms?

**7.111** In X-ray fluorescence spectroscopy, a material can be analyzed for its constituent elements by radiating the material with short-wavelength X rays, which induce the atoms to emit longer-wavelength X rays characteristic of those atoms. Tungsten, for example, emits characteristic X rays of wavelength 0.1476 nm. If an electron has an equivalent wavelength, what is its kinetic energy?

**7.112** For each of the following combinations of quantum numbers, make changes that produce an allowed combination. Count 3 for each change of  $n$ , 2 for each change of  $l$ , and 1 for each change of  $m_l$ . What is the lowest possible count that you can obtain?

**a**  $n = 3, l = 0, m_l = -2$

**b**  $n = 5, l = 5, m_l = 4$

**c**  $n = 3, l = 3, m_l = -3$

**d**  $n = 5, l = 6, m_l = 3$

**7.113** The term *degeneracy* means the number of different quantum states of an atom or molecule having the same energy. For example, the degeneracy of the  $n = 2$  level of the hydrogen atom is 4 (a  $2s$  quantum state, and three different  $2p$  states). What is the degeneracy of the  $n = 5$  level?

**7.114** In a hypothetical universe, the quantum numbers for an atomic orbital follow these rules:

$$n = \text{any positive integer value from 2 to } \infty$$

$$l = \text{any positive integer value from 2 to } n + 1$$

$$m_l = \text{any integer from } -(l - 1) \text{ to } (l - 1)$$

How many orbitals are possible for the  $n = 2$  shell?

## Capstone Problems

**Key:** The problems under this heading combine skills, strategies, and concepts learned in previous chapters with those introduced in the current one.

**7.115** The energy required to dissociate the  $\text{Cl}_2$  molecule to Cl atoms is 239 kJ/mol  $\text{Cl}_2$ . If the dissociation of a  $\text{Cl}_2$  molecule were accomplished by the absorption of a single photon whose energy was exactly the quantity required, what would be its wavelength (in meters)?

**7.116** The energy required to dissociate the  $\text{H}_2$  molecule to H atoms is 432 kJ/mol  $\text{H}_2$ . If the dissociation of an  $\text{H}_2$  molecule were accomplished by the absorption of a single photon whose energy was exactly the quantity required, what would be its wavelength (in meters)?

**7.117** A microwave oven heats by radiating food with microwave radiation, which is absorbed by the food and converted to heat. Suppose an oven's radiation wavelength is 12.5 cm. A container with 0.220 L of water was placed in the oven, and the temperature of the water rose from 20.0°C to 100.0°C. How many photons of this microwave radiation were required? Assume that all the energy from the radiation was used to raise the temperature of the water.

**7.118** Warm objects emit electromagnetic radiation in the infrared region. Heat lamps employ this principle to generate infrared radiation. Water absorbs infrared radiation with wavelengths near 2.80  $\mu\text{m}$ . Suppose this radiation is absorbed by the water and converted to heat. A 1.00-L sample of water absorbs infrared radiation, and its temperature increases from 20.0°C to 30.0°C. How many photons of this radiation are used to heat the water?

**7.119** Light with a wavelength of 425 nm fell on a potassium surface, and electrons were ejected at a speed of  $4.88 \times 10^5$  m/s. What energy was expended in removing an electron from the metal? Express the answer in joules (per electron) and in kilojoules per mole (of electrons).

**7.120** Light with a wavelength of 405 nm fell on a strontium surface, and electrons were ejected. If the speed of an ejected electron is  $3.36 \times 10^5$  m/s, what energy was expended in removing the electron from the metal? Express the answer in joules (per electron) and in kilojoules per mole (of electrons).

**7.121** When an electron is accelerated by a voltage difference, the kinetic energy acquired by the electron equals the voltage times the charge on the electron. Thus, one volt imparts a kinetic energy of  $1.602 \times 10^{-19}$  volt-coulombs, which equals  $1.602 \times 10^{-19}$  J. What is the wavelength associated with electrons accelerated by  $4.00 \times 10^3$  volts?

**7.122** When an electron is accelerated by a voltage difference, the kinetic energy acquired by the electron equals the voltage times the charge on the electron. Thus, one volt imparts a kinetic energy of  $1.602 \times 10^{-19}$  volt-coulombs, or  $1.602 \times 10^{-19}$  J. What is the wavelength for electrons accelerated by  $1.00 \times 10^4$  volts?

**7.123** The table below is partially completed for subshells A and B, where subshell B is the next subshell higher in energy compared to subshell A. For example, if subshell A is the 4s subshell, then subshell B would be the 3d subshell. Use this criteria and the information provided to complete the table.

Subshell A Designation (1s, 3d, etc.)	Value of $n_A$	Value of $l_B$	Number of orbitals in Subshell A	Subshell B Designation (1s, 3d, etc.)	Value of $n_B$	Value of $l_B$	Number of orbitals in Subshell B

# Electron Configurations and Periodicity

Sodium metal reacts vigorously with water to produce hydrogen gas (which catches fire); other Group 1A metals similarly react with water. The other product is sodium hydroxide.

Philip Evans/Visuals Unlimited, Inc.

## CONTENTS AND CONCEPTS

### Electronic Structure of Atoms

In the previous chapter, you learned that we characterize an atomic orbital by four quantum numbers:  $n$ ,  $l$ ,  $m_l$ , and  $m_s$ . In the first section, we look further at electron spin; then we discuss how electrons are distributed among the possible orbitals of an atom.

- 8.1** Electron Spin and the Pauli Exclusion Principle
- 8.2** Building-Up Principle and the Periodic Table
- 8.3** Writing Electron Configurations Using the Periodic Table
- 8.4** Orbital Diagrams of Atoms; Hund's Rule

### Periodicity of the Elements

You learned how the periodic table can be explained by the periodicity of the ground-state configurations of the elements. Now we will look at various aspects of the periodicity of the elements.

- 8.5** Mendeleev's Predictions from the Periodic Table
- 8.6** Some Periodic Properties
- 8.7** Periodicity in the Main-Group Elements

Lebrecht Music &amp; Arts/The ImageWorks

**Figure 8.1** ▲

**Marie Skłodowska Curie (1867–1934), with Pierre Curie** Marie Skłodowska Curie, born in Warsaw, Poland, began her doctoral work with Henri Becquerel soon after he discovered the spontaneous radiation emitted by uranium salts. She found this radiation to be an atomic property and coined the word *radioactivity* for it. In 1903 the Curies and Becquerel were awarded the Nobel Prize in physics for their discovery of radioactivity. Three years later, Pierre Curie was killed in a carriage accident. Marie Curie continued their work on radium and in 1911 was awarded the Nobel Prize in chemistry for the discovery of polonium and radium and the isolation of pure radium metal. This was the first time a scientist had received two Nobel awards. (Since then two others have been so honored.)

**M**arie Curie, a Polish-born French chemist, and her husband, Pierre, announced the discovery of radium in 1898 (Figure 8.1). They had separated a very radioactive mixture from pitchblende, an ore of uranium. This mixture was primarily a compound of barium. When the mixture was heated in a flame, however, it gave a new atomic line spectrum, in addition to the spectrum for barium. The Curies based their discovery of a new element, which they called radium, on this finding. It took them four more years to obtain a pure compound of radium. Finally, in 1910 Marie Curie isolated the pure metallic element. Radium, like uranium, is a radioactive element. But in most of its chemical and physical properties, radium is similar to the nonradioactive element barium. It was this similarity that made the final separation of the new element so difficult.

Chemists had long known that groups of elements have similar properties. In 1869 Dmitri Mendeleev found that the elements could be arranged in a particular way by columns, with elements in the same column displaying similar properties. Thus, Mendeleev placed beryllium, calcium, strontium, and barium in one column. Now, with the Curies' discovery, radium was added to this column.

Mendeleev's arrangement of the elements, the *periodic table*, was originally based on the observed chemical and physical properties of the elements and their compounds. We now explain this arrangement in terms of the electronic structure of atoms. In this chapter, we will look at this electronic structure and its relationship to the periodic table of elements.

## ▶ Electronic Structure of Atoms

In Chapter 7, we found that an electron in an atom has four quantum numbers— $n$ ,  $l$ ,  $m_l$ , and  $m_s$ —associated with it. The first three quantum numbers characterize the orbital that describes the region of space where an electron is most likely to be found; we say that the electron “occupies” this orbital. The spin quantum number,  $m_s$ , describes the spin orientation of an electron. In the first section, we will look further at electron spin; then we will discuss how electrons are distributed among the possible orbitals of an atom.

### 8.1 Electron Spin and the Pauli Exclusion Principle

Otto Stern and Walther Gerlach first observed electron spin magnetism in 1921. They directed a beam of silver atoms into the field of a specially designed magnet. The same experiment can be done with hydrogen atoms. The beam of hydrogen atoms is split into two by the magnetic field; half of the atoms are bent in one direction and half in the other (see Figure 8.2). The fact that the atoms are affected by the laboratory magnet shows that they themselves act as magnets.

**Figure 8.2** ▶

**The Stern–Gerlach experiment** The diagram shows the experiment using hydrogen atoms (simpler to interpret theoretically), although the original experiment employed silver atoms. A beam of hydrogen atoms (shown in blue) is split into two by a nonuniform magnetic field. One beam consists of atoms each with an electron having  $m_s = +\frac{1}{2}$ ; the other beam consists of atoms each having an electron with  $m_s = -\frac{1}{2}$ .

The beam of hydrogen atoms is split into two because the electron in each atom behaves as a tiny magnet with only two possible orientations. In effect, the electron acts as though it were a ball of spinning charge (Figure 8.3), and, like a circulating electric charge, the electron would create a magnetic field. Electron spin, however, is subject to a quantum restriction on the possible directions of the spin axis. The resulting directions of spin magnetism correspond to spin quantum numbers  $m_s = +\frac{1}{2}$  and  $m_s = -\frac{1}{2}$ . ▶

Protons and many nuclei also have spin. See the Instrumental Methods essay in this section.

### Electron Configurations and Orbital Diagrams

We describe the electrons in an atom by the atom's electron configuration. An **electron configuration** of an atom is a *particular distribution of electrons among the available subshells*. A subshell, as we noted in the previous chapter, consists of a group of orbitals having the same  $n$  and  $l$  quantum numbers but different  $m_l$  values. Recall that we denote each subshell by its principal quantum number,  $n$ , followed by a letter standing for its  $l$  quantum number ( $s$ ,  $p$ ,  $d$ ,  $f$ , etc.).

The notation for a configuration lists the subshell symbols one after the other, with a superscript giving the number of electrons in that subshell. For example, a configuration of the lithium atom (atomic number 3) with two electrons in the  $1s$  subshell and one electron in the  $2s$  subshell is written  $1s^2 2s^1$ .

Whereas the configuration gives the number of electrons in each subshell, we use a *diagram to show how the orbitals of a subshell are occupied by electrons*. It is called an **orbital diagram**.

An orbital is represented by a circle. Each group of orbitals in a subshell is labeled by its subshell notation. An electron in an orbital is shown by an arrow; the arrow points up when  $m_s = +\frac{1}{2}$  and down when  $m_s = -\frac{1}{2}$ . The orbital diagram

shows the electronic structure of an atom in which there are two electrons in the  $1s$  subshell, or orbital (one electron with  $m_s = +\frac{1}{2}$ , the other with  $m_s = -\frac{1}{2}$ ); two electrons in the  $2s$  subshell ( $m_s = +\frac{1}{2}$ ,  $m_s = -\frac{1}{2}$ ); and one electron in the  $2p$  subshell ( $m_s = +\frac{1}{2}$ ). The electron configuration is  $1s^2 2s^2 2p^1$ .

### Pauli Exclusion Principle

Not all of the conceivable arrangements of electrons among the orbitals of an atom are physically possible. The **Pauli exclusion principle**, which summarizes experimental observations, states that *no two electrons in an atom can have the same four quantum numbers*. If one electron in an atom has the quantum numbers  $n = 1$ ,  $l = 0$ ,  $m_l = 0$ , and  $m_s = +\frac{1}{2}$ , no other electron can have these same quantum numbers. In other words, you cannot place two electrons with the same value of  $m_s$  in a  $1s$  orbital. The orbital diagram

is not a possible arrangement of electrons.

Because there are only two possible values of  $m_s$ , an orbital can hold no more than two electrons—and then only if the two electrons have different spin quantum numbers. In an orbital diagram, an orbital with two electrons must be written with

**Figure 8.3** ▲

**A representation of electron spin** The two possible spin orientations are indicated by the models. By convention, the spin direction is given as shown by the large arrow on the spin axis. Electrons behave as tiny bar magnets, as shown in the figure.

## Instrumental Methods

# Nuclear Magnetic Resonance (NMR)

You have just seen that electrons have a spin and as a result behave like tiny magnets. Protons and neutrons similarly have spins. Therefore, depending on the arrangement of protons and neutrons, a nucleus could have spin. A nucleus with spin will act like a bar magnet, similar to the electron although many times smaller in magnitude. Examples of nuclei with spin are hydrogen-1 (proton), carbon-13 (but carbon-12, the most abundant nuclide of carbon, has no spin), and fluorine-19.

Although nuclear magnetism is much smaller than that of electrons, with the correct equipment it is easily seen and in fact forms the basis of *nuclear magnetic resonance* (NMR) spectroscopy, one of the most important methods for determining molecular structure. Nuclear magnetism also forms the basis of the medical diagnostic tool *magnetic resonance imaging*, or MRI (Figure 8.4).

The essential features of NMR can be seen if you consider the proton. Like the electron, the proton has two spin states. In the absence of a magnetic field, these spin states have the same energy, but in the field of a strong magnet (external field), they have different energies. The state in which the proton magnetism is aligned with the external field, so the south pole of the proton magnet faces the north pole of the external magnet, will have lower energy. The state in which the proton magnet is turned 180°, with its south pole facing the south pole of the external magnet, will have higher energy. Now if a proton in the lower spin state is irradiated with electromagnetic waves of the proper frequency (in which the photon has energy equal to the difference in energy of the spin states), the proton can change to the higher spin state. The frequency absorbed by the proton depends on the magnitude of the magnetic field. For the magnets used in NMR spectrometers, the radiation lies in the radio-frequency range.

High-resolution NMR spectrometers use large electromagnets in which the frequencies are several hundred megahertz (up to more than 900 MHz). Low-resolution instruments suitable for laboratory benchtop use employ small permanent magnets with frequencies of perhaps 90 MHz.

Figure 8.5 shows a diagram of a simple NMR spectrometer. It consists of a sample in the field of a variable

electromagnet and near two coils, one a radio wave transmitter and the other a receiver coil perpendicular to the transmitter coil (so that the receiver will not pick up the signal from the transmitter). Suppose the transmitter radiates waves of 300 MHz. If the sample absorbs these radio waves, protons will undergo transitions from the lower to the higher spin state. Once protons are in the higher energy state, they tend to lose energy, going back to the lower spin state and radiating 300-MHz radio waves. Thus, the sample acts like a transmitter, but one with coils in various directions, so the signal can be detected by the receiver coil.

In general, the sample will not absorb at the chosen frequency. But you can change the energy difference between spin states, and therefore the frequency that is absorbed by the sample, by increasing or decreasing the magnitude of the external magnetic field using small coils on the magnet pole faces. In so doing you can, in effect, "tune" the sample, or bring it into "resonance" with the transmitter frequency. (Many modern instruments actually bombard the sample with a wide range of frequencies simultaneously, analyzing the resultant transmitted wave mathematically by computer, which reduces the time taken to obtain a spectrum from 5 to 10 minutes to a few seconds.)

Because each proton in a substance is surrounded by electrons that have their own magnetic fields, the magnetic environment of a proton depends to some extent on the bonding, or chemical, environment in which the proton is involved. So, the external magnetic field needed to bring a proton into resonance with the 300-MHz radiation, say, varies with the chemical (bonding) environment. A spectrum is produced by recording the magnetic field (or frequency) at which the protons in a molecule produce a resonance signal. Figure 8.6 shows a high-resolution NMR spectrum of ethanol.

Ethanol, whose molecular structure is

### Figure 8.4 ►

**Magnetic resonance imaging** A patient's head is placed in a large magnet and subjected to a radio pulse. Proton spin transitions give rise to a radio wave emission that can be analyzed electronically and converted by computer to a two-dimensional image of a plane portion of the brain. Paul C. Lauterbur, a chemist at the University of Illinois (Urbana), and Sir Peter Mansfield, University of Nottingham (UK), won the Nobel Prize in Physiology or Medicine in 2003 for their work in the early 1970s in developing MRI.

## Instrumental Methods Nuclear Magnetic Resonance (NMR) *(continued)*

**Figure 8.5** ◀

### Nuclear magnetic resonance spectrometer

A sample in the tube is in a magnetic field, which can be varied by changing the electric current in the *sweep* coils (shown in yellow). A radio-frequency transmitter radiates radio waves from a coil (shown in red) to the sample. The sample absorbs these waves if the radio frequency corresponds to the difference in energy of the sample's nuclear spin states. When the nuclear spins go back to the ground state, the sample emits radio waves, which are detected by the receiver coil (in black).

has protons in three different chemical environments: a proton bonded to an oxygen atom (H—O—), the protons in a —CH<sub>2</sub>— group, and the protons in a —CH<sub>3</sub> group. Each of these three types of protons shows up as a peak or, as we will see, a group of peaks in the NMR spectrum. The position of the center of a group of peaks for a given proton relative to some standard is referred to as the *chemical shift* for that proton, because it depends on the chemical environment of the proton. By measuring the area under the peaks for a given type of proton (usually done electronically by the spectrometer), a researcher can discover the number of protons of that type, effectively giving the chemist structural information about the molecule.

As we noted earlier, a given proton may give rise to several peaks in a high-resolution spectrum. (At low resolution, these separate peaks may appear as only one for each proton.) For example, the protons for the —CH<sub>2</sub>— group of ethanol give four closely spaced peaks. These peaks arise because of the interaction of the proton spins on this group with those protons on the adjacent —CH<sub>3</sub> group. The number of peaks (four) for the —CH<sub>2</sub>— group is one more than the number of protons on the adjacent group (three).

NMR spectroscopy is one of the most important tools a chemist has in determining the identity of a substance and its molecular structure. The method is quick and can yield such information as the chemical bonding environment of the protons and the number of protons having a given environment. It can also give information about other nuclei, such as carbon-13.

**Figure 8.6** ▲

**High-resolution NMR spectrum of ethanol, CH<sub>3</sub>CH<sub>2</sub>OH** The protons of a given type occur as a peak or closely spaced group of peaks. The position of the center of such a group of peaks relative to some standard is referred to as the *chemical shift*,  $\delta$ . The peaks within a group arise from the interaction of the spins between protons of one type with those of another type.

■ See Problems 8.85 and 8.86.

arrows pointing in opposite directions. The two electrons are said to have opposite spins. We can restate the Pauli exclusion principle:

**Pauli exclusion principle:** An orbital can hold at most two electrons, and then only if the electrons have opposite spins.

Each subshell holds a maximum of twice as many electrons as the number of orbitals in the subshell. Thus, a  $2p$  subshell, which has three orbitals (with  $m_l = -1, 0, \text{ and } +1$ ), can hold a maximum of six electrons. The maximum number of electrons in various subshells is given in the following table.

Subshell	Number of Orbitals	Maximum Number of Electrons
$s (l = 0)$	1	2
$p (l = 1)$	3	6
$d (l = 2)$	5	10
$f (l = 3)$	7	14

### Example 8.1 Applying the Pauli Exclusion Principle

#### Gaining Mastery Toolbox

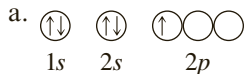

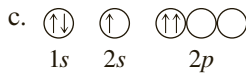

##### Critical Concept 8.1

The Pauli exclusion principle states that an orbital can hold at most two electrons and then only if the electrons have opposite spin.

##### Solution Essentials:

- Pauli exclusion principle
- The number of orbitals in a subshell of given  $l$  is  $2l + 1$

Which of the following orbital diagrams or electron configurations are possible and which are impossible, according to the Pauli exclusion principle? Explain.

- a.  b. 
- c.  d.  $1s^3 2s^1$
- e.  $1s^2 2s^1 2p^7$  f.  $1s^2 2s^2 2p^6 3s^2 3p^6 3d^8 4s^2$

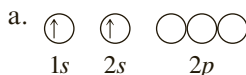

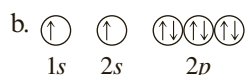

**Problem Strategy** In any orbital diagram, make sure that each orbital contains no more than two electrons, which have opposite spins. In any electron configuration, make sure that a subshell of given  $l$  contains no more than  $2(2l + 1)$  electrons (there are  $2l + 1$  different orbitals of given  $l$ , and each of these orbitals can hold two electrons).

#### Solution

a. **Possible** orbital diagram. b. **Impossible** orbital diagram; there are three electrons in the  $2s$  orbital. c. **Impossible** orbital diagram; there are two electrons in a  $2p$  orbital with the same spin. d. **Impossible** electron configuration; there are three electrons in the  $1s$  subshell (one orbital). e. **Impossible** electron configuration; there are seven electrons in the  $2p$  subshell (which can hold only six electrons). f. **Possible**. Note that the  $3d$  subshell can hold as many as ten electrons.

**Answer Check** The overarching idea here is that each orbital in an atom can hold a maximum of only two electrons, and then only if the two electrons have opposite spins. For example, a  $p$  subshell has three orbitals and therefore holds a maximum of six electrons.

**Exercise 8.1** Look at the following orbital diagrams and electron configurations. Which are possible and which are not, according to the Pauli exclusion principle? Explain.

- a.  b. 
- c.  d.  $1s^2 2s^2 2p^4$
- e.  $1s^2 2s^4 2p^2$  f.  $1s^2 2s^2 2p^6 3s^2 3p^{10} 3d^{10}$

See Problems 8.41, 8.42, 8.43, and 8.44.

## 8.2 Building-Up Principle and the Periodic Table

Every atom has an infinite number of possible electron configurations. The configuration associated with the lowest energy level of the atom corresponds to a quantum-mechanical state called the *ground state*. Other configurations correspond to *excited states*, associated with energy levels other than the lowest. For example, the ground state of the sodium atom is known from experiment to have the electron configuration  $1s^2 2s^2 2p^6 3s^1$ . The electron configuration  $1s^2 2s^2 2p^6 3p^1$  represents an excited state of the sodium atom. ▶

The chemical properties of an atom are related primarily to the electron configuration of its ground state. Table 8.1 lists the experimentally determined ground-state electron configurations of atoms  $Z = 1$  to  $Z = 36$ . (A complete table appears in Appendix D.)

### Building-Up Principle (Aufbau Principle)

Most of the configurations in Table 8.1 can be explained in terms of the **building-up principle** (or **Aufbau principle**), a scheme used to reproduce the electron configurations of the ground states of atoms by successively filling subshells with electrons in a specific order (the *building-up order*). Following this principle, you obtain the electron configuration of an atom by successively filling subshells in the following order:  $1s, 2s, 2p, 3s, 3p, 4s, 3d, 4p, 5s, 4d, 5p, 6s, 4f, 5d, 6p, 7s, 5f$ . This order reproduces the experimentally determined electron configurations (with some exceptions, which we will discuss later). You need not memorize this order. As you will see, you can very easily obtain it from the periodic table. (You can also reproduce this order from the mnemonic diagram shown in Figure 8.7.)

The building-up order corresponds for the most part to increasing energy of the subshells. You might expect this. By filling orbitals of lowest energy first, you usually get the lowest total energy (ground state) of the atom. Recall that the energy of an orbital depends only on the quantum numbers  $n$  and  $l$ . ▶ (The energy of the H atom, however, depends only on  $n$ .) Orbitals with the same  $n$  and  $l$  but

The transition of the sodium atom from the excited state  $1s^2 2s^2 2p^6 3p^1$  to the ground state  $1s^2 2s^2 2p^6 3s^1$  is accompanied by the emission of yellow light at 589 nm. Excited states of an atom are needed to describe its spectrum.

The quantum numbers and characteristics of orbitals were discussed in Section 7.5.

**Figure 8.7** ▲

#### A mnemonic diagram for the building-up order (diagonal rule)

You obtain this diagram by writing the subshell(s) in rows, each row having subshell(s) of given  $n$ . Within each row, you arrange the subshell(s) by increasing  $l$ . (You can stop after writing the  $nf$  subshell(s), since no known elements contain  $g$  or higher subshell(s).) Now, starting with the  $1s$  subshell(s), draw a series of diagonals, as shown. The building-up order is the order in which these diagonals strike the subshell(s).

**Table 8.1** Ground-State Electron Configurations of Atoms  $Z = 1$  to  $36^*$

Z	Element	Configuration	Z	Element	Configuration
1	H	$1s^1$	19	K	$1s^2 2s^2 2p^6 3s^2 3p^6 4s^1$
2	He	$1s^2$	20	Ca	$1s^2 2s^2 2p^6 3s^2 3p^6 4s^2$

18	Ar	$1s^2 2s^2 2p^6 3s^2 3p^6$	36	Kr	$1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10} 4s^2 4p^6$

\*A complete table appears in Appendix D.

Figure 8.8 ▶

**Orbital energies for the scandium atom ( $Z = 21$ )**

Note that in the scandium atom, unlike the hydrogen atom, the subshells for each  $n$  are spread apart in energy. Thus, the  $2p$  energy is above the  $2s$ . Similarly, the  $n = 3$  subshells are spread to give the order  $3s < 3p < 3d$ . The  $3d$  subshell energy is now just below the  $4s$ . (Values for this figure were calculated from theory by Charlotte F. Fischer, Vanderbilt University.)

different  $m_l$ —that is, different orbitals of the same subshell—have the same energy. The energy depends primarily on  $n$ , increasing with its value. For example, a  $3s$  orbital has greater energy than a  $2s$  orbital. Except for the H atom, the energies of orbitals with the same  $n$  increase with the  $l$  quantum number. A  $3p$  orbital has slightly greater energy than a  $3s$  orbital. The orbital of lowest energy is  $1s$ ; next higher are  $2s$  and  $2p$ , then  $3s$  and  $3p$ . The order of these subshells by energy, from  $1s$  to  $3p$ , follows the building-up order as listed earlier.

When subshells have nearly the same energy, however, the building-up order is not strictly determined by the order of their energies. The ground-state configurations, which we are trying to predict by the building-up order, are determined by the *total* energies of the atoms. The total energy of an atom depends not only on the energies of the subshells but also on the energies of interaction among the different subshells. It so happens that for all elements with  $Z = 21$  or greater, the energy of the  $3d$  subshell is lower than the energy of the  $4s$  subshell (Figure 8.8), which is opposite to the building-up order. You need the building-up order to predict the electron configurations of the ground states of atoms.

Now you can see how to reproduce the electron configurations of Table 8.1 using the building-up principle. Remember that the number of electrons in a neutral atom equals the atomic number  $Z$ . (The nuclear charge is  $+Z$ .) In the case of the simplest atom, hydrogen ( $Z = 1$ ), you obtain the ground state by placing the single electron into the  $1s$  orbital, giving the configuration  $1s^1$  (this is read as “one-ess-one”). Now you go to helium ( $Z = 2$ ). The first electron goes into the  $1s$  orbital, as in hydrogen, followed by the second electron, because any orbital can hold two electrons. The configuration is  $1s^2$ . Filling the  $n = 1$  shell creates a very stable configuration, and as a result, helium is chemically unreactive.

You continue this way through the elements, each time increasing  $Z$  by 1 and adding another electron. You obtain the configuration of an atom from that of the preceding element by adding an electron into the next available orbital, following the building-up order. In lithium ( $Z = 3$ ), the first two electrons give the configuration  $1s^2$ , like helium, but the third electron goes into the next higher orbital in the building-up order, because the  $1s$  orbital is now filled. This gives the configuration  $1s^2 2s^1$ . In beryllium ( $Z = 4$ ), the fourth electron fills the  $2s$  orbital, giving the configuration  $1s^2 2s^2$ .

Using the abbreviation [He] for  $1s^2$ , the configurations are

$Z = 3$	lithium	$1s^2 2s^1$	or	[He] $2s^1$
$Z = 4$	beryllium	$1s^2 2s^2$	or	[He] $2s^2$

With boron ( $Z = 5$ ), the electrons begin filling the  $2p$  subshell. You get

$Z = 5$	boron	$1s^2 2s^2 2p^1$	or	$[\text{He}] 2s^2 2p^1$
$Z = 6$	carbon	$1s^2 2s^2 2p^2$	or	$[\text{He}] 2s^2 2p^2$
$\vdots$				
$Z = 10$	neon	$1s^2 2s^2 2p^6$	or	$[\text{He}] 2s^2 2p^6$

Having filled the  $2p$  subshell, you again find a particularly stable configuration. Neon is chemically unreactive as a result.

With sodium ( $Z = 11$ ), the  $3s$  orbital begins to fill. Using the abbreviation  $[\text{Ne}]$  for  $1s^2 2s^2 2p^6$ , you have

$Z = 11$	sodium	$1s^2 2s^2 2p^6 3s^1$	or	$[\text{Ne}] 3s^1$
$Z = 12$	magnesium	$1s^2 2s^2 2p^6 3s^2$	or	$[\text{Ne}] 3s^2$

Then the  $3p$  subshell begins to fill.

$Z = 13$	aluminum	$1s^2 2s^2 2p^6 3s^2 3p^1$	or	$[\text{Ne}] 3s^2 3p^1$
$\vdots$				
$Z = 18$	argon	$1s^2 2s^2 2p^6 3s^2 3p^6$	or	$[\text{Ne}] 3s^2 3p^6$

With the  $3p$  subshell filled, a stable configuration has been attained; argon is an unreactive element.

Now the  $4s$  orbital begins to fill. You get  $[\text{Ar}] 4s^1$  for potassium ( $Z = 19$ ) and  $[\text{Ar}] 4s^2$  for calcium ( $Z = 20$ ) ( $[\text{Ar}] = 1s^2 2s^2 2p^6 3s^2 3p^6$ ). At this point the  $3d$  subshell begins to fill. You get  $[\text{Ar}] 3d^1 4s^2$  for scandium ( $Z = 21$ ),  $[\text{Ar}] 3d^2 4s^2$  for titanium ( $Z = 22$ ), and  $[\text{Ar}] 3d^3 4s^2$  for vanadium ( $Z = 23$ ). *Note that we have written the configurations with subshells arranged in order by shells.* This generally places the subshells in order by energy and puts the subshells involved in chemical reactions at the far right. ▶

Let us skip to zinc ( $Z = 30$ ). The  $3d$  subshell has filled; the configuration is  $[\text{Ar}] 3d^{10} 4s^2$ . Now the  $4p$  subshell begins to fill, starting with gallium ( $Z = 31$ ), configuration  $[\text{Ar}] 3d^{10} 4s^2 4p^1$ , and ending with krypton ( $Z = 36$ ), configuration  $[\text{Ar}] 3d^{10} 4s^2 4p^6$ .

### Electron Configurations and the Periodic Table

By this time you can see a pattern develop among the ground-state electron configurations of the atoms. This pattern explains the periodic table, which was briefly described in Section 2.5. Consider helium, neon, argon, and krypton, elements in Group 8A of the periodic table. Neon, argon, and krypton have configurations in which a  $p$  subshell has just filled. (Helium has a filled  $1s$  subshell; no  $1p$  subshell is possible.)

helium	$1s^2$		
neon	$1s^2 2s^2 2p^6$		
argon	$1s^2 2s^2 2p^6 3s^2 3p^6$		
krypton	$1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10} 4s^2 4p^6$		

These elements are the first members of the group called *noble gases* because of their relative unreactivity.

Look now at the configurations of beryllium, magnesium, and calcium, members of the group of *alkaline earth metals* (Group 2A), which are similar, moderately reactive elements.

beryllium	$1s^2 2s^2$	or	$[\text{He}] 2s^2$
magnesium	$1s^2 2s^2 2p^6 3s^2$	or	$[\text{Ne}] 3s^2$
calcium	$1s^2 2s^2 2p^6 3s^2 3p^6 4s^2$	or	$[\text{Ar}] 4s^2$

Although the building-up order reproduces the ground-state electron configurations, it has no other significance. The order by  $n$  (and then by  $l$  within a given  $n$ ), however, generally places the most easily ionized orbitals at the far right. For example, the electron configuration of Fe (in order by shells) is  $1s^2 2s^2 2p^6 3s^2 3p^6 3d^6 4s^2$ . The  $4s$  electrons ionize first.

Each of these configurations consists of a **noble-gas core**, that is, an *inner-shell configuration corresponding to one of the noble gases*, plus two outer electrons with an  $ns^2$  configuration.

The elements boron, aluminum, and gallium (Group 3A) also have similarities. Their configurations are

Boron and aluminum have noble-gas cores plus three electrons with the configuration  $ns^2 np^1$ . Gallium has an additional filled  $3d$  subshell. *The noble-gas core together with  $(n-1)d^{10}$  electrons* is often referred to as a **pseudo-noble-gas core**, because these electrons usually are not involved in chemical reactions.

An electron in an atom outside the noble-gas or pseudo-noble-gas core is called a **valence electron**. Such electrons are primarily involved in chemical reactions, and similarities among the configurations of valence electrons (the *valence-shell configurations*) account for similarities of the chemical properties among groups of elements.

Figure 8.9 shows a periodic table with the valence-shell configurations included. Note the similarity in electron configuration within any group (column) of elements.

Figure 8.9 ▲  
A periodic table This table shows the valence-shell configurations of the elements.

This similarity explains what chemists since Mendeleev have known—the properties of elements in any group are similar.

The *main-group* (or *representative*) *elements* all have valence-shell configurations  $ns^a np^b$ , with some choice of  $a$  and  $b$ . ( $b$  could be equal to 0.) In other words, the outer  $s$  or  $p$  subshell is being filled. Similarly, in the *d-block transition elements* (often called simply *transition elements* or *transition metals*), a  $d$  subshell is being filled. In the *f-block transition elements* (or *inner transition elements*), an  $f$  subshell is being filled. (See Figure 8.9 or Appendix D for the configurations of these elements.)

### Exceptions to the Building-Up Principle

As we have said, the building-up principle reproduces most of the ground-state configurations correctly. There are some exceptions, however, and chromium ( $Z = 24$ ) is the first we encounter. The building-up principle predicts the configuration  $[\text{Ar}]3d^4 4s^2$ , though the correct one is found experimentally to be  $[\text{Ar}]3d^5 4s^1$ . These two configurations are actually very close in total energy because of the closeness in energies of the  $3d$  and  $4s$  orbitals (Figure 8.8). For that reason, small effects can influence which of the two configurations is actually lower in energy. Copper ( $Z = 29$ ) is another exception to the building-up principle, which predicts the configuration  $[\text{Ar}]3d^9 4s^2$ , although experiment shows the ground-state configuration to be  $[\text{Ar}]3d^{10} 4s^1$ .

We need not dwell on these exceptions beyond noting that they occur. The point to remember is that the configuration predicted by the building-up principle is very close in energy to the ground-state configuration (if it is not the ground state). Most of the qualitative conclusions regarding the chemistry of an element are not materially affected by arguing from the configuration given by the building-up principle. ►

More exceptions occur among the heavier transition elements, where the outer subshells are very close together. We must concede that simplicity was not the uppermost concern in the construction of the universe!

#### CONCEPT CHECK 8.1

Imagine a world in which the Pauli principle is “No more than one electron can occupy an atomic orbital, irrespective of its spin.” How many elements would there be in the second row of the periodic table, assuming that nothing else is different about this world?

## 8.3 Writing Electron Configurations Using the Periodic Table

To discuss bonding and the chemistry of the elements coherently, you must be able to reproduce the electron configurations with ease, following the building-up principle. All you need is some facility in recall of the building-up order of subshells.

One approach is to recall the structure of the periodic table. Because that structure is basic, it offers a sound way to remember the building-up order. There is a definite pattern to the order of filling of the subshells as you go through the elements in the periodic table, and from this you can write the building-up order. Figure 8.12 shows a periodic table stressing this pattern. For example, in the violet-colored area, an  $ns$  subshell is being filled. In the blue-colored area, an  $np$  subshell is being filled. The value of  $n$  is obtained from the period (row) number. In the red area, an  $(n - 1)d$  subshell is being filled.

You read the building-up order by starting with the first period, in which the  $1s$  subshell is being filled. In the second period, you have  $2s$  (violet area); then, staying in the same period but jumping across, you have  $2p$  (blue area). In the third period, you have  $3s$  and  $3p$ ; in the fourth period,  $4s$  (violet area),  $3d$  (red area), and  $4p$  (blue area). This pattern should become clear enough to visualize with a

## Instrumental Methods

# X Rays, Atomic Numbers, and Orbital Structure (Photoelectron Spectroscopy)

In 1913 Henry G. J. Moseley, a student of Rutherford, used the technique of *X-ray spectroscopy* (just discovered by Max von Laue) to determine the atomic numbers of the elements. X rays are produced in a cathode-ray tube when the electron beam (cathode ray) falls on a metal target. The explanation for the production of X rays is as follows: When an electron in the cathode ray hits a metal atom in the target, it can (if it has sufficient energy) knock an electron from an inner shell of the atom. This produces a metal ion with an electron missing from an inner orbital. The electron configuration is unstable, and an electron from an orbital of higher energy drops into the half-filled orbital and a photon is emitted. The photon corresponds to electromagnetic radiation in the X-ray region.

The energies of the inner orbitals of an atom and the energy changes between them depend on the nuclear

charge,  $+Z$ . Therefore, the photon energies  $h\nu$  and the frequencies  $\nu$  of emitted X rays depend on the atomic number  $Z$  of the metal atom in the target. Figure 8.10 shows the X-ray spectra Moseley obtained with various metal targets. The direct dependence of the X-ray spectrum on atomic number provides an unequivocal way of deciding whether a substance is a pure element or not.

A related technique, *X-ray photoelectron spectroscopy*, experimentally confirms our theoretical view of the orbital structure of the atom. Instead of irradiating a sample with an electron beam and analyzing the frequencies of emitted X rays, you irradiate a sample with X rays and analyze the kinetic energies of ejected electrons. In other words, you observe the *photoelectric effect* on the sample (see Section 7.2).

As an example of photoelectron spectroscopy, consider a sample of neon gas (Ne atoms). Suppose the sample is

**Figure 8.10** ◀

**X-ray spectra of the elements calcium to zinc, obtained by Moseley** Each line results from an emission of given wavelength. Because of the volatility of zinc, Moseley used brass (a copper–zinc alloy) to observe the spectrum of zinc. Note the copper lines in brass. Also note how the lines progress to the right (indicating increasing wavelength or decreasing energy difference) with decreasing atomic number.

(continued)

periodic table that is not labeled with the subshells, such as the one on the inside front cover of this book. The detailed method is illustrated in the next example. (An alternative way to reconstruct the building-up order of subshells is to write the diagram in Figure 8.7.)

*Note on writing electron configurations of atoms:* If you write the configuration of an atom with its subshells arranged by shells, the orbitals will usually be in order by energy, with the subshells used to describe chemical reactivity at the far right. For example, the configuration of Br would be written  $[\text{Ar}]3d^{10}4s^24p^5$ . However, you will also see the orbitals in a configuration written in the building-up order, which is an empirical order that has been found to reproduce most of the atomic configurations. The configuration of Br would be written  $[\text{Ar}]4s^23d^{10}4p^5$ . Ask your instructor whether he or she has a preference.

## Instrumental Methods X Rays, Atomic Numbers, and Orbital Structure (Photoelectron Spectroscopy) *(continued)*

irradiated with X rays of a specific frequency great enough to remove a 1s electron from the neon atom. Part of the energy of the X-ray photon,  $h\nu$ , is used to remove the electron from the atom. (This is the *ionization energy*,  $I.E.$ , for that electron.) The remaining energy appears as kinetic energy,  $E_k$ , of the ejected electron. From the law of conservation of energy, you can write

$$E_k = h\nu - I.E.$$

Because  $h\nu$  is fixed,  $E_k$  will depend linearly on  $I.E.$ , the ionization energy.

If you look at the electrons ejected from neon, you find that they have kinetic energies related to the ionization energies from all possible orbitals (1s, 2s, and 2p) in the atom. When you scan the various kinetic energies of ejected electrons, you see a spectrum with peaks corresponding to the different occupied orbitals (see Figure 8.11a). These ionization energies are approximately equal to the positive values of the orbital energies (Figure 8.11b), so this spectrum provides direct experimental verification of the discrete energy levels associated with the electrons of the atom.

X-ray photoelectron spectrum of neon

■ See Problems 8.87 and 8.88.

**Figure 8.12** ▲

**A periodic table illustrating the building-up order** The colored areas of elements show the different subshells that are filling with those elements.

**Example 8.2** Determining the Configuration of an Atom Using the Building-Up Principle**Gaining Mastery Toolbox****Critical Concept 8.2**

To write the electron configuration for the ground state of a neutral atom of atomic number  $Z$ , write the subshells in building-up order and then distribute  $Z$  electrons into these subshells, starting with the  $1s$  subshell.

**Solution Essentials:**

- Building-up order of subshells
- Pauli exclusion principle
- The number of orbitals in a subshell of given  $l$  is  $2l + 1$

Use the building-up principle to obtain the configuration for the ground state of the gallium atom ( $Z = 31$ ). Give the configuration in complete form (do not abbreviate for the core). What is the valence-shell configuration?

**Problem Strategy** Write the subshells in their building-up order. You can use any periodic table to do this. All you have to remember is the pattern in which subshells are filled as you progress through the table (Figure 8.12). Go through the periods, starting with hydrogen, writing the subshells that are being filled, and stopping with the element whose configuration you want (gallium in this example). Then you distribute the electrons (equal to the atomic number of the element) to the subshells. The valence-shell configuration includes only the subshells outside the noble-gas or pseudo-noble-gas core.

**Solution** From a periodic table, you get the following building-up order:

	$1s$	$2s\ 2p$	$3s\ 3p$	$4s\ 3d\ 4p$
Period:	first	second	third	fourth

Now you fill the subshells with electrons, remembering that you have a total of 31 electrons to distribute. You get

Or, if you rearrange the subshells by shells, you write

The valence-shell configuration is  $4s^2 4p^1$ .

**Answer Check** The principal quantum number of the valence shell must equal the period of the element. If your answer is not consistent with this, examine your work for error. Here, gallium is in period 4, and the principal quantum number of the valence shell is 4.

**Exercise 8.2** Use the building-up principle to obtain the electron configuration for the ground state of the manganese atom ( $Z = 25$ ).

See Problems 8.47, 8.48, 8.49, and 8.50.

In many cases, you need only the configuration of the outer electrons. You can determine this from the position of the element in the periodic table. Recall that the valence-shell configuration of a main-group element is  $ns^a np^b$ , where  $n$ , the principal quantum number of the outer shell, also equals the period number for the element. The total number of valence electrons, which equals  $a + b$ , can be obtained from the group number. For example, gallium is in Period 4, so  $n = 4$ . It is in Group 3A, so the number of valence electrons is 3. This gives the valence-shell configuration  $4s^2 4p^1$ . The configuration of outer shells of a transition element is obtained in a similar fashion. The next example gives the details.

**Example 8.3** Determining the Configuration of an Atom Using the Period and Group Numbers**Gaining Mastery Toolbox****Critical Concept 8.3**

To write the valence-shell (or outer-shell) configuration of an element using the periodic table, determine the period and group number of the element, noting whether it is a main-group or transition element. The valence-shell configuration

What are the configurations for the outer electrons of a. tellurium,  $Z = 52$ , and b. nickel,  $Z = 28$ ?

**Problem Strategy** Find the period and the group number of the element for the atom. Note whether it is a main-group or a transition element.

If the atom is that of a main-group element, the valence configuration is  $ns^a np^b$ , where  $n$  equals the period of the element and  $a + b$  equals the group number (which

(continued)

**Example 8.3** (continued)

of a main-group element is  $ns^2np^b$ , where  $n$  equals the period of the element and  $a + b$  the group number. (Distribute the electrons to the  $ns$  subshell, then to the  $np$  subshell.) The outer-shell configuration of a transition element is  $(n-1)d^{a-2}ns^2$ , where  $a$  is the group number.

**Solution Essentials:**

- Determine the period and group number of an element
- Pauli exclusion principle
- The number of orbitals in a subshell of given  $l$  is  $2l + 1$

equals the number of valence electrons). Distribute these electrons to the  $ns$  orbital; then distribute any remaining electrons to the  $np$  orbitals.

If the atom is that of a transition element, the outer-shell configuration is  $(n-1)d^{a-2}ns^2$ , where  $n$  equals the period and  $a$  is the group number—except for Group 8B, which has three columns. For Group 8B, count 8, 9, then 10 for successive columns, which then equals  $a$ .

**Solution**

a. You locate tellurium in a periodic table and find it to be in Period 5, Group 6A. Thus, it is a main-group element, and the outer subshells are  $5s$  and  $5p$ . These subshells contain six electrons, because the group is 6A. The valence-shell configuration is  $5s^25p^4$ . b. Nickel is a Period 4 transition element, in which the general form of the outer-shell configuration is  $3d^{a-2}4s^2$ . To determine  $a$ , you note that it equals the group number up to iron (8). After that you count Co as 9 and Ni as 10. Hence, the outer-shell configuration is  $3d^84s^2$ .

**Answer Check** Note whether the configuration does follow the general form, either for a main-group element or a transition element. Check that the principal quantum number,  $n$ , equals the period of the element. For a main-group element, the total number of valence electrons should equal the group number. For a transition element, the number of electrons in the outer shell equals  $a$ .

**Exercise 8.3** Using the periodic table on the inside front cover, write the valence-shell configuration of arsenic (As).

See Problems 8.51, 8.52, 8.53, and 8.54.

**Exercise 8.4** The lead atom has the ground-state configuration  $[\text{Xe}]4f^{14}5d^{10}6s^26p^2$ . Find the period and group for this element. From its position in the periodic table, would you classify lead as a main-group element, a transition element, or an inner transition element?

See Problems 8.55 and 8.56.

 **CONCEPT CHECK 8.2**

Two elements in Period 3 are adjacent to one another in the periodic table. The ground-state atom of one element has only  $s$  electrons in its valence shell; the other one has at least one  $p$  electron in its valence shell. Identify the elements.

## 8.4 Orbital Diagrams of Atoms; Hund's Rule

In discussing the ground states of atoms, we have not yet described how the electrons are arranged within each subshell. There may be several different ways of arranging electrons in a particular configuration. Consider the carbon atom ( $Z = 6$ ) with the ground-state configuration  $1s^22s^22p^2$ . Three possible arrangements are given in the following orbital diagrams.

These orbital diagrams show different states of the carbon atom. Each state has a different energy and, as you will see, different magnetic characteristics.

### Hund's Rule

In about 1927, Friedrich Hund discovered an empirical rule determining the lowest-energy arrangement of electrons in a subshell. **Hund's rule** states that *the lowest-energy arrangement of electrons in a subshell is obtained by putting electrons into separate orbitals of the subshell with the same spin before pairing electrons*. Let us see how this would apply to the carbon atom, whose ground-state configuration is  $1s^2 2s^2 2p^2$ . The first four electrons go into the  $1s$  and  $2s$  orbitals.

The next two electrons go into separate  $2p$  orbitals, with both electrons having the same spin, following Hund's rule.

We see that the orbital diagram corresponding to the lowest energy is the one we previously labeled Diagram 1.

To apply Hund's rule to the oxygen atom, whose ground-state configuration is  $1s^2 2s^2 2p^4$ , we place the first seven electrons as follows:

The last electron is paired with one of the  $2p$  electrons to give a doubly occupied orbital. The orbital diagram for the ground state of the oxygen atom is

In the following example, Hund's rule is used to determine the orbital diagram for the ground state of a more complicated atom. Table 8.2 gives orbital diagrams for the ground states of the first ten elements

**Table 8.2** Orbital Diagrams for the Ground States of Atoms from  $Z = 1$  to  $Z = 10$

			Orbital Diagram		
Atom	$Z$	Configuration	$1s$	$2s$	$2p$
Hydrogen	1	$1s^1$	$\uparrow$	$\circ$	$\circ$ $\circ$ $\circ$
Helium	2	$1s^2$	$\uparrow\downarrow$	$\circ$	$\circ$ $\circ$ $\circ$
Lithium	3	$1s^2 2s^1$	$\uparrow\downarrow$	$\uparrow$	$\circ$ $\circ$ $\circ$
Beryllium	4	$1s^2 2s^2$	$\uparrow\downarrow$	$\uparrow\downarrow$	$\circ$ $\circ$ $\circ$
Boron	5	$1s^2 2s^2 2p^1$	$\uparrow\downarrow$	$\uparrow\downarrow$	$\uparrow$ $\circ$ $\circ$
Carbon	6	$1s^2 2s^2 2p^2$	$\uparrow\downarrow$	$\uparrow\downarrow$	$\uparrow$ $\uparrow$ $\circ$
Nitrogen	7	$1s^2 2s^2 2p^3$	$\uparrow\downarrow$	$\uparrow\downarrow$	$\uparrow$ $\uparrow$ $\uparrow$
Oxygen	8	$1s^2 2s^2 2p^4$	$\uparrow\downarrow$	$\uparrow\downarrow$	$\uparrow\downarrow$ $\uparrow$ $\uparrow$
Fluorine	9	$1s^2 2s^2 2p^5$	$\uparrow\downarrow$	$\uparrow\downarrow$	$\uparrow\downarrow$ $\uparrow\downarrow$ $\uparrow$
Neon	10	$1s^2 2s^2 2p^6$	$\uparrow\downarrow$	$\uparrow\downarrow$	$\uparrow\downarrow$ $\uparrow\downarrow$ $\uparrow\downarrow$

**Example 8.4 Applying Hund's Rule****Gaining Mastery Toolbox****Critical Concept 8.4**

Hund's rule states that the lowest-energy arrangement of electrons in a subshell is obtained by putting electrons with the same spin into separate orbitals of the subshell before pairing electrons.

**Solution Essentials:**

- Hund's rule
- Building-up order of subshells
- Pauli exclusion principle
- The number of orbitals in a subshell of given  $l$  is  $2l + 1$

Write an orbital diagram for the ground state of the iron atom.

**Problem Strategy** First obtain the electron configuration, as described in Example 8.2. Then draw circles for the orbitals of each subshell. A filled subshell should have doubly occupied orbitals (two electrons with opposite spins). For a partially filled subshell, apply Hund's rule, putting electrons into separate orbitals with the same spin (either all up or all down) before pairing electrons.

**Solution** The electron configuration of the iron atom is  $1s^2 2s^2 2p^6 3s^2 3p^6 3d^6 4s^2$ . All the subshells except the  $3d$  are filled. In placing the six electrons in the  $3d$  subshell, you note that the first five go into separate  $3d$  orbitals with their spin arrows in the same direction. The sixth electron must doubly occupy a  $3d$  orbital. The orbital diagram is

You can write this diagram in abbreviated form using [Ar] for the argon-like core of the iron atom:

**Answer Check** Check that you have started with the correct configuration for the atom. Then note that you have followed Hund's rule for a partially filled subshell.

**Exercise 8.5** Write an orbital diagram for the ground state of the phosphorus atom ( $Z = 15$ ). Write all orbitals.

See Problems 8.57 and 8.58.

**Magnetic Properties of Atoms**

The magnetic properties of a substance can reveal certain information about the arrangement of electrons in an atom (or molecule). Although an electron in an atom behaves like a small magnet, the magnetic attractions from two electrons that are opposite in spin cancel each other. As a result, an atom that has only doubly occupied orbitals has no net spin magnetism. However, an atom with *unpaired* electrons—that is, with an excess of one kind of spin—does exhibit a net magnetism.

The magnetic properties of an atom can be observed. The most direct way is to determine whether the atomic substance is attracted to the field of a strong magnet. A **paramagnetic substance** is a substance that is weakly attracted by a magnetic field, and this attraction is generally the result of unpaired electrons. ▶ For example, sodium vapor has been found experimentally to be paramagnetic. The explanation is that the vapor consists primarily of sodium atoms, each containing an unpaired electron. (The configuration is  $[\text{Ne}]3s^1$ .) A **diamagnetic substance** is a substance that is not attracted by a magnetic field or is very slightly repelled by such a field. This property generally means that the substance has only paired electrons. Mercury vapor is found experimentally to be diamagnetic. The explanation is that mercury vapor consists of mercury atoms, with the electron configuration  $[\text{Xe}]4f^{14}5d^{10}6s^2$ , which has only paired electrons.

We expect the different orbital diagrams presented at the beginning of this section for the  $1s^2 2s^2 2p^2$  configuration of the carbon atom to have different magnetic properties. Diagram 1, predicted by Hund's rule to be the ground state, would give a magnetic atom, whereas the other diagrams would not. If we could prepare a vapor of carbon atoms, it should be attracted to a magnet. (It should be paramagnetic.) It is difficult to prepare a vapor of free carbon atoms in sufficient concentration to

The strong, permanent magnetism seen in iron objects is called ferromagnetism and is due to the cooperative alignment of electron spins in many iron atoms. Paramagnetism is a much weaker effect. Nevertheless, paramagnetic substances can be attracted to a strong magnet. Liquid oxygen is composed of paramagnetic  $\text{O}_2$  molecules. When poured over a magnet, the liquid clings to the poles. (See Figure 10.29.)

## Frontiers

A CHEMIST Looks at . . .

## Levitating Frogs and People

Have you ever seen a magic act in which a person rises above the stage in apparent defiance of gravity? Magicians have often included such acts of “levitation” as part of their performances. Of course, magical levitation uses tricks to deceive you. But levitation can be done, without tricks, using the known laws of electromagnetism.

Recently, researchers wanted to demonstrate that you can levitate almost anything if you have the proper magnetic field. They placed a frog within the magnetic field of a powerful electromagnet (which consists of an electric current flowing through a coil of wire). The frog floated in midair above the coil, at the point where the upward repulsion of the frog from the magnetic field just balanced the downward force of gravity (Figure 8.13).

We don’t usually think of things such as frogs as being magnetic. In fact, most materials, including most substances in a biological organism, are diamagnetic. They contain pairs of electrons, in which the magnetism of each electron in a pair offsets the equal and opposite magnetism of the other electron. You might expect diamagnetic materials to be nonmagnetic because of this balance of opposite electron spins. But when you place a diamagnetic material in an external magnetic field, its electrons move so as to induce, or generate, a smaller magnetic field that is opposite in direction to the external field. This results in a repulsive force between the diamagnetic material and the external field. The repulsive force, though generally small, can be easily observed if the external magnet is large enough. Although, with a sufficiently large magnet, it would be possible to levitate a person as well as a frog, the researchers don’t plan to do that.

Courtesy of A. Geim, University of Nijmegen

**Figure 8.13** ▲

**Levitation of a frog** A frog placed in a powerful magnetic field, generated by a current flowing through a water-cooled coil of wire, appears to float in midair in defiance of gravity. The frog contains materials that are diamagnetic (composed of electron pairs), which are repelled by the magnetic field.

■ See Problems 8.89 and 8.90.

observe a result. However, the visible–ultraviolet spectrum of carbon atoms can be obtained easily from dilute vapor. From an analysis of this spectrum, it is possible to show that the ground-state atom is magnetic, which is consistent with the prediction of Hund’s rule.

## ► Periodicity of the Elements

You have seen that the periodic table that Mendeleev discovered in 1869 can be explained by the periodicity of the ground-state electron configurations of the atoms. Now we will look at various aspects of the periodicity of the elements.

### 8.5 Mendeleev’s Predictions from the Periodic Table

One of Mendeleev’s periodic tables is reproduced in Figure 8.14. Though somewhat different from modern tables, it shows essentially the same arrangement. In this early form of the periodic table, within each column some elements were placed toward the left side and some toward the right. With some exceptions, the elements on a given

Figure 8.14 ◀

Mendeleev's periodic table This one was published in 1872.

side have similar properties. Mendeleev left spaces in his periodic table for what he felt were undiscovered elements. There are blank spaces in his row 5—for example, one directly under aluminum and another under silicon (looking at just the elements on the right side of the column). By writing the known elements in this row with their atomic weights, he could determine approximate values (between the known ones) for the missing elements (values in parentheses).

Cu	Zn	—	—	As	Se	Br
63 amu	65 amu	(68 amu)	(72 amu)	75 amu	78 amu	80 amu

The Group III element (the Group 3A element in modern tables) directly under aluminum Mendeleev called eka-aluminum, with the symbol Ea. (*Eka* is the Sanskrit word meaning “first”; thus eka-aluminum is the first element under aluminum.) The known Group III elements have oxides of the form  $R_2O_3$ , so Mendeleev predicted that eka-aluminum would have an oxide with the formula  $Ea_2O_3$ .

The physical properties of this undiscovered element could be predicted by comparing values for the neighboring known elements. For eka-aluminum Mendeleev predicted a density of  $5.9 \text{ g/cm}^3$ , a low *melting point* (the temperature at which a substance melts), and a high *boiling point* (the temperature at which a substance boils).

In 1874 the French chemist Paul-Émile Lecoq de Boisbaudran found two previously unidentified violet lines in the atomic spectrum of a sample of sphalerite (a zinc sulfide,  $ZnS$ , mineral). Realizing he was on the verge of a discovery of a new element, Lecoq de Boisbaudran quickly prepared a large batch of the zinc mineral, from which he isolated a gram of a new element. He called this new element gallium. The properties of gallium were remarkably close to those Mendeleev predicted for eka-aluminum.

<i>Property</i>	<i>Predicted for Eka-Aluminum</i>	<i>Found for Gallium</i>
Atomic weight	68 amu	69.7 amu
Formula of oxide	$Ea_2O_3$	$Ga_2O_3$
Density of the element	$5.9 \text{ g/cm}^3$	$5.91 \text{ g/cm}^3$
Melting point of the element	Low	$30.1^\circ\text{C}$
Boiling point of the element	High	$1983^\circ\text{C}$

The predictive power of Mendeleev's periodic table was demonstrated again when scandium (eka-boron) was discovered in 1879 and germanium (eka-silicon) in 1886. Both elements had properties remarkably like those predicted by Mendeleev.

Figure 8.15 ▲

**Electron distribution for the argon atom** This is a radial distribution, showing the probability of finding an electron at a given distance from the nucleus. The distribution shows three maxima, for the  $n = 1$ ,  $n = 2$ , and  $n = 3$  shells. The outermost maximum occurs at 71 pm; then the distribution falls steadily, becoming negligibly small after several hundred picometers.

These early successes won acceptance for the organizational and predictive power of the periodic table.

## 8.6 Some Periodic Properties

The electron configurations of the atoms display a periodic variation with increasing atomic number (nuclear charge). As a result, the elements show periodic variations of physical and chemical behavior. The **periodic law** states that *when the elements are arranged by atomic number, their physical and chemical properties vary periodically*. In this section, we will look at three physical properties of an atom: atomic radius, ionization energy, and electron affinity. These three quantities, especially ionization energy and electron affinity, are important in discussions of chemical bonding (the subject of Chapter 9).

### Atomic Radius

The definition of atomic radius is somewhat arbitrary; in fact, different definitions have been given. Because the statistical

distribution of electrons does not abruptly end but merely decreases to smaller and smaller values as the distance from the nucleus increases, an atom has no definite boundary. You can see this in the plot of the electron distribution for the argon atom, shown in Figure 8.15. This distribution has been calculated from an approximate wavefunction obtained for the isolated atom. Note that the distribution shows a maximum at each shell of the atom and falls steadily to a negligible value after the maximum for the outer shell, which occurs at 71 pm.

It seems reasonable, as one possibility, to define the **atomic radius** (calculated from theory for the isolated atom) as *the maximum in the radial distribution function of the outer shell of the atom*. From this definition, we would say that argon has a radius of 71 pm. Similar calculations have been done on most of the atoms in the periodic table. In Figure 8.16, we have graphically plotted the atomic radii from a particular set of calculations versus atomic number to display their periodic variations. Figure 8.17 shows the same data visually.

Figure 8.16 ►

**Atomic radius (isolated atom) versus atomic number** These radii are calculated values for isolated atoms. Note that the curve is periodic (tends to repeat). Each period of elements begins with the Group 1A atom, and the atomic radius tends to decrease until the Group 8A atom.

Figure 8.17 ▲

**Representation of atomic radii (isolated atoms)** The atomic radii are in picometers. Note the trends within each period and each group.

There are other definitions of atomic radii. As we will discuss in the next chapter on chemical bonding, the *covalent bond* is one type of chemical bond, and atomic radii have been defined in a way that reproduces the empirically determined covalent bond distances (the distances between atomic nuclei) in chemical compounds. By this definition, the **atomic radius** (in this case, often called the **covalent radius**) is *the value for that atom in a set of covalent radii assigned to atoms in such a way that the sum of the covalent radii of atoms A and B predicts the approximate A—B bond length*. Note that these atomic radii are from empirical data rather than calculated from wavefunctions, and as we noted, they refer to atoms in compounds and not to isolated atoms. We will discuss these covalent radii again in Section 9.10.

Although the definition of atomic radius is somewhat arbitrary, as long as we refer to a set of values obtained in a consistent manner, they can be useful. In particular, atomic radii in a given set follow general periodic trends, which can be seen in Figures 8.16 and 8.17. These trends are:

1. **Within each period (horizontal row)**, the atomic radius tends to decrease with increasing atomic number (nuclear charge). Thus, the largest atom in a period tends to be the Group 1A atom and the smallest the noble-gas atom.
2. **Within each group (vertical column)**, the atomic radius tends to increase with the period number.

Note that the atomic radius increases greatly going from any noble-gas atom to the following Group 1A atom, giving the curve in Figure 8.16 a saw-toothed appearance. We should stress that these are general trends, and you may see occasional exceptions from these trends in some lists of atomic radii.

These general trends in atomic radius can be explained if you look at the two factors that primarily determine the size of the outermost orbital. One factor is the principal quantum number  $n$  of the orbital; the larger  $n$  is, the larger the size of the orbital. The other factor is the effective nuclear charge acting on an electron

in the orbital; increasing the effective nuclear charge reduces the size of the orbital by pulling the electrons inward. The **effective nuclear charge** is *the positive charge that an electron experiences from the nucleus, equal to the nuclear charge but reduced by any shielding or screening from any intervening electron distribution*. Consider the effective nuclear charge on the 2s electron in the lithium atom (configuration  $1s^2 2s^1$ ). The nuclear charge is  $3e$ , but the effect of this charge on the 2s electron is reduced by the distribution of the two 1s electrons lying between the nucleus and the 2s electron (roughly, each core electron reduces the nuclear charge by  $1e$ ).

Consider a given period of elements. The principal quantum number of the outer orbitals remains constant. However, the effective nuclear charge increases, because the nuclear charge increases and the number of core electrons remains constant. Consequently, the size of the outermost orbital and, therefore, the radius of the atom decrease with increasing  $Z$  in any period.

Now consider a given column of elements. The effective nuclear charge remains nearly constant (approximately equal to  $e$  times the number of valence electrons), but  $n$  gets larger. You observe that the atomic radius increases.

### Example 8.5 Determining Relative Atomic Sizes from Periodic Trends

#### Gaining Mastery Toolbox

##### Critical Concept 8.5

The general trends in atomic radii are that they decrease left to right in a period and increase from top to bottom in a group.

##### Solution Essentials:

- General trends of atomic radii

Refer to a periodic table and use the trends noted for size of atomic radii to arrange the following in order of increasing atomic radius: Al, C, Si.

**Problem Strategy** The general trends in atomic radius are that it decreases left to right in a period and that it increases from top to bottom of a group. Compare any two elements in the same period, or in the same group, to decide which of the two is smaller. From this, decide the order of the elements.

**Solution** Note that C is above Si in Group 4A. Therefore, the radius of C is smaller than that of Si (the atomic radius increases going down a group of elements). Note that Al and Si are in the same period. Therefore, the radius of Si is smaller than that of Al (radius decreases with  $Z$  in a period). Hence the order of elements by increasing radius is **C, Si, Al**.

**Answer Check** After you have decided on the order of the atoms, check that the atomic radius does indeed increase, left to right.

**Exercise 8.6** Using a periodic table, arrange the following in order of increasing atomic radius: Na, Be, Mg. | See Problems 8.61 and 8.62.

### Ionization Energy

The **first ionization energy** (or **first ionization potential**) of an atom is *the minimum energy needed to remove the highest-energy (that is, the outermost) electron from the neutral atom in the gaseous state*. (When the unqualified term *ionization energy* is used, it generally means first ionization energy.) For the lithium atom, the first ionization energy is the energy needed for the following process (electron configurations are in parentheses):

Values of this energy are often quoted for one mole of atoms ( $6.02 \times 10^{23}$  atoms). Thus, the ionization energy of the lithium atom is 520 kJ/mol. ◀

Ionization energies display a periodic variation when plotted against atomic number, as Figure 8.18 shows. Within any period, values tend to increase with atomic number. Thus, the lowest values in a period are found for the Group 1A elements (*alkali metals*). It is characteristic of reactive metals such as these to lose electrons easily. The largest ionization energies in any period occur for the noble-gas elements. In other words, a noble-gas atom loses electrons with difficulty, which is

Ionization energies are also given in electron volts (eV). This is the amount of energy imparted to an electron when it is accelerated through an electrical potential of one volt. One electron volt is equivalent to 96.5 kJ/mol. (This is an easy conversion to remember; it is approximately one hundred kilojoules per mole.)

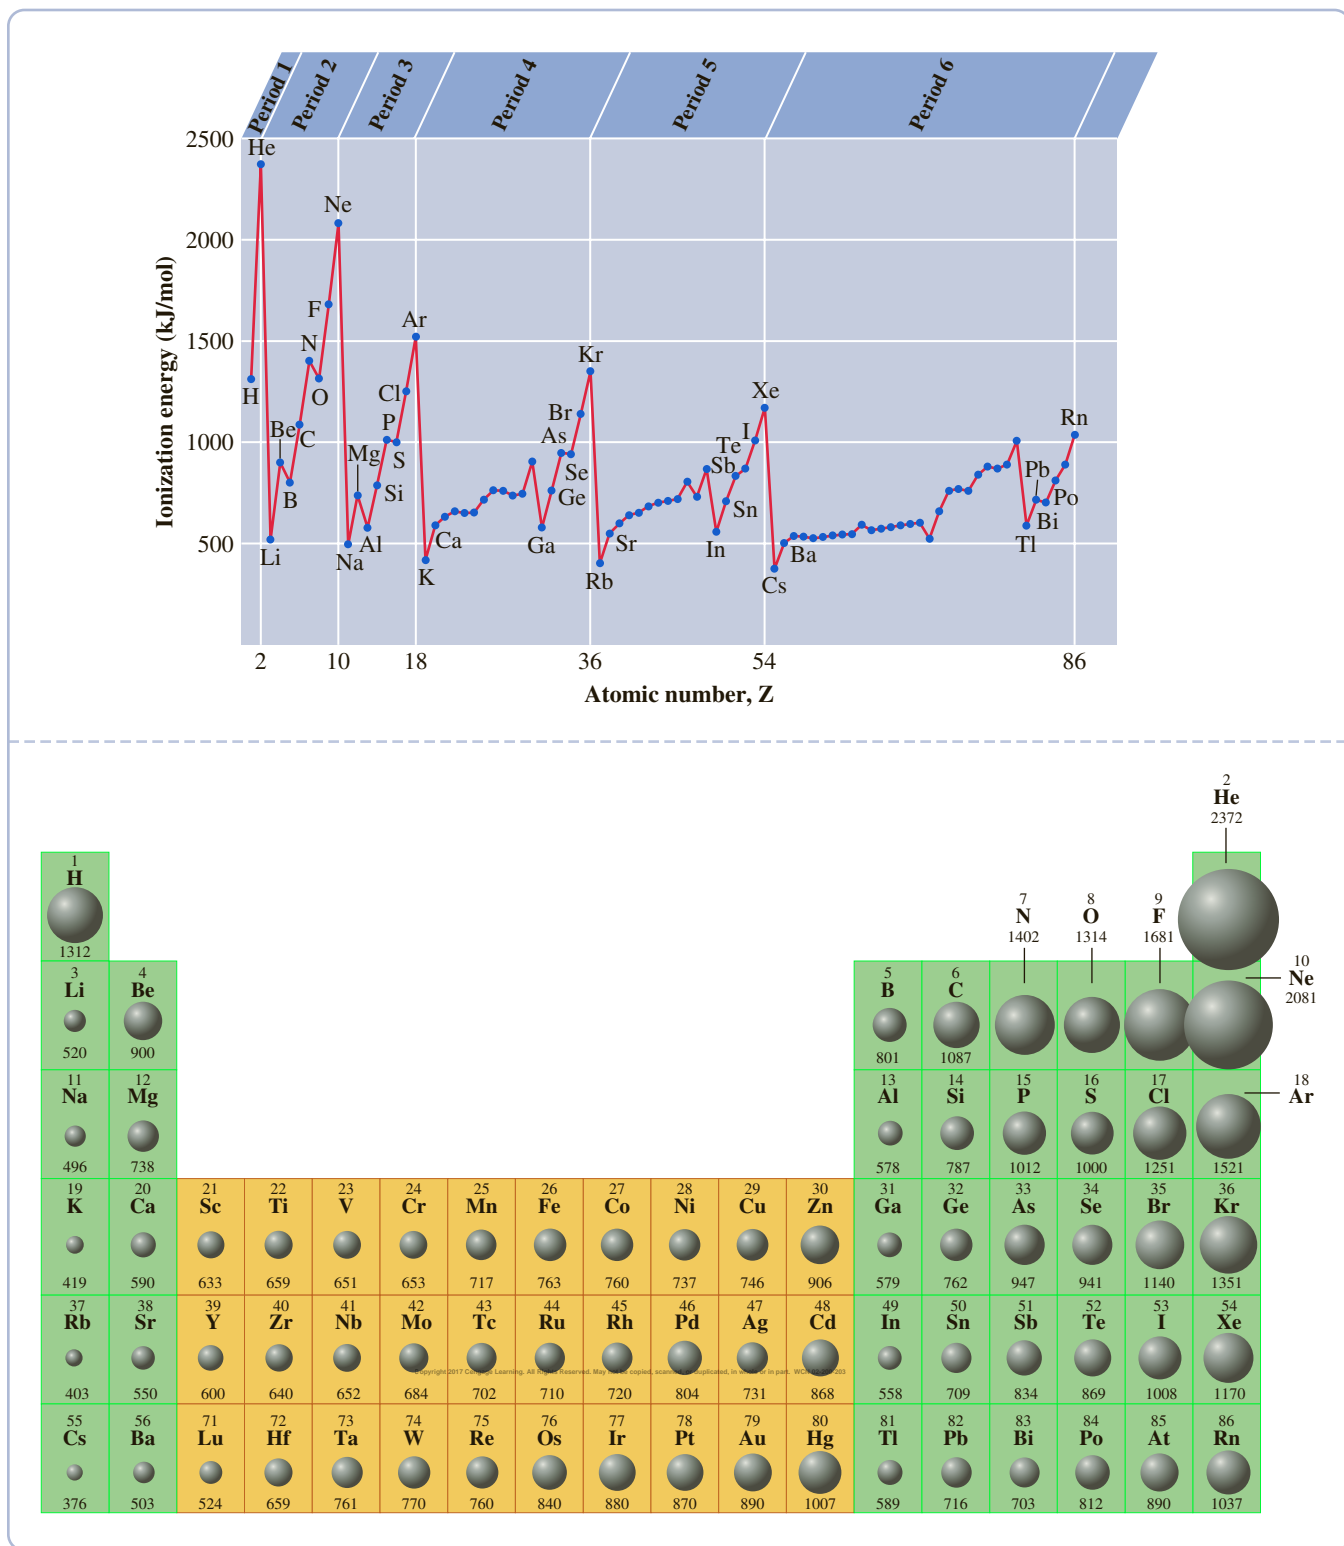

Figure 8.18 ▲

**Ionization energy versus atomic number** *Top:* Note that the values tend to increase within each period, except for small drops in ionization energy at the Group 3A and 6A elements. Large drops occur when a new period begins. *Bottom:* Note the trends within each period. The size of the sphere for each atom indicates the relative magnitude of ionization energy. The values given are in kilojoules/mole.

partly responsible for the stability of the noble-gas configurations and the unreactivity of the noble gases.

This general trend—increasing ionization energy with atomic number in a given period—can be explained as follows: The energy needed to remove an electron from the outer shell is proportional to the effective nuclear charge divided by the average distance between electron and nucleus. (This distance is inversely proportional to the effective nuclear charge.) Hence, the ionization energy is proportional to the square of the effective nuclear charge and increases going across a period.

Small deviations from this general trend occur. A 3A element ( $ns^2np^1$ ) has smaller ionization energy than the preceding 2A element ( $ns^2$ ). Apparently, the  $np$  electron of the 3A element is more easily removed than one of the  $ns$  electrons of the preceding 2A element. Also note that a 6A element ( $ns^2np^4$ ) has smaller ionization energy than the preceding 5A element. As a result of electron repulsion, it is easier to remove an electron from the doubly occupied  $np$  orbital of the 6A element than from a singly occupied orbital of the preceding 5A element.

Ionization energies tend to decrease going down any column of main-group elements. This is because atomic size increases going down the column.

### Example 8.6 Determining Relative Ionization Energies from Periodic Trends

#### Gaining Mastery Toolbox

##### Critical Concept 8.6

The general trends in first ionization energy are that it increases left to right in a period and decreases from top to bottom in a group.

##### Solution Essentials:

- General trends of first ionization energy

Using a periodic table only, arrange the following elements in order of increasing ionization energy: Ar, Se, S.

**Problem Strategy** The general trends in (first) ionization energy are that it increases from left to right in a period and that it decreases from top to bottom of a group. Compare any two elements in the same period, or in the same group, to decide which of the two is smaller. From this, decide the order of the elements.

**Solution** Note that Se is below S in Group 6A. Therefore, the ionization energy of Se should be less than that of S. Also, S and Ar are in the same period, with  $Z$  increasing from S to Ar. Therefore, the ionization energy of S should be less than that of Ar. Hence the order is **Se, S, Ar**.

**Answer Check** After you have decided on the order of the atoms, check that the ionization energy does indeed increase, left to right.

**Exercise 8.7** The first ionization energy of the chlorine atom is 1251 kJ/mol. Without looking at Figure 8.18, state which of the following values would be the more likely ionization energy for the iodine atom. Explain.  
a. 1000 kJ/mol. b. 1400 kJ/mol.

See Problems 8.63 and 8.64.

The electrons of an atom can be removed successively. The energies required at each step are known as the *first* ionization energy, the *second* ionization energy, and so forth. Table 8.3 lists the successive ionization energies of the first ten elements. Note that the ionization energies for a given element increase as more electrons are removed. The first and second ionization energies of beryllium (electron configuration  $1s^22s^2$ ) are 900 kJ/mol and 1757 kJ/mol, respectively. The first ionization energy is the energy needed to remove a  $2s$  electron from the Be atom. The second ionization energy is the energy needed to remove a  $2s$  electron from the positive ion  $\text{Be}^+$ . Its value is greater than that of the first ionization energy because the electron is being removed from a positive ion, which strongly attracts the electron.

Note that there is a large jump in value from the second ionization energy of Be (1757 kJ/mol) to the third ionization energy (14,848 kJ/mol). The second ionization energy corresponds to removing a valence electron (from the  $2s$  orbital), which is relatively easy. The third ionization energy corresponds to removing an electron from the core of the atom (from the  $1s$  orbital)—that is, from a noble-gas configuration ( $1s^2$ ). A vertical line in Table 8.3 separates the energies needed to remove valence

Element	First	Second	Third	Fourth	Fifth	Sixth	Seventh
H	1312						
He	2372	5250					
Li	520	7298	11,815				
Be	900	1757	14,848	21,006			
B	801	2427	3660	25,026	32,827		
C	1086	2353	4620	6223	37,831	47,277	
N	1402	2856	4578	7475	9445	53,267	64,360
O	1314	3388	5300	7469	10,990	13,326	71,330
F	1681	3374	6050	8408	11,023	15,164	17,868
Ne	2081	3952	6122	9371	12,177	15,238	19,999

\*Ionization energies to the right of a vertical line correspond to removal of electrons from the core of the atom.

electrons from those needed to remove core electrons. For each element, a large increase in ionization energy occurs when this line is crossed. The large increase results from the fact that once the valence electrons are removed, a stable noble-gas configuration is obtained. Further ionizations become much more difficult. We will see in Chapter 9 that metal atoms often form compounds by losing valence electrons; core electrons are not significantly involved in the formation of compounds.

### Electron Affinity

When a neutral atom in the gaseous state picks up an electron to form a stable negative ion, energy is released. For example, a chlorine atom can pick up an electron to give a chloride ion,  $\text{Cl}^-$ , and 349 kJ/mol of energy is released. We can write this process, including the electron configurations, as follows:

What is often measured is the energy of the *electron detachment* from the negative ion, which is essentially the ionization energy of the negative ion.

The **electron affinity** of an atom is defined as *the energy required to remove an electron from the atom's negative ion (in its ground state)*. Or, if you wish, the electron affinity is the negative of the energy change obtained when the neutral atom picks up an electron. The quantity is positive if a stable negative ion forms. A large positive value means that the neutral atom has a strong affinity for an electron (picks up an electron easily). Table 8.4 displays the electron affinities of the main-group elements. ▶

It should be noted that electron affinities are also defined with the opposite sign. In this convention, the electron affinity of the chlorine atom is  $-349 \text{ kJ/mol}$ . This is essentially the energy change (energy is released) in adding an electron to the chlorine atom, Cl.

Figure 8.19 ►

**Electron affinity versus atomic number in the main-group elements**

Electron affinities in the main-group elements show a periodic variation when plotted against atomic number, although this variation is somewhat more complicated than that displayed by ionization energies. In a given period, the electron affinity rises from the Group 1A element to the Group 7A element but with sharp drops in the Group 2A and Group 5A elements.

If we look at these main-group elements, we see that the electron affinities vary in going across any period in a fairly predictable fashion. See the graph in Figure 8.19. Broadly speaking, the general trend in any period of the main-group elements is an increase in electron affinities from left to right, although the 2A element and the 5A element tend to have smaller electron affinities than the preceding element, and the Group 8A elements (noble gases) have zero or small negative values (indicating unstable negative ions). Note especially that the Group 6A and Group 7A elements have the largest electron affinities of any of the other main-group elements. The stability of the negative ions of these elements explains why they have compounds with monatomic anions (such as  $F^-$ ). While the trend in going across a period is rather clear, this is not the case in going down a column of elements; there is no simple trend.

Let's look more closely at these main-group elements. Consider those in Group 1A. All of the Group 1A elements have moderately positive electron affinities, as you might expect since the added electron just completes the outer  $ns$  subshell. When you add an electron to a potassium atom, for example, it goes into the  $4s$  orbital to form a moderately stable negative ion, releasing energy and yielding a positive electron affinity (EA):

The Group 2A elements have a filled outer  $ns$  subshell, so the added electron has to go into the next higher subshell, the  $np$  subshell. Thus, we expect the electron affinities of these elements to be smaller than those for the 1A elements. Beryllium and magnesium appear to have values close to zero (no stable negative ions found), whereas the elements from calcium on have small positive values (weakly stable negative ions). For the calcium atom, we have

From the Group 3A elements to the Group 7A elements, the added electron goes into the outer  $np$  subshell, which already has one or more electrons in it. With the exception of the Group 5A element, the electron affinity in any period

tends to rise from the Group 2A element to the Group 7A element. For example, in the Period 4 elements from gallium to bromine, we observe:

The drop in electron affinity of the Group 5A element from the preceding element is easily explained. In the Group 5A element (arsenic, As, in the above list), the added electron must pair up with one of the  $np$  electrons since all of the  $np$  orbitals have one electron, whereas in the preceding element the extra electron goes into an empty  $np$  orbital. This pairing of electrons in an orbital requires some energy, resulting in a smaller electron affinity for the Group 5A element compared with the preceding 4A element.

No stable negative ions of the Group 8A elements (noble-gas elements) have been found. We might expect this since these atoms have filled outer shells so that the addition of an electron would have to go into the next higher shell. The electron affinities are therefore zero (or possibly negative), as we noted earlier.

**Exercise 8.8** Without looking at Table 8.4 but using the general comments in this section, decide which has the larger electron affinity, C or F.

See Problems 8.65 and 8.66.

### CONCEPT CHECK 8.3

Given the following information for element E, identify the element's group in the periodic table: The electron affinity of E is negative (that is, it does not form a stable negative ion). The first ionization energy of E is less than the second ionization energy, which in turn is very much less than its third ionization energy.

## 8.7 Periodicity in the Main-Group Elements

The chemical and physical properties of the main-group elements clearly display periodic character. For instance, as pointed out in Section 2.5, the metallic elements lie to the left of the “staircase” line in the periodic table (see inside front cover), nonmetals lie to the right, and the metalloids (with intermediate characteristics) lie along this line. So, as you move left to right in any row of the periodic table, the metallic character of the elements decreases. As you progress down a column, however, the elements tend to increase in metallic character.

These variations of metallic–nonmetallic character can be attributed in part to variations in the ionization energies of the corresponding atoms. Elements with low ionization energy tend to be metallic, whereas those with high ionization energy tend to be nonmetallic. As you saw in the previous section, ionization energy is a periodic property, so it is not surprising that the metallic–nonmetallic character of an element is similarly periodic.

The basic–acidic behavior of the oxides of the elements is a good indicator of the metallic–nonmetallic character of the elements. Oxides are classified as basic or acidic depending on their reactions with acids and bases. A **basic oxide** is an oxide that reacts with acids. Most metal oxides are basic. An **acidic oxide** is an oxide that reacts with bases. Most nonmetal oxides are acidic oxides. An **amphoteric oxide** is an oxide that has both basic and acidic properties.

In the following brief descriptions of the main-group elements, we will note the metallic–nonmetallic behavior of the elements, as well as the basic–acidic

character of the oxides. Although elements in a given group are expected to be similar, the degree of similarity does vary among the groups. The alkali metals (Group 1A) show marked similarities, as do the halogens (Group 7A). On the other hand, the Group 4A elements range from a nonmetal (carbon) at the top of the column to a metal (lead) at the bottom. In either case, however, the changes from one element in a column to the next lower one are systematic, and the periodic table helps us to correlate these systematic changes.

### Hydrogen ( $1s^1$ )

Although the electron configuration of hydrogen would seem to place the element in Group 1A, its properties are quite different, and it seems best to consider this element as belonging in a group by itself. The element is a colorless gas composed of  $H_2$  molecules. ◀

### Group 1A Elements, the Alkali Metals ( $ns^1$ )

The *alkali metals* are soft and reactive, with the reactivities increasing as you move down the column of elements. All of the metals react with water to produce hydrogen.

The vigor of the reaction increases from lithium (moderate) to rubidium (violent). All of the alkali metals form basic oxides with the general formula  $R_2O$ .

### Group 2A Elements, the Alkaline Earth Metals ( $ns^2$ )

The *alkaline earth metals* are also chemically reactive but much less so than the alkali metals. Reactivities increase going down the group. The alkaline earth metals form basic oxides with the general formula  $RO$ .

### Group 3A Elements ( $ns^2np^1$ )

Groups 1A and 2A exhibit only slight increases in metallic character down a column, but with Group 3A we see a significant increase. The first Group 3A element, boron, is a metalloid. Other elements in this group—aluminum, gallium, indium, and thallium—are metals. (Gallium is a curious metal; it melts readily in the palm of the hand—see Figure 8.20.)

The oxides in this group have the general formula  $R_2O_3$ . Boron oxide,  $B_2O_3$ , is an acidic oxide; aluminum oxide,  $Al_2O_3$ , and gallium oxide,  $Ga_2O_3$ , are amphoteric oxides. Indium oxide,  $In_2O_3$ , and thallium oxide,  $Tl_2O_3$ , are basic. The change in the oxides from acidic to amphoteric to basic is indicative of an increase in metallic character of the elements.

### Group 4A Elements ( $ns^2np^2$ )

This group shows the most distinct change in metallic character. It begins with the nonmetal carbon, C, followed by the metalloids silicon, Si, and germanium, Ge, and then the metals tin, Sn, and lead, Pb. Both tin and lead were known to the ancients. ◀

All the elements in this group form oxides with the general formula  $RO_2$ , which progress from acidic to amphoteric. Carbon dioxide,  $CO_2$ , an acidic oxide, is a gas. (Carbon also forms the monoxide, CO.) Silicon dioxide,  $SiO_2$ , an acidic oxide, exists as quartz and white sand (particles of quartz). Germanium dioxide,  $GeO_2$ , is acidic, though less so than silicon dioxide. Tin dioxide,  $SnO_2$ , an amphoteric oxide, is found as the mineral cassiterite, the principal ore of tin. Lead(IV) oxide,  $PbO_2$ , is amphoteric. Lead has a more stable monoxide,  $PbO$ . Figure 8.21 shows oxides of some Group 4A elements.

### Group 5A Elements ( $ns^2np^3$ )

The Group 5A elements also show the distinct transition from nonmetal (nitrogen, N, and phosphorus, P) to metalloid (arsenic, As, and antimony, Sb) to metal (bismuth, Bi). Nitrogen occurs as a colorless, odorless, relatively unreactive gas with  $N_2$  molecules; white phosphorus is a white, waxy solid with  $P_4$  molecules. Gray arsenic

At very high pressures, however, hydrogen is believed to have metallic properties.

**Oxides of some Group 4A elements**

Powdered lead(II) oxide (yellow), lead(IV) oxide (dark brown), tin dioxide (white), and crystalline silicon dioxide (clear quartz).

is a brittle solid with metallic luster; antimony is a brittle solid with a silvery, metallic luster. Bismuth is a hard, lustrous metal with a pinkish tinge.

The Group 5A elements form oxides with empirical formulas  $R_2O_3$  and  $R_2O_5$ . In some cases, the molecular formulas are twice these formulas—that is,  $R_4O_6$  and  $R_4O_{10}$ . Nitrogen has the acidic oxides  $N_2O_3$  and  $N_2O_5$ , although it also has other, better known oxides, such as NO. Phosphorus has the acidic oxides  $P_4O_6$  and  $P_4O_{10}$ . Arsenic has the acidic oxides  $As_2O_3$  and  $As_2O_5$ ; antimony has the amphoteric oxides  $Sb_2O_3$  and  $Sb_2O_5$ ; and bismuth has the basic oxide  $Bi_2O_3$ .

### Group 6A Elements, the Chalcogens ( $ns^2np^4$ )

These elements, the *chalcogens* (pronounced kal'-ke-jens), show the transition from nonmetal (oxygen, O, sulfur, S, and selenium, Se) to metalloid (tellurium, Te) to metal (polonium, Po). Oxygen occurs as a colorless, odorless gas with  $O_2$  molecules. It also has an allotrope, ozone, with molecular formula  $O_3$ . Sulfur is a brittle, yellow solid with molecular formula  $S_8$ . Tellurium is a shiny gray, brittle solid; polonium is a silvery metal.

Sulfur, selenium, and tellurium form oxides with the formulas  $RO_2$  and  $RO_3$ . (Sulfur burns in air to form sulfur dioxide; see Figure 8.22.) These oxides, except for  $TeO_2$ , are acidic;  $TeO_2$  is amphoteric. Polonium has an oxide  $PoO_2$ , which is amphoteric, though more basic in character than  $TeO_2$ .

### Group 7A Elements, the Halogens ( $ns^2np^5$ )

The *halogens* are reactive nonmetals with the general molecular formula  $X_2$ , where X symbolizes a halogen. Fluorine,  $F_2$ , is a pale yellow gas; chlorine,  $Cl_2$ , a pale greenish yellow gas; bromine,  $Br_2$ , a reddish brown liquid; and iodine,  $I_2$ , a bluish black solid that has a violet vapor (see Figure 8.23). All isotopes of astatine have very short half-lives, and observable quantities of the element have not been prepared. (The half-life of a radioactive isotope is the time it takes for half of the isotope to decay, or break down, to another element.) Astatine might be expected to be a metalloid.

Each halogen forms several compounds with oxygen; these are generally unstable, acidic oxides.

### Group 8A Elements, the Noble Gases ( $ns^2np^6$ )

The Group 8A elements exist as gases consisting of uncombined atoms. For a long time these elements were thought to be chemically inert, because no compounds were known. Then, in the early 1960s, several compounds of xenon were prepared. Now compounds are also known for argon, krypton, and radon. These elements are known as the *noble gases* because of their relative unreactivity.

#### CONCEPT CHECK 8.4

A certain element is a metalloid that forms an acidic oxide with the formula  $R_2O_5$ . Identify the element.

## A Checklist for Review

### Summary of Facts and Concepts

To understand the similarities that exist among the members of a group of elements, it is necessary to know the *electron configurations* for the ground states of atoms. Only those arrangements of electrons allowed by the *Pauli exclusion principle* are possible. The ground-state configuration of an atom represents the electron arrangement that has the lowest total energy. This arrangement can be reproduced

by the *building-up principle* (Aufbau principle), where electrons fill the subshells in particular order (the building-up order) consistent with the Pauli exclusion principle. The arrangement of electrons in partially filled subshells is governed by *Hund's rule*.

Elements in the same group of the periodic table have similar valence-shell configurations. As a result, chemical

Figure 8.22 ▲

**Burning sulfur** The combustion of sulfur in air gives a blue flame. The product is primarily sulfur dioxide, detectable by its acrid odor. (Solid sulfur, the yellow powder, melts to form a reddish brown liquid.)

Figure 8.23 ▲

**The halogens** From left to right, the flasks contain chlorine, bromine, and iodine. (Bromine and iodine were warmed to produce the vapors; bromine is normally a reddish brown liquid and iodine a bluish black solid.)

and physical properties of the elements show periodic behavior. *Atomic radii*, for example, tend to decrease across any period (left to right) and increase down any group (top

to bottom). *First ionization energies* tend to increase across a period and decrease down a group. *Electron affinities* of the Group 6A and Group 7A elements have large values.

## Learning Objectives

## Important Terms

### 8.1 Electron Spin and the Pauli Exclusion Principle

- Define *electron configuration* and *orbital diagram*.
- State the Pauli exclusion principle.
- Apply the Pauli exclusion principle. **Example 8.1**

**electron configuration**  
**orbital diagram**  
**Pauli exclusion principle**

### 8.2 Building-Up Principle and the Periodic Table

- Define *building-up principle*.
- Define *noble-gas core*, *pseudo-noble-gas core*, and *valence electron*.
- Define *main-group element* and (*d-block* and *f-block*) *transition element*.

**building-up (Aufbau) principle**  
**noble-gas core**  
**pseudo-noble-gas core**  
**valence electron**

### 8.3 Writing Electron Configurations Using the Periodic Table

- Determine the configuration of an atom using the building-up principle. **Example 8.2**
- Determine the configuration of an atom using the period and group numbers. **Example 8.3**

### 8.4 Orbital Diagrams of Atoms; Hund's Rule

- State Hund's rule.
- Apply Hund's rule. **Example 8.4**
- Define *paramagnetic substance* and *diamagnetic substance*.

**Hund's rule**  
**paramagnetic substance**  
**diamagnetic substance**

### 8.5 Mendeleev's Predictions from the Periodic Table

- Describe how Mendeleev predicted the properties of undiscovered elements.

### 8.6 Some Periodic Properties

- State the periodic law.
- State the general periodic trends in size of atomic radii.
- Define *effective nuclear charge*.
- Determine relative atomic sizes from periodic trends. **Example 8.5**
- State the general periodic trends in ionization energy.
- Define *first ionization energy*.
- Determine relative ionization energies from periodic trends. **Example 8.6**
- Define *electron affinity*.
- State the broad general trend in electron affinity across any period.

**periodic law**  
**atomic radius**  
**effective nuclear charge**  
**first ionization energy (first ionization potential)**  
**electron affinity**

### 8.7 Periodicity in the Main-Group Elements

- Define *basic oxide*, *acidic oxide*, and *amphoteric oxide*.
- State the main group corresponding to an *alkali metal*, an *alkaline earth metal*, a *chalcogen*, a *halogen*, and a *noble gas*.
- Describe the change in metallic/nonmetallic character (or reactivities) in going through any main group of elements.

**basic oxide**  
**acidic oxide**  
**amphoteric oxide**

## Questions and Problems

### Self-Assessment and Review Questions

**Key:** These questions test your understanding of the ideas you worked with in the chapter. These problems vary in difficulty and often can be used for the basis of discussion.

**8.1** Describe the experiment of Stern and Gerlach. How are the results for the hydrogen atom explained?

**8.2** Describe the model of electron spin given in the text. What are the restrictions on electron spin?

**8.3** How does the Pauli exclusion principle limit the possible electron configurations of an atom?

**8.4** What is the maximum number of electrons that can occupy a  $f$  subshell ( $l = 3$ )?

**8.5** List the orbitals in order of increasing orbital energy up to and including  $3p$  orbitals.

**8.6** Define each of the following: noble-gas core, pseudo-noble-gas core, valence electron.

**8.7** Give two different possible orbital diagrams for the  $1s^2 2s^2 2p^4$  configuration of the oxygen atom, one of which should correspond to the ground state. Label the diagram for the ground state.

**8.8** Define the terms *diamagnetic substance* and *paramagnetic substance*. Does the ground-state oxygen atom give a diamagnetic or a paramagnetic substance? Explain.

**8.9** What kind of subshell is being filled in Groups 1A and 2A? in Groups 3A to 8A? in the transition elements? in the lanthanides and actinides?

**8.10** How was Mendeleev able to predict the properties of gallium before it was discovered?

**8.11** Describe the major trends that emerge when atomic radii are plotted against atomic number. Describe the trends observed when first ionization energies are plotted against atomic number.

**8.12** What atom has the smallest radius among the chalcogens

**8.13** What main group in the periodic table has elements with the largest electron affinities for each period? What group of elements has only unstable negative ions?

**8.14** The ions  $K^+$  and  $Ca^{2+}$  occur in chemical compounds, but the ions  $K^{2+}$  and  $Ca^{3+}$  do not. Explain.

**8.15** Describe the major trends in metallic character observed in the periodic table of the elements.

**8.16** Distinguish between an acidic and a basic oxide. Give examples of each.

**8.17** What is the name of the alkali metal atom with valence-shell configuration  $6s^1$ ?

**8.18** What would you predict for the atomic number of the chalcogen in Period 7?

**8.19** List the elements in Groups 3A to 6A in the same order as in the periodic table. Label each element as a metal, a metalloid, or a nonmetal. Does each column of elements display the expected trend of increasing metallic characteristics?

**8.20** For the list of elements you made for Question 8.19, note whether the oxides of each element are acidic, basic, or amphoteric.

**8.21** Write an equation for the reaction of potassium metal with water.

**8.22** From what is said in Section 8.7 about Group 2A elements, list some properties of calcium.

**8.23** Give the names and formulas of two oxides of carbon.

**8.24** Match each description in the left column with the appropriate element in the right column.

- |          |   |                  |
|----------|---|------------------|
| <b>a</b> | A waxy, white solid, normally stored under water      | Sulfur           |
| <b>b</b> | A yellow solid that burns in air                      | Sodium           |
| <b>c</b> | A reddish brown liquid                                | White phosphorus |
| <b>d</b> | A soft, light metal that reacts vigorously with water | Bromine          |

**8.25** Phosphorus has \_\_\_\_\_ unpaired electrons.

- a** 1    **b** 2    **c** 3    **d** 4    **e** 5

**8.26** Which of the following atoms, designated by their electron configurations, has the *highest* ionization energy?

- a**  $[\text{Ne}]3s^2 3p^2$   
**b**  $[\text{Ne}]3s^2 3p^3$   
**c**  $[\text{Ar}]3d^{10} 4s^2 4p^3$   
**d**  $[\text{Kr}]4d^{10} 5s^2 5p^3$   
**e**  $[\text{Xe}]4f^{14} 5d^{10} 6s^2 6p^3$

**8.27** When trying to remove electrons from Be, which of the following sets of ionization energy makes the most sense going from first to third ionization energy? Explain your answer.

- a** First IE 900 KJ/mol, second IE 1750 kJ/mol, third IE 15,000 kJ/mol  
**b** First IE 1750 KJ/mol, second IE 900 kJ/mol, third IE 15,000 kJ/mol  
**c** First IE 15,000 KJ/mol, second IE 1750 kJ/mol, third IE 900 kJ/mol  
**d** First IE 900 KJ/mol, second IE 15,000 kJ/mol, third IE 22,000 kJ/mol  
**e** First IE 900 KJ/mol, second IE 1750 kJ/mol, third IE 1850 kJ/mol

**8.28** Consider the following orderings.

I.  $\text{Al} < \text{Si} < \text{P} < \text{S}$

II.  $\text{Be} < \text{Mg} < \text{Ca} < \text{Sr}$

III.  $\text{I} < \text{Br} < \text{Cl} < \text{F}$

Which of these give(s) a correct trend in atomic size?

- a** I only  
**b** II only  
**c** III only  
**d** I and II only  
**e** II and III only

## Concept Explorations

**Key:** Concept explorations are comprehensive problems that provide a framework that will enable you to explore and learn many of the critical concepts and ideas in each chapter. If you master the concepts associated with these explorations, you will have a better understanding of many important chemistry ideas and will be more successful in solving all types of chemistry problems. These problems are well suited for group work and for use as in-class activities.

### 8.29 Periodic Properties I

A hypothetical element, X, has the following ionization energy values:

- First ionization energy: 900 kJ/mol
- Second ionization energy: 1750 kJ/mol
- Third ionization energy: 14,900 kJ/mol
- Fourth ionization energy: 21,000 kJ/mol

Another element, Y, has the following ionization energy values:

- First ionization energy: 1200 kJ/mol
- Second ionization energy: 2500 kJ/mol
- Third ionization energy: 19,900 kJ/mol
- Fourth ionization energy: 26,000 kJ/mol

- a To what family of the periodic table would element X be most likely to belong? Explain?
- b What charge would you expect element X to have when it forms an ion?
- c If you were to place elements X and Y into the periodic table, would element Y be in the same period as element X? If not in the same period, where might they be relative to each other in the periodic table?
- d Would an atom of Y be smaller or larger than an atom of X? Explain your reasoning.

### 8.30 Periodic Properties II

Consider two hypothetical elements, X and Z. Element X has an electron affinity of 300 kJ/mol, and element Z has an electron affinity of 75 kJ/mol.

- a If you have an  $X^-$  ion and  $Z^-$  ion, from which ion would it require more energy to remove an electron? Explain your answer.
- b If elements X and Z are in the same period of the periodic table, which atom would you expect to have the greater atomic radius? Why?
- c Assuming that the elements are in the same period, which element would you expect to have the smaller first ionization energy?
- d Do the valence electrons in element Z feel a greater effective nuclear charge than those in element X? Explain how you arrived at your answer.

## Conceptual Problems

**Key:** These problems are designed to check your understanding of the concepts associated with some of the main topics presented in each chapter. A strong conceptual understanding of chemistry is the foundation for both applying chemical knowledge and solving chemical problems. These problems vary in level of difficulty and often can be used as a basis for group discussion.

**8.31** Suppose that the Pauli exclusion principle were “No more than two electrons can have the same four quantum numbers.” What would be the electron configurations of the ground states for the first six elements of the periodic table, assuming that, except for the Pauli principle, the usual building-up principle held?

**8.32** Imagine a world in which all quantum numbers, except the  $l$  quantum number, are as they are in the real world. In this imaginary world,  $l$  begins with 1 and goes up to  $n$  (the value of the principal quantum number). Assume that the orbitals fill in the order by  $n$ , then  $l$ ; that is, the first orbital to fill is for  $n = 1, l = 1$ ; the next orbital to fill is for  $n = 2, l = 1$ , and so forth. How many elements would there be in the first period of the periodic table?

**8.33** Two elements in Period 4 are adjacent to one another in the periodic table. The ground-state atom of one element has only  $s$  electrons in its valence shell; the other has at least one  $d$  electron in an unfilled shell. Identify the elements.

**8.34** Two elements are in the same column of the periodic table, one above the other. The ground-state atom of one element has two  $s$  electrons in its outer shell, and no  $d$  electrons anywhere in its configuration. The other element has  $d$  electrons in its configuration. Identify the elements.

**8.35** You travel to an alternate universe where the atomic orbitals are different from those on earth, but all other aspects of the atoms are the same. In this universe, you find that the first (lowest energy) orbital is filled with three electrons and the second orbital can hold a maximum of nine electrons. You discover an element Z that has five electrons in its atom. Would you expect Z to be more likely to form a cation or an anion? Indicate a possible charge on this ion.

**8.36** Would you expect to find an element having both a very large (positive) first ionization energy and an electron affinity that is also a large positive number? Explain.

**8.37** Two elements are in the same group, one following the other. One is a metalloid; the other is a metal. Both form oxides of the formula  $RO_2$ . The first is acidic; the next is amphoteric. Identify the two elements.

**8.38** A metalloid has an acidic oxide of the formula  $R_2O_3$ . The element has no oxide of the formula  $R_2O_5$ . What is the name of the element?

**8.39** Given the following information, identify the group from the periodic table that contains elements that behave like main-group element “E.”

- The electron affinity of E is small.
- The ionization energy (IE) trend for element E is: first ionization energy < second ionization energy <<< third ionization energy.
- Samples of E are lustrous and are good electrical conductors.

**8.40** A hypothetical element A has the following properties:

First ionization energy: 850 kJ/mol  
 Second ionization energy: 1700 kJ/mol  
 Third ionization energy: 13,999 kJ/mol

- If you were to react element A with oxygen, what would be the chemical formula of the resulting compound?
- Write the balanced chemical reaction of A reacting with oxygen to give the product from part a.
- Would you expect the product of the chemical reaction of A with oxygen to be a basic, an acidic, or an amphoteric oxide?

## Practice Problems

**Key:** These problems are for practice in applying problem-solving skills. They are divided by topic, and some are keyed to exercises (see the ends of the exercises). The problems are arranged in matching pairs; the odd-numbered problem of each pair is listed first, and its answer is given in the back of the book.

### Pauli Exclusion Principle

**8.41** Which of the following orbital diagrams are allowed by the Pauli exclusion principle? Explain how you arrived at this decision. Give the electron configuration for the allowed ones.

**8.42** Which of the following orbital diagrams are allowed and which are not allowed by the Pauli exclusion principle? Explain. For those that are allowed, write the electron configuration.

**8.43** Which of the following electron configurations are possible? Explain why the others are not.

**8.44** Choose the electron configurations that are possible from among the following. Explain why the others are impossible.

**8.45** Write all of the possible orbital diagrams for the electron configuration  $1s^2 2p^1$ . (There are six different diagrams.)

**8.46** Give the different orbital diagrams for the configuration  $1s^1 2p^1$ . (There are twelve different diagrams.)

### Building-Up Principle and Hund's Rule

**8.47** Give the electron configuration of the ground state of tellurium, using the building-up principle.

**8.48** Use the building-up principle to obtain the ground-state configuration of arsenic.

**8.49** Use the building-up principle to obtain the electron configuration of the ground state of manganese.

**8.50** Give the electron configuration of the ground state of nickel, using the building-up principle.

**8.51** Barium is a Group 2A element in Period 6. Deduce the valence-shell configuration of barium.

**8.52** Bismuth is a Group 5A element in Period 6. Write the valence-shell configuration of bismuth.

**8.53** Tungsten is a Group 6B element in Period 6. What would you expect for the valence-shell configuration of tungsten?

**8.54** Manganese is a Group 7B element in Period 4. What would you expect for the configuration of outer electrons of manganese?

**8.55** Thallium has the ground-state configuration  $[\text{Xe}]4f^{14}5d^{10}6s^2 6p^1$ . Give the group and period for this element. Classify it as a main-group, a *d*-transition, or an *f*-transition element.

**8.56** The configuration for the ground state of iridium is  $[\text{Xe}]4f^{14}5d^7 6s^2$ . What are the group and period for this element? Is it a main-group, a *d*-transition, or an *f*-transition element?

**8.57** Write the orbital diagram for the ground state of cobalt. The electron configuration is  $[\text{Ar}]3d^7 4s^2$ .

**8.58** Write the orbital diagram for the ground state of samarium. The electron configuration is  $[\text{Xe}]4f^6 6s^2$ .

**8.59** Write an orbital diagram for the ground state of the potassium atom. Is the atomic substance diamagnetic or paramagnetic?

**8.60** Write an orbital diagram for the ground state of the zinc atom. Is the atomic substance diamagnetic or paramagnetic?

**Periodic Trends**

**8.61** Order the following elements by increasing atomic radius according to what you expect from periodic trends: Se, S, As.

**8.62** Using periodic trends, arrange the following elements in order of increasing atomic radius: C, Al, Si.

**8.63** Using periodic trends, arrange the following elements by increasing ionization energy: Ar, Na, Cl, Al.

**8.64** Arrange the following elements in order of increasing ionization energy: Mg, Ca, S. Do not look at Figure 8.18.

**General Problems**

**Key:** These problems provide more practice but are not divided by topic or keyed to exercises. Each section ends with essay questions, each of which is color coded to refer to the *Instrumental Methods* (brown) and *A Chemist Looks at Frontiers* (purple) chapter essay on which it is based. Odd-numbered problems and the even-numbered problems that follow are similar; answers to all odd-numbered problems except the essay questions are given in the back of the book.

**8.69** Write the complete ground-state electron configuration of the strontium atom, Sr, using the building-up principle.

**8.70** Write the complete ground-state electron configuration of the tellurium atom, Te, using the building-up principle.

**8.71** Obtain the valence-shell configuration of the polonium atom, Po, using the position of this atom in the periodic table.

**8.72** Obtain the valence-shell configuration of the lead atom, Pb, using the position of this atom in the periodic table.

**8.73** Write the orbital diagram for the ground state of the arsenic atom. Give all orbitals.

**8.74** Write the orbital diagram for the ground state of the selenium atom. Give all orbitals.

**8.75** For eka-lead, predict the electron configuration, whether the element is a metal or nonmetal, and the formula of an oxide.

**8.76** For eka-bismuth, predict the electron configuration, whether the element is a metal or nonmetal, and the formula of an oxide.

**8.77** From Figure 8.18, predict the first ionization energy of francium ( $Z = 87$ ).

**8.78** From Figure 8.18, predict the first ionization energy of ununseptium ( $Z = 117$ ).

**8.79** Write the valence orbital diagram corresponding to the ground state of Nb, whose configuration is  $[\text{Kr}]4d^45s^1$ .

**8.80** Write the valence orbital diagram for the ground state of rhodium. The configuration is  $[\text{Kr}]4d^85s^1$ .

**8.65** From what you know in a general way about electron affinities, state which member of each of the following pairs has the greater value: **a** As, Br **b** F, Li.

**8.66** From what you know in a general way about electron affinities, state which member of each of the following pairs has the greater value: **a** Cl, S **b** Se, K.

**8.67** If potassium chlorate has the formula  $\text{KClO}_3$ , what formula would you expect for lithium bromate?

**8.68** Write the simplest formulas expected for two oxides of selenium.

**8.81** Match each set of characteristics on the left with an element in the column at the right.

<b>a</b> reactive nonmetal; the atom has a large electron affinity	Sodium (Na) Antimony (Sb) Argon (Ar) Chlorine ( $\text{Cl}_2$ )
--	--

**b** A soft metal; the atom has a low ionization energy

**c** A metalloid that forms an oxide of formula  $\text{R}_2\text{O}_3$

**d** A chemically unreactive gas

**8.82** Match each element on the right with a set of characteristics on the left.

<b>a</b> A reactive, pale yellow gas; the atom has a large electron affinity	Oxygen ( $\text{O}_2$ ) Gallium (Ga) Barium (Ba)
--	--

**b** A soft metal that reacts with water to produce hydrogen

**c** A metal that forms an oxide of formula  $\text{R}_2\text{O}_3$

**d** A colorless gas; the atom has a moderately large negative electron affinity

**8.83** Find the electron configuration of the element with  $Z = 23$ . From this, give its group and period in the periodic table. Classify the element as a main-group, a  $d$ -block transition, or an  $f$ -block transition element.

**8.84** Find the electron configuration of the element with  $Z = 33$ . From this, give its group and period in the periodic table. Is this a main-group, a  $d$ -block transition, or an  $f$ -block transition element?

**8.85** What property of an atom does nuclear magnetic resonance depend on? What frequency range of the electromagnetic spectrum does NMR use?

**8.86** Explain the origin of the "chemical shift" seen for a proton in a molecule.

**8.87** Explain how X rays are produced when an electron beam falls on a metal target.

**8.88** Describe how X-ray photoelectron spectroscopy is done. What kind of information is obtained from photoelectron spectroscopy?

**8.89** How is it possible for a diamagnetic material to be levitated by a magnetic field?

**8.90** Researchers have shown that it is possible to levitate diamagnetic materials. What animal did they use in their experiments to show this?

## Strategy Problems

**Key:** As noted earlier, all of the practice and general problems are matched pairs. This section is a selection of problems that are not in matched-pair format. These challenging problems require that you employ many of the concepts and strategies that were developed in the chapter. In some cases, you will have to integrate several concepts and operational skills in order to solve the problem successfully.

**8.91** The following are orbital diagrams for presumed ground-state atoms. Several, though, violate Pauli's principle or Hund's rule. Which of these follow both Pauli's principle and Hund's rule, and which violate one or the other (state whether Pauli's principle or Hund's rule is violated)?

**8.92** As we noted at the beginning of Section 8.2, an atom has an infinite number of electron configurations, including not just the ground state but excited states as well. The following are excited states of neutral atoms. Identify the element and write the ground-state electron configuration for that atom.

**8.93** A metallic element, M, reacts vigorously with water to form a solution of MOH. If M is in Period 5, what is the ground-state electron configuration of the atom?

**8.94** A nonmetallic element, R, burns brightly in air to give the oxide  $R_4O_{10}$ . If R is in Period 3, what is the ground-state valence-shell configuration of the atom?

**8.95** The ground-state electron configuration of an atom is  $1s^2 2s^2 2p^6 3s^2 3p^4$ . What is the valence-shell configuration of the atom in the same group, but in Period 5?

**8.96** An atom of an element has the following ground-state configuration:  $[\text{Xe}]4f^{14}5d^9 6s^1$ . Using this configuration, give the symbol of the element. Explain your reasoning.

**8.97** An atom of an element has the following ground-state configuration:  $[\text{Kr}]4d^{10} 5s^2 5p^b$ . If the element is in Group 6A, what is the symbol of the element? What is  $b$ ?

**8.98** A main-group atom in Period 5 has the following orbital diagram for its valence shell (ground state):

What is the symbol for the element? Write the formula of the oxide containing the most oxygen.

**8.99** The following are electron configurations of neutral atoms, which may or may not be in ground states:  $1s^2 2s^2$

$2p^5 3s^2 3p^2$  and  $1s^2 2s^2 2p^6 3s^2 3p^5$ . Write the formula of a compound of these two elements.

**8.100** A neutral atom has the electron configuration  $1s^2 2s^2 2p^6 3s^1 3p^2$ . Is this the ground-state configuration? What is the period and column of the element? What is the name of the element? What is the formula of the oxide of this element?

**8.101** A moderately reactive metallic element (whose melting point is  $850^\circ\text{C}$ ) burns in a container of a greenish gas (also an element) to produce a white solid. The white solid dissolves in water to form a clear solution. When carbon dioxide gas,  $\text{CO}_2$ , is bubbled into this solution, it produces a white precipitate. Identify, by names and formulas, the substances referred to as the white solid and the white precipitate. Use a handbook of chemistry to obtain any data you may need.

**8.102** A metallic element reacts vigorously with water, evolving hydrogen gas. An excited atom of this element has its outer electron in the  $3p$  orbital. When this electron drops to its ground state in the  $3s$  orbital, light is emitted of wavelength 589 nm. What is the identity of the element? Explain how you arrived at your answer. What is the color of the emitted light?

**8.103** All elements up to atomic number 118 have been discovered. What electron configuration would you expect for the yet-to-be discovered element 120? Explain your answer.

**8.104** The densities (in  $\text{g}/\text{cm}^3$ ) of some elements in Period 5 that span indium, In, are as follows: Ag, 10.49; Cd, 8.65; Sn, 7.31; and Sb, 6.68. Plot the density of each element against its atomic number. Using the graph, estimate the density of indium. Calculate the percentage error between the value estimated from the graph and the accepted value of  $7.31 \text{ g}/\text{cm}^3$ .

**8.105** Write the orbital diagram for the ground-state valence electrons of the main-group atom in Period 5 that has the smallest radius. Explain how you got this answer.

**8.106** Using the periodic table, decide which of the following atoms you expect to have the largest radius: H, Sc, As, Br, V, K. Why?

**8.107** An atom easily loses two electrons to form the ion  $R^{2+}$ . The element, which is in Period 6, forms the oxides RO and  $\text{RO}_2$ . Give the orbital diagram for the ground-state valence shell of the element that immediately follows R in the periodic table.

**8.108** List three elements in order of increasing ionization energy. Two of the elements should be halogens (but not F), and the other should be Se.

**8.109** The energy of dissociation of the  $\text{Cl}_2$  molecule is 240 kJ/mol. Using the appropriate data from this chapter, calculate the energy obtained (or released) in adding electrons to the  $\text{Cl}_2$  molecule to produce  $\text{Cl}^-$  ions. Is this process endothermic or exothermic?

**8.110** The electron affinity of the lutetium atom (element 71) was measured using the technique of photoelectron spectroscopy with an infrared laser (the essay on p. 310 describes this instrumental method, using X rays). In this experiment, a beam of lutetium negative ions,  $\text{Lu}^-$ , was prepared and irradiated with a laser beam having a wavelength

at 1064 nm. The energy supplied by a photon in this laser beam removes an electron from a negative ion, leaving the neutral atom. The energy needed to remove the electron from the negative ion to give the neutral atom (both in their ground states) is the electron affinity of lutetium. Any

excess energy of the photon shows up as kinetic energy of the emitted electron. If the emitted electron in this experiment has a kinetic energy of 0.825 eV, what is the electron affinity of lutetium?

## Capstone Problems

**Key:** The problems under this heading combine skills, strategies, and concepts learned in previous chapters with those introduced in the current one.

**8.111** A 2.17-g sample of barium reacted completely with water. What is the equation for the reaction? How many milliliters of dry  $\text{H}_2$  evolved at  $21^\circ\text{C}$  and 748 mmHg?

**8.112** A sample of cesium metal reacted completely with water, evolving 48.1 mL of dry  $\text{H}_2$  at  $19^\circ\text{C}$  and 768 mmHg. What is the equation for the reaction? What was the mass of cesium in the sample?

**8.113** What is the formula of radium oxide? What is the mass percentage of radium in this oxide?

**8.114** What is the formula of hydrogen telluride? What is the mass percentage of tellurium in this compound?

**8.115** How much energy would be required to ionize 5.00 mg of  $\text{Na}(g)$  atoms to  $\text{Na}^+(g)$  ions? The first ionization energy of Na atoms is 496 kJ/mol.

**8.116** How much energy is evolved when 2.65 mg of  $\text{Cl}(g)$  atoms adds electrons to give  $\text{Cl}^2(g)$  ions?

**8.117** Using the Bohr formula for the energy levels, calculate the energy required to raise the electron in a hydrogen atom from  $n = 1$  to  $n = \infty$ . Express the result for 1 mol H atoms. Because the  $n = \infty$  level corresponds to removal of the electron from the atom, this energy equals the ionization energy of the H atom. Use your result to calculate the kinetic energy

(in Joules) of an electron emitted when a H atom is ionized by a 25.0-nm photon.

**8.118** Calculate the ionization energy of the  $\text{He}^+$  ion in kJ/mol (this would be the second ionization energy of He). See Problem 8.117. The Bohr formula for the energy levels of an ion consisting of a nucleus of charge  $Z$  and a single electron is  $-R_{\text{H}}Z^2/n^2$ . Use your result to calculate the kinetic energy (in Joules) of an electron emitted when a  $\text{He}^+$  ion is ionized to  $\text{He}^{2+}$  by a 15.0-nm photon.

**8.119** The lattice energy of an ionic solid such as NaCl is the enthalpy change  $\Delta H^\circ$  for the process in which the solid changes to ions. For example,

Assume that the ionization energy and electron affinity are  $\Delta H$  values for the processes defined by those terms. The ionization energy of Na is 496 kJ/mol. Use this, the electron affinity from Table 8.4, and the lattice energy of NaCl to calculate  $\Delta H$  for the following process:

**8.120** Calculate  $\Delta H$  for the following process:

The lattice energy of KBr is 689 kJ/mol, and the ionization energy of K is 419 kJ/mol. The electron affinity of Br is given in Table 8.4. See Problem 8.119.

**Ionic Bonds**

Molten salts and aqueous solutions of salts are electrically conducting. This conductivity results from the motion of ions in the liquids. This suggests the possibility that ions exist in certain solids, held together by the attraction of ions of opposite charge.

**Covalent Bonds**

Not all bonds can be ionic. Hydrogen,  $\text{H}_2$ , is a clear example, in which there is a strong bond between two like atoms. The bonding in the hydrogen molecule is covalent. A *covalent bond* forms between atoms by the sharing of a pair of electrons.

**Sodium chloride crystals** Natural crystals of sodium chloride mineral (halite).

**T**he properties of a substance, such as sodium chloride (Figure 9.1), are determined in part by the chemical bonds that hold the atoms together. A *chemical bond* is a strong attractive force that exists between certain atoms in a substance. In Chapter 2, we described how sodium (a silvery metal) reacts with chlorine (a pale greenish yellow gas) to produce sodium chloride (table salt, a white solid). The substances in this reaction are quite different, as are their chemical bonds. Sodium chloride, NaCl, consists of  $\text{Na}^+$  and  $\text{Cl}^-$  ions held in a regular arrangement, or crystal, by *ionic bonds*. Ionic bonding results from the attractive force of oppositely charged ions.

A second kind of chemical bond is a *covalent bond*. In a covalent bond, two atoms share valence electrons (outer-shell electrons), which are attracted to the positively charged cores of both atoms, thus linking them. For example, chlorine gas consists of  $\text{Cl}_2$  molecules. You would not expect the two Cl atoms in each  $\text{Cl}_2$  molecule to acquire the opposite charges required for ionic bonding. Rather, a covalent bond holds the two atoms together. This is consistent with the equal sharing of electrons that you would expect between identical atoms. In most molecules, the atoms are linked by covalent bonds.

*Metallic bonding*, seen in sodium and other metals, represents another important type of bonding. A crystal of sodium metal consists of a regular arrangement of sodium atoms. The valence electrons of these atoms move throughout the crystal, attracted to the positive cores of all  $\text{Na}^+$  ions. This attraction holds the crystal together.

What determines the type of bonding in each substance? How do you describe the bonding in various substances? In this chapter, we will look at some simple, useful concepts of bonding that can help us answer these questions. We will be concerned with ionic and covalent bonds in particular.

## ► Ionic Bonds

The first explanation of chemical bonding was suggested by the properties of *salts*, substances now known to be ionic. Salts are generally crystalline solids that melt at high temperatures. Sodium chloride, for example, melts at  $801^\circ\text{C}$ . A molten salt (the liquid after melting) conducts an electric current. A salt dissolved in water gives a solution that also conducts an electric current. The electrical conductivity of the molten salt and the salt solution results from the motion of ions in the liquids. This suggests the possibility that ions exist in certain solids, held together by the attraction of opposite charges.

### 9.1 Describing Ionic Bonds

An **ionic bond** is a chemical bond formed by the electrostatic attraction between positive and negative ions. The bond forms between two atoms when one or more electrons are transferred from the valence shell of one atom to the valence shell of the other. The atom that loses electrons becomes a *cation* (positive ion), and the atom that gains electrons becomes an *anion* (negative ion). ◀ Any given ion tends to attract as many neighboring ions of opposite charge as possible. When large numbers of ions gather together, they form an ionic solid. The solid normally has a regular, crystalline structure that allows for the maximum attraction of ions, given their particular sizes.

To understand why ionic bonding occurs, consider the transfer of a valence electron from a sodium atom (electron configuration  $[\text{Ne}]3s^1$ ) to the valence shell of a chlorine atom ( $[\text{Ne}]3s^23p^5$ ). You can represent the electron transfer by the following equation:

As a result of the electron transfer, ions are formed, each of which has a noble-gas configuration. The sodium atom has lost its 3s electron and has taken on the neon

The terms ion, anion, and cation were coined by the chemist and physicist Michael Faraday (1791–1867) during his study of the electrical properties of salt solutions.

Table 9.1 Lewis Electron-Dot Symbols for Atoms of the Second and Third Periods

Period	1A $ns^1$	2A $ns^2$	3A $ns^2np^1$	4A $ns^2np^2$	5A $ns^2np^3$	6A $ns^2np^4$	7A $ns^2np^5$	8A $ns^2np^6$
Second	Li·	·Be·	·B·	·C·	:N·	:O·	:F·	:Ne:
Third	Na·	·Mg·	·Al·	·Si·	:P·	:S·	:Cl·	:Ar:

configuration, [Ne]. The chlorine atom has accepted the electron into its  $3p$  subshell and has taken on the argon configuration,  $[\text{Ne}]3s^23p^6$ . Such noble-gas configurations and the corresponding ions are particularly stable. This stability of the ions accounts in part for the formation of the ionic solid NaCl. Once a cation or anion forms, it attracts ions of opposite charge. Within the sodium chloride crystal, NaCl, every  $\text{Na}^+$  ion is surrounded by six  $\text{Cl}^-$  ions, and every  $\text{Cl}^-$  ion by six  $\text{Na}^+$  ions. (Figure 2.19 shows the arrangement of ions in the NaCl crystal.)

### Lewis Electron-Dot Symbols

You can simplify the preceding equation for the electron transfer between Na and Cl by writing Lewis electron-dot symbols for the atoms and monatomic ions. A **Lewis electron-dot symbol** is a symbol in which the electrons in the valence shell of an atom or ion are represented by dots placed around the letter symbol of the element. Table 9.1 lists Lewis symbols and corresponding valence-shell electron configurations for the atoms of the second and third periods. Note that dots are placed one to each side of a letter symbol until all four sides are occupied. Then the dots are written two to a side until all valence electrons are accounted for. The exact placement of the single dots is immaterial. For example, the single dot in the Lewis symbol for chlorine can be written on any one of the four sides. [This pairing of dots does not always correspond to the pairing of electrons in the ground state. Thus, you write  $\cdot\text{B}\cdot$  for boron, rather than  $:\text{B}:$ , which more closely corresponds to the ground-state configuration  $[\text{He}]2s^22p^1$ . The first symbol better reflects boron's chemistry, in which each single electron (single dot) tends to be involved in bond formation.]

The equation representing the transfer of an electron from the sodium atom to the chlorine atom is

The noble-gas configurations of the ions are apparent from the symbols. No dots are shown for the cation. (All valence electrons have been removed, leaving the noble-gas core.) Eight dots are shown in brackets for the anion (noble-gas configuration  $ns^2np^6$ ).

### Example 9.1 Using Lewis Symbols to Represent Ionic Bond Formation

#### Gaining Mastery Toolbox

##### Critical Concept 9.1

To represent the formation of the ions of an ionic compound from the atoms using Lewis symbols, you show dots being transferred from the metal to nonmetal atoms to give the ions with noble-gas configurations.

##### Solution Essentials:

- Lewis electron-dot symbols
- Noble-gas configuration
- Formula of a binary ionic compound

Use Lewis electron-dot symbols to represent the transfer of electrons from magnesium to fluorine atoms to form ions with noble-gas configurations.

**Problem Strategy** Write down the Lewis symbols for the two atoms. Note how many electrons the metal atom should lose to assume a noble-gas configuration (all of the dots, representing valence electrons) and how many electrons the nonmetal atom should gain to assume such a configuration (enough to give eight dots about the atomic symbol). Represent the transfer of electrons between ions diagrammatically in the form of an equation.

(continued)

**Example 9.1** (continued)

**Solution** The Lewis symbols for the atoms are  $\cdot\ddot{\text{F}}\cdot$  and  $\cdot\text{Mg}\cdot$  (see Table 9.1). The magnesium atom loses two electrons to assume a noble-gas configuration. But because a fluorine atom can accept only one electron to fill its valence shell, two fluorine atoms must take part in the electron transfer. We can represent this electron transfer as follows:

**Answer Check** Check that you have the correct symbols for the atoms and that the symbols for the ions do have noble-gas configurations.

**Exercise 9.1** Represent the transfer of electrons from magnesium to oxygen atoms to assume noble-gas configurations. Use Lewis electron-dot symbols.

See Problems 9.37 and 9.38.

**Energy Involved in Ionic Bonding**

You have seen in a qualitative way why a sodium atom and a chlorine atom might be expected to form an ionic bond. It is instructive, however, to look at the energy changes involved in ionic bond formation. From this analysis, you can gain further understanding of why certain atoms bond ionically and others do not.

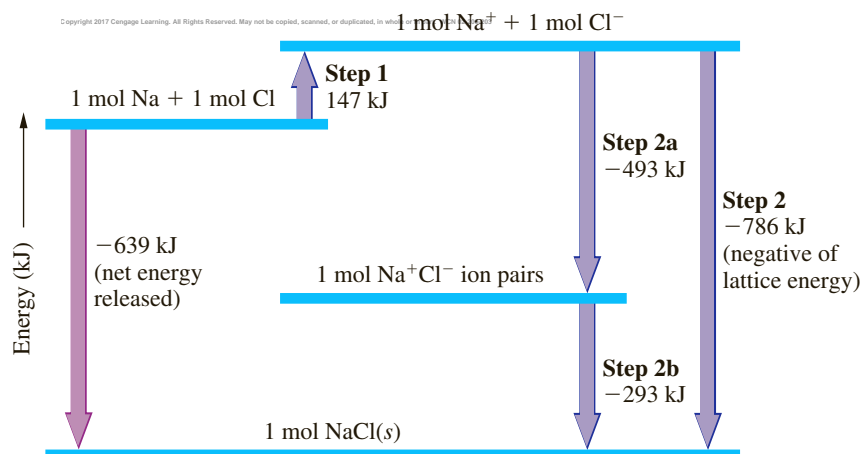

If atoms come together and bond, there should be a net decrease in energy, because the bonded state should be more stable and therefore at a lower energy level. Consider again the formation of an ionic bond between a sodium atom and a chlorine atom. You can think of this as occurring in two steps: (1) An electron is transferred between the two separate atoms to give ions. (2) The ions then attract one another to form an ionic bond. In reality, the transfer of the electron and the formation of an ionic bond occur simultaneously, rather than in discrete steps, as the atoms approach one another. But the *net* quantity of energy involved is the same whether the steps occur one after the other or at the same time.

The first step requires removal of the 3s electron from the sodium atom and the addition of this electron to the valence shell of the chlorine atom. Removing the electron from the sodium atom requires energy (the first ionization energy of the sodium atom, which equals 496 kJ/mol). Adding the electron to the chlorine atom releases energy (equal to  $-349$  kJ/mol, which is the negative of the electron affinity of the chlorine atom). ◀ The overall energy of this step is  $(496 - 349)$  kJ/mol, or 147 kJ/mol (Figure 9.2, Step 1). So, the process requires more energy to remove an electron from

Ionization energies and electron affinities of atoms were discussed in Section 8.6.

**Figure 9.2** ▶

**Energetics of ionic bonding** The transfer of an electron from a Na atom to a Cl atom is not in itself energetically favorable; it requires 147 kJ/mol of energy (Step 1). However, 493 kJ of energy is released when these oppositely charged ions come together to form ion pairs (Step 2a). Moreover, additional energy (293 kJ) is released when these ion pairs form the solid NaCl crystal (Step 2b). The lattice energy released when one mole each of  $\text{Na}^+$  and  $\text{Cl}^-$  ions react to produce  $\text{NaCl}(s)$  is 786 kJ/mol, and the overall process of NaCl formation is energetically favorable, releasing 639 kJ/mol if one starts with gaseous Na and Cl atoms.

the sodium atom than is gained when the electron is added to the chlorine atom. The formation of ions from the atoms is not in itself energetically favorable.

When positive and negative ions bond, however, more than enough energy is released to make the overall process favorable. What principally determines the energy released when ions bond is the attraction of oppositely charged ions. To see this, let's look first at the energy obtained when a  $\text{Na}^+$  ion and a  $\text{Cl}^-$  ion come together to form an ion-pair molecule. We will estimate this energy by making the simplifying assumption that the ions are spheres, just touching, with the distance between the nuclei of the ions equal to this distance in the NaCl crystal. From experiment, this distance is known to be 282 pm, or  $2.82 \times 10^{-10}$  m. To calculate the energy obtained when the ion spheres come together, we use Coulomb's law.

**Coulomb's law** states that *the potential energy obtained in bringing two charges  $Q_1$  and  $Q_2$ , initially far apart, up to a distance  $r$  apart is directly proportional to the product of the charges and inversely proportional to the distance between them:*

$$E = \frac{kQ_1Q_2}{r}$$

Here  $k$  is a physical constant, equal to  $8.99 \times 10^9 \text{ J}\cdot\text{m}/\text{C}^2$  ( $C$  is the symbol for coulomb). The charge on  $\text{Na}^+$  is  $+e$  and that on  $\text{Cl}^-$  is  $-e$ , where  $e$  equals  $1.602 \times 10^{-19} \text{ C}$ . Thus, our estimate of the energy of attraction of  $\text{Na}^+$  and  $\text{Cl}^-$  ions to form an ion pair is

$$E = \frac{-(8.99 \times 10^9 \text{ J}\cdot\text{m}/\text{C}^2) \times (1.602 \times 10^{-19} \text{ C})^2}{2.82 \times 10^{-10} \text{ m}} = -8.18 \times 10^{-19} \text{ J}$$

The minus sign means energy is released. This energy is for the formation of one ion pair. To express this for one mole of  $\text{Na}^+\text{Cl}^-$  ion pairs, we multiply by Avogadro's number,  $6.02 \times 10^{23}$ . We obtain  $-493 \text{ kJ/mol}$  for the energy obtained when one mole of  $\text{Na}^+$  and one mole of  $\text{Cl}^-$  come together to form  $\text{Na}^+\text{Cl}^-$  ion pairs (Figure 9.2, Step 2a). ▶

What we see is that the formation of ion pairs from sodium and chlorine atoms is energetically favorable. The attraction of oppositely charged ions, however, does not stop with the bonding of pairs of ions. The maximum attraction of ions of opposite charge with the minimum repulsion of ions of the same charge is obtained with the formation of the crystalline solid. Then additional energy is released. The energy of this step (Figure 9.2, Step 2b) is most easily obtained as the difference between Figure 9.2, Step 2a, which we just calculated, and Figure 9.2, Step 2, the energy released when a crystalline solid forms from the ions. This is the negative of the *lattice energy* of NaCl. The additional energy (in going from ion pairs to the crystalline solid), Figure 9.2, Step 2b, equals  $-293 \text{ kJ/mol}$ .

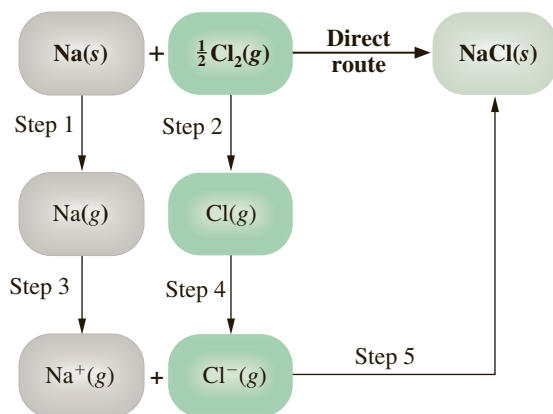

The **lattice energy** is *the change in energy that occurs when an ionic solid is separated into isolated ions in the gas phase*. For sodium chloride, the process is

The distances between ions in the crystal are continuously enlarged until the ions are very far apart. You can obtain an experimental value for this process from thermodynamic data (see the Born–Haber cycle on the next page). The lattice energy for NaCl is  $786 \text{ kJ/mol}$  so that for the reverse process, when the ions come together to bond, the energy is  $-786 \text{ kJ/mol}$  (Figure 9.2, Step 2). Consequently, the net energy obtained when gaseous Na and Cl atoms form solid NaCl is  $(-786 + 147) \text{ kJ/mol} = -639 \text{ kJ/mol}$ . The negative sign shows that there has been a net decrease in energy, which you expect when stable bonding has occurred.

From this energy analysis, you can see that two elements bond ionically if the ionization energy of one is sufficiently small and the electron affinity of the other is sufficiently large. This situation exists between a reactive metal (which has low ionization energy) and a reactive nonmetal (which has large electron affinity). In general, bonding between a metal and a nonmetal is ionic. This energy analysis also explains why ionic bonding normally results in a solid rather than in ion-pair molecules.

The energy value  $-493 \text{ kJ/mol}$  is approximate, because of the simplifying assumption we made (that the ions are spheres, just touching).

**Figure 9.3** ▲

**Born-Haber cycle for NaCl** The formation of  $\text{NaCl}(s)$  from the elements is accomplished by two different routes. The direct route is the formation reaction (shown in boldface), and the enthalpy change is  $\Delta H_f^\circ$ . The indirect route occurs in five steps.

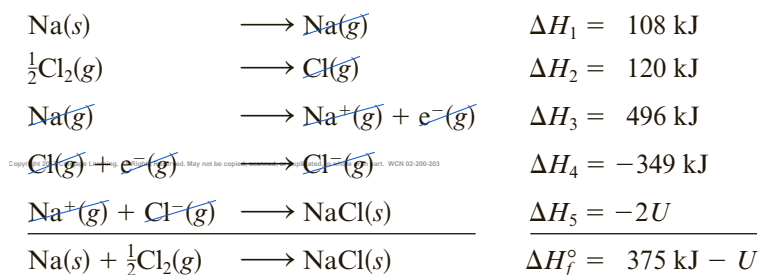

### Lattice Energies from the Born-Haber Cycle

The preceding energy analysis requires us to know the lattice energy of solid sodium chloride. Direct experimental determination of the lattice energy of an ionic solid is difficult. However, this quantity can be indirectly determined from experiment by means of a thermochemical “cycle” originated by Max Born and Fritz Haber in 1919 and now called the *Born-Haber cycle*. The reasoning is based on Hess’s law.

To obtain the lattice energy of  $\text{NaCl}$ , you think of solid sodium chloride being formed from the elements by two different routes, as shown in Figure 9.3. In one route,  $\text{NaCl}(s)$  is formed directly from the elements,  $\text{Na}(s)$  and  $\frac{1}{2}\text{Cl}_2(g)$ . The enthalpy change for this is  $\Delta H_f^\circ$ , which is given in Table 6.2 as  $-411$  kJ per mole of  $\text{NaCl}$ . The second route consists of the following five steps, along with the enthalpy change for each. (To be precise, the ionization energy and electron affinity are energy changes,  $\Delta E$ , and we should add small corrections to give the enthalpy changes,  $\Delta H$ .)

1. *Sublimation of sodium.* Metallic sodium is vaporized to a gas of sodium atoms. (*Sublimation* is the transformation of a solid to a gas.) The enthalpy change for this process, measured experimentally, is 108 kJ per mole of sodium.
2. *Dissociation of chlorine.* Chlorine molecules are dissociated to atoms. The enthalpy change for this equals the Cl—Cl bond dissociation energy, which is 240 kJ per mole of bonds, or 120 kJ per mole of Cl atoms.
3. *Ionization of sodium.* Sodium atoms are ionized to  $\text{Na}^+$  ions. The enthalpy change is essentially the ionization energy of atomic sodium, which equals 496 kJ per mole of Na.
4. *Formation of chloride ion.* The electrons from the ionization of sodium atoms are transferred to chlorine atoms. The enthalpy change for this is the negative of the electron affinity of atomic chlorine, equal to  $-349$  kJ per mole of Cl atoms.
5. *Formation of NaCl(s) from ions.* The ions  $\text{Na}^+$  and  $\text{Cl}^-$  formed in Steps 3 and 4 combine to give solid sodium chloride. Because this process is just the reverse of the one corresponding to the lattice energy (breaking the solid into ions), the enthalpy change is the negative of the lattice energy. If we let  $U$  be the lattice energy, the enthalpy change for Step 5 is  $-U$ .

Let us write these five steps and add them. We also add the corresponding enthalpy changes, following Hess’s law.

In summing the equations, we have canceled terms that appear on both the left and right sides of the arrows. The final equation is simply the formation reaction for  $\text{NaCl}(s)$ . Adding the enthalpy changes, we find that the enthalpy change for this formation reaction is  $375 \text{ kJ} - U$ . But the enthalpy of formation has been determined calorimetrically and equals  $-411$  kJ. Equating these two values, we get

$$375 \text{ kJ} - U = -411 \text{ kJ}$$

Solving for  $U$  yields the lattice energy of  $\text{NaCl}$ :

$$U = (375 + 411) \text{ kJ} = 786 \text{ kJ}$$

A CHEMIST Looks at ...

# Ionic Liquids and Green Chemistry

New substances with peculiar or strange behavior have always intrigued chemists. The German chemist Hennig Brand in 1669 discovered a white, waxy solid that he called "cold fire," because it glowed in the dark—a strange property then and still captivating today. He tried to keep the recipe (lengthy boiling of putrid urine) secret, but people's fascination with the waxy solid, which was white phosphorus, proved irresistible.

Modern chemists continue to expand the boundaries of known materials. They have discovered plastics that conduct electricity like metals and materials that look solid but are so porous they are almost as light as air. Now chemists have produced room-temperature ionic liquids (Figure 9.4). Most of these are clear, well-behaved substances that look and pour much like water, and like water their strength is as solvents (liquids that dissolve other substances). In fact, they promise to be "super solvents." Given a material—an organic substance, a plastic, or even a rock—researchers believe you will be able to find an ionic liquid that is capable of dissolving it!

Compare room-temperature ionic liquids with their more prosaic cousins. Sodium chloride, a typical example, is solid at room temperature and doesn't melt until exposed to

Martyn Earle 2007/Quill Research Centre

**Figure 9.4** ▲

**Room-temperature ionic liquids** A series of tubes containing luminescent ionic liquids, spelling out QUILL (Queen's University Ionic Liquid Laboratories Research Centre, Belfast, Ireland).

temperatures over 800°C. The molten liquid, though clear, is very corrosive (chemically reactive). The high melting point of sodium chloride is easily explained. It consists of small, spherical ions that pack closely together. Thus, the ions interact strongly, giving a solid with a high melting point. Room-temperature ionic liquids, by contrast, consist of large, nonspherical cations with various anions (Figure 9.5). It is the large, bulky cations that keep the ions from packing closely; the large distances between ions result in weak interactions, yielding a substance whose melting point is often well below room temperature.

The demand for *green chemistry*, the commercial production of chemicals using environmentally sound methods, has spurred much of the research into ionic liquids. Many chemical processes use volatile organic solvents. These solvents are liquids that evaporate easily into the surrounding air, where they can contribute to air pollution. Organic solvents are often flammable, too. Ionic liquids are neither volatile nor flammable. In addition to these environmental rewards, however, ionic liquids appear to offer another bonus: The proper choice of ionic liquid may improve the yield and lower the costs of a chemical process.

■ See Problems 9.111 and 9.112.

## Properties of Ionic Substances

Typically, ionic substances are high-melting solids. Sodium chloride, NaCl, ordinary salt, melts at 801°C, and magnesium oxide, MgO, a ceramic, melts at 2800°C. The explanation for the high melting points of these substances is simple.

Small, spherical cations and anions interact by strong bonds that essentially depend on the electrical force of attraction described by Coulomb's law. Large groups of such cations and anions attract one another with strong ionic bonds linking all of the ions together, forming a crystalline solid. When you heat any solid, the atoms or ions of that solid begin to vibrate; and, as you raise the temperature, these atoms or ions vibrate through larger and larger distances. At a high enough temperature, the atoms or ions of the solid may move sufficiently far apart that the solid melts to a liquid (or the solid may simply decompose to different substances). The temperature at which melting occurs depends on the strength of the interaction between the atoms or ions. Typical ionic solids require high temperatures for this process to occur because of the strong interactions between the ions.

Coulomb's law also explains why magnesium oxide, which is composed of ions having double charges ( $\text{Mg}^{2+}$  and  $\text{O}^{2-}$ ), has such a high melting point compared with sodium chloride ( $\text{Na}^+$  and  $\text{Cl}^-$ ). Coulombic interactions depend on the product of the ion charges. For NaCl, this is  $1 \times 1$ , whereas for MgO, this is  $2 \times 2$ , or 4 times greater. (Coulomb's law also depends on the distance between charges, or ions, which is about the same in NaCl and MgO.) The much larger Coulombic interaction in MgO requires a much greater temperature to initiate melting.

The liquid melt from an ionic solid consists of ions, and so the liquid conducts an electric current. If the ionic solid dissolves in a molecular liquid, such as water, the resulting solution consists of ions dispersed among molecules; the solution also conducts an electric current.

Recently, as the accompanying essay on ionic liquids describes, chemists have prepared ionic substances that behave atypically. Their unusual properties are the result of large, nonspherical cations that lead to especially weak ionic bonding. The melting points of these ionic substances are unusually low; often they are liquids at room temperature (that is, their melting points are below room temperature).

## 9.2 Electron Configurations of Ions

In the previous section, we described the formation of ions from atoms. Often you can understand what monatomic ions form by looking at the electron configurations of the atoms and deciding what configurations you would expect for the ions.

### Ions of the Main-Group Elements

In Chapter 2, we listed the common monatomic ions of the main-group elements (Table 2.3). Most of the cations are obtained by removing all the valence electrons from the atoms of metallic elements. Once these atoms have lost their valence electrons, they have stable noble-gas or pseudo-noble-gas configurations. The stability of these configurations can be seen by looking at the successive ionization energies of some atoms. Table 9.2 lists the first through the fourth ionization energies of Na, Mg, and Al.

**Table 9.2** Ionization Energies of Na, Mg, and Al (in kJ/mol)\*

Element	Successive Ionization Energies			
	First	Second	Third	Fourth
Na	496	4,562	6,910	9,543
Mg	738	1,451	7,733	10,542
Al	578	1,817	2,745	11,577

\*Energies for the ionization of valence electrons lie to the left of the colored line.

and Al. The energy needed to remove the first electron from the Na atom is only 496 kJ/mol (first ionization energy). But the energy required to remove another electron (the second ionization energy) is nearly ten times greater (4562 kJ/mol). The electron in this case must be taken from  $\text{Na}^+$ , which has a neon configuration. Magnesium and aluminum atoms are similar. Their valence electrons are easily removed, but the energy needed to take an electron from either of the ions that result ( $\text{Mg}^{2+}$  and  $\text{Al}^{3+}$ ) is extremely high. That is why no compounds are found with ions having charges greater than the group number.

The loss of successive electrons from an atom requires increasingly more energy. Consequently, Group 3A elements show less tendency to form ionic compounds than do Group 1A and 2A elements, which primarily form ionic compounds. Boron, in fact, forms no compounds with  $\text{B}^{3+}$  ions. The bonding is normally covalent, a topic discussed later in this chapter. However, the tendency to form ions becomes greater going down any column of the periodic table because of decreasing ionization energy. The remaining elements of Group 3A do form compounds containing  $3+$  ions.

There is also a tendency for Group 3A to 5A elements of higher periods, particularly Period 6, to form compounds with ions having a positive charge of two less than the group number. Thallium in 3A, Period 6, has compounds with  $1+$  ions and compounds with  $3+$  ions. Ions with charge equal to the group number minus two are obtained when the  $np$  electrons of an atom are lost but the  $ns^2$  electrons are retained. For example,

Few compounds of  $4+$  ions are known because the energy required to form  $4+$  ions is so great. The first three elements of Group 4A—C, Si, and Ge—are nonmetals (or metalloids) and usually form covalent rather than ionic bonds. Tin and lead, however, the fourth and fifth elements of Group 4A, commonly form compounds with  $2+$  ions (ionic charge equal to the group number minus two). For example, tin forms tin(II) chloride,  $\text{SnCl}_2$ , which is an ionic compound. It also forms tin(IV) chloride,  $\text{SnCl}_4$ , but this is a covalent, not an ionic, compound. Bismuth, in Group 5A, is a metallic element that forms compounds of  $\text{Bi}^{3+}$  (ionic charge equal to the group number minus two), where only the  $6p$  electrons have been lost.

Group 6A and Group 7A elements, whose atoms have the largest electron affinities, would be expected to form monatomic ions by gaining electrons to give noble-gas or pseudo-noble-gas configurations. An atom of a Group 7A element (valence-shell configuration  $ns^2np^5$ ) picks up one electron to give a  $1-$  anion ( $ns^2np^6$ ); examples are  $\text{F}^-$  and  $\text{Cl}^-$ . (Hydrogen also forms compounds of the  $1-$  ion,  $\text{H}^-$ . The hydride ion,  $\text{H}^-$ , has a  $1s^2$  configuration, like the noble-gas atom helium.) An atom of a Group 6A element (valence-shell configuration  $ns^2np^4$ ) picks up two electrons to give a  $2-$  anion ( $ns^2np^6$ ); examples are  $\text{O}^{2-}$  and  $\text{S}^{2-}$ . Although the electron affinity of nitrogen ( $2s^22p^3$ ) is essentially zero, the  $\text{N}^{3-}$  ion ( $2s^22p^6$ ) is stable in the presence of certain positive ions, including  $\text{Li}^+$  and those of the alkaline earth elements. ▶

To summarize, the common monatomic ions found in compounds of the main-group elements fall into three categories (see Table 2.3):

1. Cations of Groups 1A to 3A having noble-gas or pseudo-noble-gas configurations. The ion charges equal the group numbers.
2. Cations of Groups 3A to 5A having  $ns^2$  electron configurations. The ion charges equal the group numbers minus two. Examples are  $\text{Tl}^+$ ,  $\text{Sn}^{2+}$ ,  $\text{Pb}^{2+}$ , and  $\text{Bi}^{3+}$ .
3. Anions of Groups 5A to 7A having noble-gas or pseudo-noble-gas configurations. The ion charges equal the group numbers minus eight.

Interestingly, lithium metal reacts with nitrogen at room temperature to form a layer of lithium nitride,  $\text{Li}_3\text{N}$ , on the metal surface (see photo above).

**Example 9.2 Writing the Electron Configuration and Lewis Symbol for a Main-Group Ion****Gaining Mastery Toolbox****Critical Concept 9.2**

The common monatomic ions in the main-group elements fall into three categories: (1) cations of Groups 1A to 3A usually have ion charges equal to group numbers, (2) cations of Groups 3A to 5A may have ion charges equal to group numbers minus two—an example is  $\text{Tl}^+$ ; and (3) anions of Groups 5A to 7A have charges equal to the group numbers minus eight.

**Solution Essentials:**

- Categories of main-group monatomic ions
- Number of valence electrons in a main-group atom
- Electron configuration of an atom

Write the electron configuration and the Lewis symbol for  $\text{N}^{3-}$ .

**Problem Strategy** Recall the three categories of main-group monatomic ions: (1) cations of Groups 1A to 3A usually have ion charges equal to group numbers; (2) cations of Groups 3A to 5A may have ion charges equal to group numbers minus two—an example is  $\text{Tl}^+$ ; and (3) anions of Groups 5A to 7A have charges equal to the group numbers minus eight. Write the electron configuration of the atom, and then subtract or add electrons to give the ion. Similarly, write the Lewis symbol of the atom, and subtract or add dots to give the ion.

**Solution** The electron configuration of the N atom is  $[\text{He}]2s^22p^3$ . By gaining three electrons, the atom assumes a  $3-$  charge and the neon configuration  $[\text{He}]2s^22p^6$ . The Lewis symbol is

**Answer Check** Check that the ion has a noble-gas or pseudo-noble-gas configuration and that the Lewis symbol has eight dots, or none, around the atomic symbol.

**Exercise 9.2** Write the electron configuration and the Lewis symbol for  $\text{Ca}^{2+}$  and for  $\text{S}^{2-}$ .

See Problems 9.39 and 9.40.

**Exercise 9.3** Write the electron configurations of Pb and  $\text{Pb}^{2+}$ .

See Problems 9.41 and 9.42.

**Polyatomic Ions**

Many ions, particularly anions, are polyatomic. Some common polyatomic ions are listed in Table 2.5. The atoms in these ions are held together by covalent bonds, which we will discuss in Section 9.4.

**Transition-Metal Ions**

Most transition elements form several cations of different charges. For example, iron has the cations  $\text{Fe}^{2+}$  and  $\text{Fe}^{3+}$ . Neither has a noble-gas configuration; that would require the energetically impossible loss of eight electrons from the neutral atom.

In forming ions in compounds, the atoms of transition elements generally lose the  $ns$  electrons first; then they may lose one or more  $(n-1)d$  electrons. The  $2+$  ions are common for the transition elements and are obtained by the loss of the highest-energy  $s$  electrons from the atom. Many transition elements also form  $3+$  ions by losing one  $(n-1)d$  electron in addition to the two  $ns$  electrons. Table 2.4 lists some common transition-metal ions. Many compounds of transition-metal ions are colored because of transitions involving  $d$  electrons, whereas the compounds of the main-group elements are usually colorless (Figure 9.6).

**Figure 9.6** ▶

**Common transition-metal cations in aqueous solution** Left to right:  $\text{Cr}^{3+}$  (red-violet),  $\text{Mn}^{2+}$  (pale pink),  $\text{Fe}^{2+}$  (pale green),  $\text{Fe}^{3+}$  (pale yellow),  $\text{Co}^{2+}$  (pink),  $\text{Ni}^{2+}$  (green),  $\text{Cu}^{2+}$  (blue), and  $\text{Zn}^{2+}$  (colorless).

**Example 9.3 Writing Electron Configurations of Transition-Metal Ions****Gaining Mastery Toolbox****Critical Concept 9.3**

The atoms of transition elements generally lose the  $ns$  electrons first; then they may lose one or more  $(n - 1)d$  electrons.

**Solution Essentials:**

- Electron configuration of a transition-metal atom
- Building-up principle

Write the electron configurations of  $\text{Fe}^{2+}$  and  $\text{Fe}^{3+}$ .

**Problem Strategy** After obtaining the electron configuration of the atom (using the building-up principle as in Example 8.2 or Example 8.3), remove  $ns$  electrons, then  $(n - 1)d$  electrons, until you have the correct positive charge on the ion.

**Solution** The electron configuration of the Fe atom ( $Z = 26$ ) is  $[\text{Ar}]3d^64s^2$ . To obtain the configuration of  $\text{Fe}^{2+}$ , remove the  $4s^2$  electrons. To obtain the configuration of  $\text{Fe}^{3+}$ , also remove a  $3d$  electron. **The configuration of  $\text{Fe}^{2+}$  is  $[\text{Ar}]3d^6$ , and that of  $\text{Fe}^{3+}$  is  $[\text{Ar}]3d^5$ .**

**Answer Check** Check that the number of outer electrons in an ion is correct. The number of outer electrons equals the group number (but count the columns of Group 8B as 8, 9, and 10) minus the ion charge. For example, the configuration of  $\text{Fe}^{2+}$  is given as  $[\text{Ar}]3d^6$ . Iron is in the first column of Group 8B (count 8); the ion has two fewer electrons ( $8 - 2 = 6$ ). This checks with the configuration as written.

**Exercise 9.4** Write the electron configuration of  $\text{Mn}^{2+}$ .

See Problems 9.43 and 9.44.

**CONCEPT CHECK 9.1**

The following are electron configurations for some ions. Which ones would you expect to see in chemical compounds? State the concept or rule you used to decide for or against any ion.

**9.3 Ionic Radii**

A monatomic ion, like an atom, is a nucleus surrounded by a distribution of electrons. The **ionic radius** is a measure of the size of the spherical region around the nucleus of an ion within which the electrons are most likely to be found. As for an atomic radius, defining an ionic radius is somewhat arbitrary, because an electron distribution never abruptly ends. However, if we imagine ions to be spheres of definite size, we can obtain their radii from known distances between nuclei in crystals. (These distances can be determined accurately by observing how crystals diffract X rays.) ▶

To understand how you compute ionic radii, consider the determination of the radius of an  $\text{I}^-$  ion in a lithium iodide (LiI) crystal. Figure 9.7 depicts a layer of ions in LiI. The distance between adjacent iodine nuclei equals twice the  $\text{I}^-$  radius. From X-ray diffraction experiments, the iodine–iodine distance is found to be 426 pm ( $1 \text{ pm} = 1 \times 10^{-12} \text{ m}$ ). Therefore, the  $\text{I}^-$  radius in LiI is  $\frac{1}{2} \times 426 \text{ pm} = 213 \text{ pm}$ . Other crystals give approximately the same radius for the  $\text{I}^-$  ion. Table 9.3, which lists average values of ionic radii obtained from many compounds of the main-group elements, gives 216 pm for the  $\text{I}^-$  radius.

That you can find values of ionic radii that agree with the known structures of many crystals is strong evidence for the existence of ions in the solid state. Moreover, these values of ionic radii compare with atomic radii in ways that you might expect. For example, you expect a cation to be smaller and an anion to be larger than the corresponding atom (see Figure 9.8).

A cation formed when an atom loses all its valence electrons is smaller than the atom because it has one less shell of electrons. But even when only some of

The study of crystal structure by X-ray diffraction is discussed in Chapter 11.

Figure 9.7 ▶

Determining the iodide ion radius in the lithium iodide (LiI) crystal

a A three-dimensional view of the crystal.

b Cross section through a layer of ions. Iodide ions are assumed to be spheres in contact with one another. The distance between iodine nuclei (426 pm) is determined experimentally. One-half of this distance (213 pm) equals the iodide ion radius.

Figure 9.8 ▲

#### Comparison of atomic and ionic radii

Note that the sodium atom loses its outer shell in forming the Na<sup>+</sup> ion. Thus, the cation is smaller than the atom. The Cl<sup>-</sup> ion is larger than the Cl atom, because the same nuclear charge holds a greater number of electrons less strongly.

Table 9.3 Ionic Radii (in pm) of Some Main-Group Elements

Period	1A	2A	3A	6A	7A
2	Li <sup>+</sup> 60	Be <sup>2+</sup> 31		O <sup>2-</sup> 140	F <sup>-</sup> 136
3	Na <sup>+</sup> 95	Mg <sup>2+</sup> 65	Al <sup>3+</sup> 50	S <sup>2-</sup> 184	Cl <sup>-</sup> 181
4	K <sup>+</sup> 133	Ca <sup>2+</sup> 99	Ga <sup>3+</sup> 62	Se <sup>2-</sup> 198	Br <sup>-</sup> 195
5	Rb <sup>+</sup> 148	Sr <sup>2+</sup> 113	In <sup>3+</sup> 81	Te <sup>2-</sup> 221	I <sup>-</sup> 216
6	Cs <sup>+</sup> 169	Ba <sup>2+</sup> 135	Tl <sup>3+</sup> 95		

the valence electrons are lost from an atom, the ion is smaller. With fewer electrons in the valence orbitals, the electron–electron repulsion is initially less, so these orbitals can shrink to increase the attraction of the electrons for the nucleus. Similarly, because an anion has more electrons than the atom, the electron–electron repulsion is greater, so the valence orbitals expand. Thus, the anion radius is larger than the atomic radius.

**Exercise 9.5** Which has the larger radius, S or S<sup>2-</sup>? Explain.

See Problems 9.45 and 9.46.

The ionic radii of the main-group elements shown in Table 9.3 follow a regular pattern, just as atomic radii do. *Ionic radii increase down any column because of the addition of electron shells.*

**Exercise 9.6** Without looking at Table 9.3, arrange the following ions in order of increasing ionic radius: Sr<sup>2+</sup>, Mg<sup>2+</sup>, Ca<sup>2+</sup>. (You may use a periodic table.)

See Problems 9.47 and 9.48.

The pattern across a period becomes clear if you look first at the cations and then at the anions. For example, in the third period we have

Cation	Na <sup>+</sup>	Mg <sup>2+</sup>	Al <sup>3+</sup>
Radius (pm)	95	65	50

All of these ions have the neon configuration  $1s^2 2s^2 2p^6$  but different nuclear charges; that is, they are isoelectronic. **Isoelectronic** refers to different species having the same number and configuration of electrons. To understand the decrease in radius from Na<sup>+</sup> to Al<sup>3+</sup>, imagine the nuclear charge (atomic number) of Na<sup>+</sup> to increase. With each increase of charge, the orbitals contract due to the greater attractive force of the nucleus. Thus, in any isoelectronic sequence of atomic ions, the ionic radius decreases with increasing atomic number (just as it does for the atoms).

If you look at the anions in the third-period elements, you notice that they are much larger than the cations in the same period. This abrupt increase in ionic radius is due to the fact that the anions S<sup>2-</sup> and Cl<sup>-</sup> have configurations with one more shell of electrons than the cations. And because these anions also constitute an isoelectronic sequence (with argon configuration), the ionic radius decreases with atomic number (as with the atoms):

Anion	S <sup>2-</sup>	Cl <sup>-</sup>
Radius (pm)	184	181

Thus, in general, across a period the cations decrease in radius. When you reach the anions, there is an abrupt increase in radius, and then the radius again decreases.

### Example 9.4 Using Periodic Trends to Obtain Relative Ionic Radii

#### Gaining Mastery Toolbox

##### Critical Concept 9.4

In any series of isoelectronic ions, the ionic radius decreases with increasing atomic number. Thus, across a period, the cations decrease in radius; however, when you reach the anions in that period, you find an abrupt increase in radius, followed by a further decrease in radius.

##### Solution Essentials:

- Obtain valence-shell configuration using periodic table
- Building-up principle

Without looking at Table 9.3, arrange the following ions in order of decreasing ionic radius: F<sup>-</sup>, Mg<sup>2+</sup>, O<sup>2-</sup>. (You may use a periodic table.)

**Problem Strategy** Note that in a series of isoelectronic ions, the ion radius decreases with an increase in nuclear charge (or atomic number).

**Solution** Note that F<sup>-</sup>, Mg<sup>2+</sup>, and O<sup>2-</sup> are isoelectronic. If you arrange them by increasing nuclear charge, they will be in order of decreasing ionic radius. **The order is O<sup>2-</sup>, F<sup>-</sup>, Mg<sup>2+</sup>.**

**Answer Check** Check that the ions are isoelectronic by writing their electron configurations.

**Exercise 9.7** Without looking at Table 9.3, arrange the following ions in order of increasing ionic radius: Cl<sup>-</sup>, Ca<sup>2+</sup>, P<sup>3-</sup>. (You may use a periodic table.)

See Problems 9.49 and 9.50.

## ▶ Covalent Bonds

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. WCN 02-200-203

In the preceding sections we looked at ionic substances, which are typically high-melting solids. Many substances, however, are molecular—gases, liquids, or low-melting solids consisting of molecules (Figure 9.9). A molecule is a group of atoms, frequently nonmetal atoms, strongly linked by chemical bonds. Often the forces that hold atoms together in a molecular substance cannot be understood on the basis of the attraction of oppositely charged ions (the ionic model). An obvious example is the molecule H<sub>2</sub>, in which the two H atoms are held together tightly and no ions are present. In 1916, Gilbert Newton Lewis proposed that the strong attractive force between two atoms in a molecule results from a **covalent bond**, a chemical bond formed by the sharing of a pair of electrons between atoms. ▶ In 1926, Walter Heitler and Fritz London showed that the covalent bond in H<sub>2</sub> could be quantitatively explained by the newly discovered theory of quantum mechanics. We will discuss the descriptive aspects of covalent bonding in the following sections.

G. N. Lewis (1875–1946) was professor of chemistry at the University of California at Berkeley. Well known for work on chemical bonding, he was also noted for his research in molecular spectroscopy and thermodynamics (the study of heat involved in chemical and physical processes).

Figure 9.9 ▶

Two molecular substances

Figure 9.10 ▲

**The electron probability distribution for the H<sub>2</sub> molecule**

The electron density (shown in red) occupies the space around both atoms.

## 9.4 Describing Covalent Bonds

Consider the formation of a covalent bond between two H atoms to give the H<sub>2</sub> molecule. As the atoms approach one another, their 1s orbitals begin to overlap. Each electron can then occupy the space around both atoms. In other words, the two electrons can be shared by the atoms (Figure 9.10). The electrons are attracted simultaneously by the positive charges of the two hydrogen nuclei. This attraction that bonds the electrons to both nuclei is the force holding the atoms together. Although ions do not exist in H<sub>2</sub>, the force that holds the atoms together can still be regarded as arising from the attraction of oppositely charged particles: nuclei and electrons.

It is interesting to see how the potential energy of the atoms changes as they approach and then bond. Figure 9.11 shows the potential energy of the atoms for various distances between nuclei. The potential energy of the atoms when they are some distance apart is indicated by a position on the potential-energy curve at the far right. As the atoms approach (moving from right to left on the potential-energy curve), the potential energy gets lower and lower. The decrease in energy is a reflection of the bonding of the atoms. Eventually, as the atoms get close enough, the repulsion of the positive charges on the nuclei becomes larger than the attraction of electrons for nuclei. In other words, the potential energy reaches a minimum value and then increases. The distance between nuclei at this minimum energy is called the *bond length* of H<sub>2</sub>. It is the normal distance between nuclei in the molecule.

Now imagine the reverse process. You start with the H<sub>2</sub> molecule, the atoms at their normal bond length apart (at the minimum of the potential-energy curve). To separate the atoms in the molecule, energy must be added (you move along the curve to the flat portion at the right). The energy that must be added is called the *bond dissociation energy*. The larger the bond dissociation energy, the stronger the bond.

Figure 9.11 ◀

**Potential-energy curve for H<sub>2</sub>** The stable molecule occurs at the bond distance corresponding to the minimum in the potential-energy curve.

### Lewis Formulas

You can represent the formation of the covalent bond in H<sub>2</sub> from atoms as follows:

This uses the Lewis electron-dot symbol for the hydrogen atoms and represents the covalent bond by a pair of dots. Recall that the two electrons from the covalent bond spend part of the time in the region of each atom. In this sense, each atom in H<sub>2</sub> has a helium configuration. We can draw a circle about each atom to emphasize this.

The formation of a bond between H and Cl to give an HCl molecule can be represented in a similar way.

As the two atoms approach each other, unpaired electrons on each atom pair up to form a covalent bond. The pair of electrons is shared by the two atoms. Each atom then acquires a noble-gas configuration of electrons, the H atom having two electrons about it (as in He), and the Cl atom having eight valence electrons about it (as in Ar).

A formula using dots to represent valence electrons is called a **Lewis electron-dot formula**. An electron pair represented by a pair of dots in such a formula is either a **bonding pair** (an electron pair shared between two atoms) or a **lone, or nonbonding, pair** (an electron pair that remains on one atom and is not shared). For example,

Bonding pairs are often represented by dashes rather than by pairs of dots.

Frequently, the number of covalent bonds formed by an atom equals the number of unpaired electrons shown in its Lewis symbol. Consider the formation of NH<sub>3</sub>.

The numbers of unpaired electrons in the Lewis symbols for the atoms of elements in Groups 1A and 3A equal the group numbers. But except for the first elements of these groups, the atoms usually form ionic bonds.

Each bond is formed between an unpaired electron on one atom and an unpaired electron on another atom. In many instances, the number of bonds formed by an atom in Groups 4A to 7A equals the number of unpaired electrons, which is eight minus the group number. For example, a nitrogen atom (Group 5A) forms  $8 - 5 = 3$  covalent bonds. ◀

### Coordinate Covalent Bonds

When bonds form between atoms that both donate an electron, you have

However, it is possible for both electrons to come from the same atom. A **coordinate covalent bond** is a bond formed when both electrons of the bond are donated by one atom:

A coordinate covalent bond is not essentially different from other covalent bonds; it involves the sharing of a pair of electrons between two atoms. An example is the formation of the ammonium ion, in which an electron pair on the N atom of  $\text{NH}_3$  forms a bond with  $\text{H}^+$ .

The new N—H bond is clearly identical to the other N—H bonds.

### Octet Rule

In each of the molecules we have described so far, the atoms have obtained noble-gas configurations through the sharing of electrons. Atoms other than hydrogen have obtained eight electrons in their valence shells; hydrogen atoms have obtained two. *The tendency of atoms in molecules to have eight electrons in their valence shells (two for hydrogen atoms)* is known as the **octet rule**. Many of the molecules we will discuss follow the octet rule. Some do not.

### Multiple Bonds

In the molecules we have described so far, each of the bonds has been a **single bond**—that is, a covalent bond in which a single pair of electrons is shared by two atoms. But it is possible for atoms to share two or more electron pairs. A **double bond** is a covalent bond in which two pairs of electrons are shared by two atoms. A **triple bond** is a covalent bond in which three pairs of electrons are shared by two atoms. As examples, consider ethylene,  $\text{C}_2\text{H}_4$ , and acetylene,  $\text{C}_2\text{H}_2$ . Their Lewis formulas are

Ethylene

Acetylene

Note the octet of electrons on each C atom. Double bonds form primarily with C, N, O, and S atoms. Triple bonds form mostly to C and N atoms.

## 9.5 Polar Covalent Bonds; Electronegativity

A covalent bond involves the sharing of at least one pair of electrons between two atoms. When the atoms are alike, as in the case of the H—H bond of  $\text{H}_2$ , the bonding electrons are shared equally. That is, the electrons spend the same amount of time in

## Daily Life

A CHEMIST Looks at . . .

## Chemical Bonds in Nitroglycerin

Nitroglycerin gained a nasty reputation soon after its discovery in 1846. Unless kept cold, the pale yellow, oily liquid detonates from even the mildest vibration. In the French film *The Wages of Fear*, four men agree to drive two trucks loaded with nitroglycerin over mountainous roads from a remote village in South America. They are to drive the nitroglycerin to an out-of-control oil-well fire, where the explosive will be used to close off the well. On the way, they find the road obstructed by a huge boulder that has rolled across it, and they decide to blast the boulder out of their way using some of their explosive cargo. You see one of the men gingerly pouring nitroglycerin from a thermos bottle down a stick and into a hole in the rock. Beads of sweat form on his contorted face, while he tries desperately to suspend his breathing and any extra movement that might set off the nitroglycerin.

Here is the structure of nitroglycerin (also see the molecular model in Figure 9.12):

Figure 9.12 ▲

**Molecular model of nitroglycerin** In this ball-and-stick model, carbon atoms are gray, hydrogen atoms are light blue, oxygen atoms are red, and nitrogen atoms are dark blue.

With just a little jostling, nitroglycerin,  $\text{C}_3\text{H}_5(\text{ONO}_2)_3$ , can rearrange its atoms to give stable products:

The stability of the products results from their strong bonds, which are much stronger than those in nitroglycerin. Nitrogen, for example, has a strong nitrogen–nitrogen triple bond, and carbon dioxide has two strong carbon–oxygen double bonds. The explosive force of the reaction results from both the rapid reaction and from the large volume increase on forming gaseous products.

In 1867, the Swedish chemist Alfred Nobel discovered that nitroglycerin behaved better when absorbed on diatomaceous earth, a crumbly rock, giving an explosive mixture that Nobel called *dynamite*. Part of the wealth he made from his explosive factories was left in trust to establish the Nobel Prizes. Although explosives are often associated in people's minds with war, they do have many peacetime uses, including road building, mining, and demolition (Figure 9.13).

Figure 9.13 ▲

**Demolition of a building** Explosives are placed at predetermined positions so that when they are detonated, the building collapses on itself.

■ See Problems 9.113 and 9.114.

Figure 9.14 ▲

**The HCl molecule** A molecular model.

The diagram below the electron-dot formulas shows red regions of a molecule as electron rich and blue regions as electron poor.

The bonding pairs of electrons are equally shared in H<sub>2</sub>, unequally shared in HCl, and essentially not shared in NaCl. Thus, it is possible to arrange different bonds to form a gradual transition from nonpolar covalent to ionic.

Note that a polar bond results when the bonding pair is drawn more toward one atom than the other. The concept of electronegativity is useful in judging whether a bond will be polar or not. **Electronegativity** is a measure of the ability of an atom in a molecule to draw bonding electrons to itself. Several electronegativity scales have been proposed. In 1934, Robert S. Mulliken suggested on theoretical grounds that the electronegativity ( $X$ ) of an atom be given as half its ionization energy ( $I.E.$ ) plus electron affinity ( $E.A.$ ). ◀

$$X = \frac{I.E. + E.A.}{2}$$

An atom such as fluorine that tends to pick up electrons easily (large  $E.A.$ ) and hold on to them strongly (large  $I.E.$ ) has a large electronegativity. On the other hand, an atom such as lithium or cesium that loses electrons readily (small  $I.E.$ ) and has little tendency to gain electrons (small  $E.A.$ ) has a small electronegativity. Until recently, only a few electron affinities had been measured. For this reason, Mulliken's scale has had limited utility. A more widely used scale was derived earlier by Linus Pauling from bond enthalpies, which are discussed later in this chapter. Pauling's electronegativity values are given in Figure 9.15. Because electronegativities depend somewhat on the bonds formed, these values are actually average ones. ◀

Fluorine, the most electronegative element, was assigned a value of 4.0 on Pauling's scale. Lithium, at the left end of the same period, has a value of 1.0. Cesium, in the same column but below lithium, has a value of 0.7. In general, electronegativity increases from left to right and decreases from top to bottom in the periodic table. Metals are the least electronegative elements (they are electropositive) and nonmetals the most electronegative.

The absolute value of the difference in electronegativity of two bonded atoms gives a rough measure of the polarity to be expected in a bond. When this difference is small, the bond is nonpolar. When it is large, the bond is polar (or, if the difference is very large, perhaps ionic). The electronegativity differences for the bonds H—H, H—Cl, and Na—Cl are 0.0, 0.9, and 2.1, respectively, following the expected order. Differences in electronegativity explain why ionic bonds usually form between a metal atom and a nonmetal atom; the electronegativity difference would be largest between these elements. On the other hand, covalent bonds form primarily between two nonmetals because the electronegativity differences are small. ◀

Robert S. Mulliken received the Nobel Prize in chemistry in 1966 for his work on molecular orbital theory (discussed in Chapter 10).

Linus Pauling received the Nobel Prize in chemistry in 1954 for his work on the nature of the chemical bond. In 1962 he received the Nobel Peace Prize.

The electronegativity difference in metal-metal bonding would also be small. This bonding frequently involves delocalized *metallic bonding*, briefly described in Section 9.7.

Figure 9.15 ▲

**Electronegativities of the elements** The values given are those of Pauling (those in gray are not known).

Example 9.5 Using Electronegativities to Obtain Relative Bond Polarities	
<p><b>Gaining Mastery Toolbox</b></p> <p><b>Critical Concept 9.5</b> The absolute value of the difference in electronegativity of two bonded atoms is a rough measure of the polarity of the bond. (A useful rule to remember is that electronegativity increases left to right and decreases top to bottom in the periodic table.)</p> <p><b>Solution Essentials:</b></p> <ul style="list-style-type: none"> <li>• Electronegativity</li> </ul>	<p>Use electronegativity values (Figure 9.15) to arrange the following bonds in order of increasing polarity: P—H, H—O, C—Cl.</p> <p><b>Problem Strategy</b> Order the bonds by the increasing positive value of the difference of electronegativities of the atoms forming the bond. The bonds should then be roughly in order of increasing polarity.</p> <p><b>Solution</b> The absolute values of the electronegativity differences are P—H, 0.0; H—O, 1.4; C—Cl, 0.5. Hence, the order is <b>P—H, C—Cl, H—O</b>.</p> <p><b>Answer Check</b> Make sure you have the correct electronegativities and differences.</p> <p><b>Exercise 9.8</b> Using electronegativities, decide which of the following bonds is most polar: C—O, C—S, H—Br.</p>
	See Problems 9.57 and 9.58.

You can use an electronegativity scale to predict the direction in which the electrons shift during bond formation; the electrons are pulled toward the more electronegative atom. For example, consider the H—Cl bond. Because the Cl atom ( $X = 3.0$ ) is more electronegative than the H atom ( $X = 2.1$ ), the bonding electrons in H—Cl are pulled toward Cl. Because the bonding electrons spend most of their time around the Cl atom, that end of the bond acquires a partial negative charge (indicated  $\delta^-$ ). The H-atom end of the bond has a partial positive charge ( $\delta^+$ ). You can show this as follows:

The HCl molecule is said to be a *polar molecule*. We will say more about polar molecules when we look at molecular structures in Chapter 10.

## 9.6 Writing Lewis Electron-Dot Formulas

The Lewis electron-dot formula of a molecule is similar to the structural formula in that it shows how atoms are bonded. Bonding electron pairs are indicated either by

Lewis formulas do not directly convey information about molecular shape. For example, the Lewis formula of methane,  $\text{CH}_4$ , is written as the flat (two-dimensional) formula

The actual methane molecule, however, is not flat; it has a three-dimensional structure, as explained in Chapter 10.

two dots or by a dash. In addition to the bonding electrons, however, an electron-dot formula shows the positions of lone pairs of electrons, whereas the structural formula does not. Thus, the electron-dot formula is a simple two-dimensional representation of the positions of electrons in a molecule. In the next chapter, we will see how to predict the three-dimensional shape of a molecule from the two-dimensional electron-dot formula. In this section, we will discuss the steps for writing the electron-dot formula for a molecule made from atoms of the main-group elements. ◀

Before you can write the Lewis formula of a molecule (or a polyatomic ion), you must know the *skeleton structure* of the molecule. The skeleton structure tells you which atoms are bonded to one another (without regard to whether the bonds are single or not).

Normally the skeleton structure must be found by experiment. For simple molecules, you can often predict the skeleton structure. For instance, many small molecules or polyatomic ions consist of a central atom around which are bonded atoms of greater electronegativity, such as F, Cl, and O. Note the structural formula (and molecular model) of phosphorus oxychloride,  $\text{POCl}_3$  (Figure 9.16). The phosphorus atom is surrounded by more electronegative atoms. (In some cases, H atoms surround a more electronegative atom as in  $\text{H}_2\text{O}$  and  $\text{NH}_3$ , but H cannot be a central atom because it normally forms only one bond.) Similarly, *oxoacids* are substances in which O atoms (and possibly other electronegative atoms) are bonded to a central atom, with one or more H atoms usually bonded to O atoms. An example is chlorosulfonic acid,  $\text{HSO}_3\text{Cl}$  (Figure 9.17).

Another useful idea for predicting skeleton structures is that molecules or polyatomic ions with symmetrical formulas often have symmetrical structures. For example, disulfur dichloride,  $\text{S}_2\text{Cl}_2$ , is symmetrical, with the more electronegative Cl atoms around the S atoms:  $\text{Cl}-\text{S}-\text{S}-\text{Cl}$ .

Once you know the skeleton structure of a molecule, you can find the Lewis formula by applying the following four steps. These steps allow you to write electron-dot formulas even when the central atom does not follow the octet rule.

**Step 1:** Calculate the total number of valence electrons for the molecule by summing the number of valence electrons (= group number) for each atom. If you are writing the Lewis formula of a polyatomic anion, you *add* the number

Figure 9.16 ▶

**Lewis formula and molecular model of phosphorus oxychloride molecule** The central atom, P, is surrounded by O and Cl atoms.

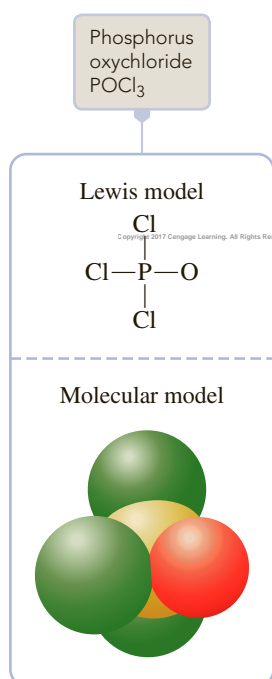

Figure 9.17 ▶

**Lewis formula and molecular model of chlorosulfonic acid molecule** This oxoacid has the central atom, S, surrounded by O atoms and a Cl atom.

of negative charges to this total. (For  $\text{CO}_3^{2-}$  you add 2 because the  $-2$  charge indicates that there are two more electrons than are provided by the neutral atoms.) For a polyatomic cation, you *subtract* the number of positive charges from the total. (For  $\text{NH}_4^+$  you subtract 1.)

- Step 2:** Write the skeleton structure of the molecule or ion, connecting every bonded pair of atoms by a pair of dots (or a dash).
- Step 3:** Distribute electrons to the atoms surrounding the central atom (or atoms) to satisfy the octet rule for these surrounding atoms.
- Step 4:** Distribute the remaining electrons as pairs to the central atom (or atoms), after subtracting the number of electrons already distributed from the total found in Step 1. If there are fewer than eight electrons on the central atom, this suggests that a multiple bond is present. (Two electrons fewer than an octet suggests a double bond; four fewer suggests a triple bond or two double bonds.) To obtain a multiple bond, move one or two electron pairs (depending on whether the bond is to be double or triple) from a surrounding atom to the bond connecting the central atom. Atoms that often form multiple bonds are C, N, O, and S.

The next several examples illustrate how to write the Lewis electron-dot formula for a small molecule, given the molecular formula.

### Example 9.6 Writing Lewis Formulas (Single Bonds Only)

#### Gaining Mastery Toolbox

##### Critical Concept 9.6

To write the Lewis electron-dot formula for a molecule, first obtain the total number of valence electrons for the molecule; second, write the skeleton structure, allowing two electrons for each bond between atoms; third, distribute electrons to the outer atoms in order to satisfy the octet rule for each atom; and finally distribute the remaining electrons to the central atom.

##### Solution Essentials:

- Skeleton structure of a molecule
- Octet rule
- Number of valence electrons in a main-group atom

Sulfur dichloride,  $\text{SCl}_2$ , is a red, fuming liquid used in the manufacture of insecticides. Write the Lewis formula for the molecule.

**Problem Strategy** You follow the four steps: (1) Calculate the total number of valence electrons. (2) Write the skeleton structure with two electrons to each bond between atoms. (3) Distribute electrons to the outer atoms to satisfy the octet rule. (4) Distribute the remaining electrons to the central atom.

**Solution** The number of valence electrons from an atom equals the group number: 6 for S, 7 for each Cl, for a total of 20 electrons. You expect the skeleton structure to have S as the central atom, with the more electronegative Cl atoms bonded to it. After connecting atoms by electron pairs and distributing electrons to the outer atoms, you have

This accounts for 8 electron pairs, or 16 electrons. Subtracting this from the total number of electrons (20) gives 4 electrons, or 2 electron pairs. You place these on the central atom (S). The final Lewis formula is

**Answer Check** In general, atoms surrounding the central atom have four electron pairs (an octet) about them. Note that our answer follows this “octet” rule. Even the central atom often follows this octet rule, as it does here. (We will see some exceptions to this octet rule for the central atom, however.)

**Exercise 9.9** Dichlorodifluoromethane,  $\text{CCl}_2\text{F}_2$ , is a gas used as a refrigerant and aerosol propellant. Write the Lewis formula for  $\text{CCl}_2\text{F}_2$ .

See Problems 9.61 and 9.62.

**Example 9.7 Writing Lewis Formulas (Including Multiple Bonds)****Gaining Mastery Toolbox****Critical Concept 9.7**

If after following the rules for writing an electron-dot formula, you find that the central atom does not have enough electrons for an octet, transfer electron pairs from outer atoms to form multiple bonds in order to give an octet to the central atom.

**Solution Essentials:**

- Skeleton structure of a molecule
- Lewis representation of multiple bonds
- Octet rule
- Number of valence electrons in a main-group atom

Carbonyl chloride, or phosgene,  $\text{COCl}_2$ , is a highly toxic gas used as a starting material for the preparation of polyurethane plastics. What is the electron-dot formula of  $\text{COCl}_2$ ?

**Problem Strategy** You follow the four steps as in the previous example, but after distributing the remaining electrons to the central atom, you find that it does not have enough electrons to give an octet. To rectify this, you transfer an electron pair from an outer atom to form a double bond (part of Step 4). Do you move the electron pair from the Cl or the O atom? It helps to remember that C, N, O, and S atoms often form double bonds. In this case, you move the electron pair from the O atom.

**Solution** The total number of valence electrons is  $4 + 6 + (2 \times 7) = 24$ . You expect the more electropositive atom, C, to be central, with the O and Cl atoms bonded to it. After distributing electron pairs to these surrounding atoms, you have

This accounts for all 24 valence electrons, leaving only 6 electrons on C. This is two fewer than an octet, so you move a pair of electrons on the O atom to give a carbon–oxygen double bond. The electron-dot formula of  $\text{COCl}_2$  is

**Answer Check** Note that the atoms surrounding the central atom have four electron pairs about them; that is, they follow the octet rule. The central atom also follows the octet rule, although exceptions occur.

**Exercise 9.10** Write the electron-dot formula of carbon dioxide,  $\text{CO}_2$ .

See Problems 9.63 and 9.64.

**Example 9.8 Writing Lewis Formulas (Ionic Species)****Gaining Mastery Toolbox****Critical Concept 9.8**

In obtaining the Lewis formula for an ion, note that the total number of valence electrons equals that for the neutral molecule less the charge on the ion (that is, subtract if a positive ion and add if a negative ion).

**Solution Essentials:**

- Skeleton structure of a molecule
- Lewis representation of multiple bonds
- Octet rule
- Number of valence electrons in a main-group atom

Obtain the electron-dot formula (Lewis formula) of the  $\text{BF}_4^-$  ion.

**Problem Strategy** After calculating the total number of valence electrons for the neutral atoms, you add or subtract electrons to account for the ion charge. If the ion is negative, add electrons to give the negative charge. If the ion is positive, subtract electrons to give the positive charge. Once you have the total number of valence electrons in the ion, proceed with the rest of the steps to write the electron-dot formula.

**Solution** The total valence electrons provided by the boron and four fluorine atoms is  $3 + (4 \times 7) = 31$ . Because the anion has a charge of  $-1$ , it has one more electron than is provided by the neutral atoms. Thus, the total number of valence electrons is 32 (or 16 electron pairs). You assume that the skeleton structure has boron as the central

(continued)

**Example 9.8** (continued)

atom, with the more electronegative F atoms bonded to it. After connecting the B and F atoms by bonds and placing electron pairs around the F atoms to satisfy the octet rule, you obtain

This uses up all 32 electrons. The charge on the entire ion is indicated by the minus sign written as a superscript to square brackets enclosing the electron-dot formula.

**Answer Check** Note that the atoms surrounding the central atom have four electron pairs about them; that is, they follow the octet rule. The central atom also follows the octet rule, although exceptions occur.

**Exercise 9.11** Write the electron-dot formula of a. the hydrogen ion,  $\text{H}_3\text{O}^+$ ; b. the chlorite ion,  $\text{ClO}_2^-$ .

See Problems 9.65 and 9.66.

**CONCEPT CHECK 9.2**

Each of the following may seem, at first glance, to be plausible electron-dot formulas for the molecule  $\text{N}_2\text{F}_2$ . Most, however, are incorrect for some reason. What concepts or rules apply to each, either to cast it aside or to keep it as the correct formula?

## 9.7 Delocalized Bonding: Resonance

We have assumed up to now that the bonding electrons are localized in the region between two atoms. In some cases, however, this assumption does not fit the experimental data. Suppose, for example, that you try to write an electron-dot formula for ozone,  $\text{O}_3$ . You find that you can write two formulas:

In formula A, the oxygen–oxygen bond on the left is a double bond and the oxygen–oxygen bond on the right is a single bond. In formula B, the situation is just the opposite. Experiment shows, however, that both bonds in  $\text{O}_3$  are identical. Therefore, neither formula can be correct. ►

According to theory, one of the bonding pairs in ozone is spread over the region of all three atoms rather than associated with a particular oxygen–oxygen

The lengths of the two oxygen–oxygen bonds (that is, the distances between the atomic nuclei) are both 128 pm.

bond. This is called **delocalized bonding**, a type of bonding in which a bonding pair of electrons is spread over a number of atoms rather than localized between two. We might symbolically describe the delocalized bonding in ozone as follows:

(For clarity, only the bonding pairs are given.) The broken line indicates a bonding pair of electrons that spans three nuclei rather than only two. In effect, the oxygen–oxygen bond is neither a single bond nor a double bond but an intermediate type.

A single electron-dot formula cannot properly describe delocalized bonding. Instead, a resonance description is often used. According to the **resonance description**, you describe the electron structure of a molecule having delocalized bonding by writing all possible electron-dot formulas. These are called the *resonance formulas* of the molecule. The actual electron distribution of the molecule is a composite of these resonance formulas.

The electron structure of ozone can be described in terms of the two resonance formulas presented at the start of this section. By convention, we usually write all of the resonance formulas and connect them by double-headed arrows. For ozone we would write

Unfortunately, this notation can be misinterpreted. It does not mean that the ozone molecule flips back and forth between two forms. There is only one ozone molecule. The double-headed arrow means that you should form a mental picture of the molecule by fusing the various resonance formulas. The left oxygen–oxygen bond is double in formula A and the right one is double in formula B, so you must picture an electron pair that actually encompasses both bonds.

Attempting to write electron-dot formulas leads you to recognize that delocalized bonding exists in many molecules. Whenever you can write several plausible electron-dot formulas—which often differ merely in the allocation of single and double bonds to the same kinds of atoms (as in ozone)—you can expect delocalized bonding.

### Example 9.9 Writing Resonance Formulas

#### Gaining Mastery Toolbox

##### Critical Concept 9.9

Having written one electron-dot formula containing single and double bonds, note whether it is possible to write other electron-dot formulas that differ in the placement of these single and double bonds.

##### Solution Essentials:

- Resonance
- Skeleton structure of a molecule
- Lewis representation of multiple bonds
- Octet rule
- Number of valence electrons in a main-group atom

Describe the electron structure of the carbonate ion,  $\text{CO}_3^{2-}$ , in terms of electron-dot formulas.

**Problem Strategy** Write at least one electron-dot formula for a molecule or ion. If the formula has both single and multiple bonds, note whether it is possible to write other electron-dot formulas differing only in the placement of single and double bonds.

**Solution** One possible electron-dot formula for the carbonate ion is

Because you expect all carbon–oxygen bonds to be equivalent, you must describe the electron structure in resonance terms.

(continued)

**Example 9.9** (continued)

You expect one electron pair to be delocalized over the region of all three carbon–oxygen bonds.

**Answer Check** Note that the skeleton structure is the same for all resonance formulas. This must be so, because they represent the same molecule. Also, note that the atoms about the central atom follow the octet rule. (The central atom in this case also follows the octet rule.)

**Exercise 9.12** Describe the bonding in  $\text{NO}_3^-$  using resonance formulas.

See Problems 9.67, 9.68, 9.69, and 9.70.

Metals are extreme examples of delocalized bonding. A sodium metal crystal, for example, can be regarded as an array of  $\text{Na}^+$  ions surrounded by a “sea” of electrons (Figure 9.18). The valence, or bonding, electrons are delocalized over the entire metal crystal. The freedom of these electrons to move throughout the crystal is responsible for the electrical conductivity of a metal.

## 9.8 Exceptions to the Octet Rule

Many molecules composed of atoms of the main-group elements have electronic structures that satisfy the octet rule, but a number of them do not. A few molecules, such as  $\text{NO}$ , have an odd number of electrons and so cannot satisfy the octet rule. Other exceptions to the octet rule fall into two groups—one a group of molecules with an atom having fewer than eight valence electrons around it and the other a group of molecules with an atom having more than eight valence electrons around it.

The exceptions in which the central atom has more than eight valence electrons around it are fairly numerous. Phosphorus pentafluoride is a simple example. This is a colorless gas of  $\text{PF}_5$  molecules. Each molecule consists of a phosphorus atom surrounded by the more electronegative fluorine atoms (Figure 9.19). Following the steps outlined in Section 9.6, you arrive at the following electron-dot formula, in which the phosphorus atom has ten valence electrons around it:

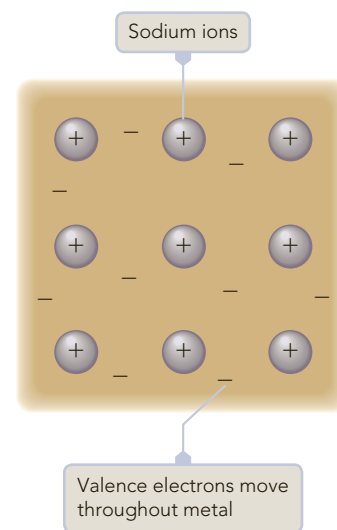

The octet rule stems from the fact that the main-group elements in most cases employ only an  $ns$  and three  $np$  valence-shell orbitals in bonding, and these orbitals hold eight electrons. Elements of the second period are restricted to these

**Figure 9.19** ▲

**Phosphorus pentafluoride,  $\text{PF}_5$**  A ball-and-stick molecular model.

**Figure 9.18** ▲

**Delocalized bonding in sodium metal** The metal consists of positive sodium ions in a “sea” of valence electrons. Valence (bonding) electrons are free to move throughout the metal crystal (beige area).

orbitals, but from the third period on, the elements also have unfilled  $nd$  orbitals, which may be used in bonding. For example, the valence-shell configuration of phosphorus is  $3s^23p^3$ . Using just these  $3s$  and  $3p$  orbitals, the phosphorus atom can accept only three additional electrons, forming three covalent bonds (as in  $\text{PF}_3$ ). However, more bonds can be formed if the empty  $3d$  orbitals of the atom are used. If each of the five electrons of the phosphorus atom is paired with unpaired electrons of fluorine atoms,  $\text{PF}_5$  can be formed. In this way, phosphorus forms both the trifluoride and the pentafluoride. By contrast, nitrogen (which has no available  $d$  orbitals in its valence shell) forms only the trifluoride,  $\text{NF}_3$ .

### Example 9.10 Writing Lewis Formulas (Exceptions to the Octet Rule)

#### Gaining Mastery Toolbox

##### Critical Concept 9.10

In the final step in writing an electron-dot formula (in which you distribute the remaining electrons to the central atom), you may discover that this atom now has more than an octet of electrons.

##### Solution Essentials:

- Skeleton structure of a molecule
- Lewis representation of multiple bonds
- Octet rule
- Number of valence electrons in a main-group atom

Xenon, a noble gas, forms a number of compounds. One of these is xenon tetrafluoride,  $\text{XeF}_4$ , a white, crystalline solid first prepared in 1962. What is the electron-dot formula of the  $\text{XeF}_4$  molecule?

**Problem Strategy** You follow the four steps outlined in Section 9.6. In Step 4, when you distribute the remaining electrons to the central atom, you find that it has more than an octet.

**Solution** There are 8 valence electrons from the Xe atom and 7 from each F atom, for a total of 36 valence electrons. For the skeleton structure, you draw the Xe atom surrounded by the electronegative F atoms. After placing electron pairs on the F atoms to satisfy the octet rule for them, you have:

This accounts for 16 pairs, or 32 electrons. A total of 36 electrons is available, so you put an additional  $36 - 32 = 4$  electrons (2 pairs) on the Xe atom. The Lewis formula is

**Answer Check** Note that the atoms surrounding the central atom follow the octet rule, although the central atom itself does not. The central atom is from a period greater than 2, so it has a valence shell that can accommodate more than eight electrons.

**Exercise 9.13** Sulfur tetrafluoride,  $\text{SF}_4$ , is a colorless gas. Write the electron-dot formula of the  $\text{SF}_4$  molecule.

See Problems 9.71 and 9.72.

The other group of exceptions to the octet rule consists mostly of molecules containing Group 2A or 3A atoms. Consider boron trifluoride,  $\text{BF}_3$ . The molecule consists of boron surrounded by the much more electronegative fluorine atoms. The total number of valence electrons is  $3 + (3 \times 7) = 24$ . If you connect boron and fluorine atoms by electron pairs and fill out the fluorine atoms with octets of electrons, you obtain

If you now follow with Step 4 of the procedure outlined in Section 9.6, you note that the boron atom has only six electrons on it. You write the following resonance formulas, each having a double bond:

In fact, there is evidence to suggest that the first formula written—the one with all single bonds and in which boron has only six electrons around it—describes the chemistry of boron trifluoride very well. For example, boron trifluoride reacts with molecules having a lone pair, such as with ammonia,  $\text{NH}_3$ , to give the compound  $\text{BF}_3\text{NH}_3$ . The reaction is easy to describe in terms of the formula in which boron has only six electrons around it.

In this reaction, a coordinate covalent bond forms between the boron and nitrogen atoms, and the boron achieves an octet of electrons.

The chemistry of  $\text{BF}_3$  thus appears to support an electron structure with boron having only six electrons around it. No doubt, resonance involving all four of the Lewis formulas that we have drawn best describes the actual electron structure of boron trifluoride, but the relative importance of the different resonance formulas is not settled. ▶

Other examples of molecules with Group 3A atoms (such as Al) or Group 2A atoms (such as Be) display electron structures similar to that of boron trifluoride. For example, the  $\text{BeF}_2$  molecule (found in the vapor over the heated solid  $\text{BeF}_2$ ) has the Lewis formula

Aluminum chloride,  $\text{AlCl}_3$ , offers an interesting study in bonding. At room temperature, the substance is a white, crystalline solid and an ionic compound, as might be expected for a binary compound of a metal and a nonmetal. However, the substance has a relatively low melting point ( $192^\circ\text{C}$ ) for an ionic compound. Apparently this is due to the fact that instead of melting to a liquid of ions, as happens with most ionic solids, the compound forms  $\text{Al}_2\text{Cl}_6$  molecules (Figure 9.20), with Lewis formula

Each atom has an octet of electrons around it. Note that two of the Cl atoms are in *bridge* positions, with each Cl atom having two covalent bonds. When this liquid is heated, it vaporizes as  $\text{Al}_2\text{Cl}_6$  molecules. As the vapor is further heated, these molecules break up into  $\text{AlCl}_3$  molecules. These molecules have an electron structure similar to that of  $\text{BF}_3$ .

The B–F bond length (130 pm) is shorter than expected for a single bond (152 pm), which indicates partial double-bond character. See the discussion in Section 9.10 on bond length and bond order.

**Figure 9.20** ▲

**The  $\text{Al}_2\text{Cl}_6$  molecule** A ball-and-stick molecular model.

**Exercise 9.14** Beryllium chloride,  $\text{BeCl}_2$ , is a solid substance consisting of long (essentially infinite) chains of atoms with Cl atoms in bridge positions.

See Problems 9.73 and 9.74.

However, if the solid is heated, it forms a vapor of  $\text{BeCl}_2$  molecules. Write the electron-dot formula of the  $\text{BeCl}_2$  molecule.

## 9.9 Formal Charge and Lewis Formulas

Earlier we looked at writing the Lewis formula for carbonyl chloride,  $\text{COCl}_2$  (Example 9.7). In the solution to that example, we wrote the answer as follows:

You may recall that we had to decide whether to draw the double bond between C and O or between C and Cl. We decided in favor of a carbon–oxygen double bond by applying the simple idea that multiple bonds most likely involve C, N, O, and S atoms. In this section, we will describe how you can use the concept of formal charge to determine the best Lewis formula. Formal charge is also a help in writing the skeleton structure of a molecule.

The **formal charge** of an atom in a Lewis formula is *the hypothetical charge you obtain for an atom by assuming that bonding electrons are equally shared between bonded atoms and that the electrons of each lone pair belong completely to one atom*. ◀ When you use the Lewis formula that most clearly describes the bonding, the formal charges give you an approximate distribution of electrons in the molecule. Let us see how you would obtain the formal charges, given several possible Lewis formulas of a molecule, and how you would use these formal charges to determine the best Lewis formula.

You begin by writing the possible Lewis formulas. For  $\text{COCl}_2$ , you can write

For each formula, you apply the following *rules for formal charge* to assign the valence electrons to individual atoms:

1. Half of the electrons of a bond are assigned to each atom in the bond (counting each dash as two electrons).
2. Both electrons of a lone pair are assigned to the atom to which the lone pair belongs.

You calculate the formal charge on an atom by taking the number of valence electrons on the free atom (equal to the group number) and subtracting the number of electrons you assigned the atom by the rules of formal charge; that is,

$$\text{Formal charge} = \text{valence electrons on free atom} - \frac{1}{2} (\text{number of electrons in a bond}) - (\text{number of lone-pair electrons})$$

As a check on your work, you should note that the sum of the formal charges equals the charge on the molecular species (zero for a neutral molecule).

Consider a Cl atom in the first Lewis formula we wrote for  $\text{COCl}_2$ . You begin by counting the electrons assigned to the Cl atom by the rules of formal charge. You have 1 electron from the single bond and 6 from the lone-pair electrons, for a total of 7. The formal charge of Cl equals the number of valence electrons (7) less the number

The rules for computing oxidation number are similar, except that both bonding electrons are assigned to the more electronegative atom.

of assigned electrons (7). This gives a formal charge of 0 for the Cl atom. Similar calculations of formal charge give 0 for each of the other atoms in the Lewis formula.

Now look at the second Lewis formula we wrote for  $\text{COCl}_2$  and assign the electrons by the rules for formal charge. For the Cl atom having the double bond, you count 2 electrons from the double bond and 4 from the lone pairs, for a total of 6. The formal charge of the Cl atom is  $7 - 6 = +1$ . For the O atom, you count 1 electron from the single bond and 6 from the lone-pair electrons, for a total of 7. The number of valence electrons on the free O atom is 6, so the formal charge of the O atom is  $6 - 7 = -1$ . The formal charge of each of the other atoms is 0.

We indicate the formal charges in a Lewis formula by inserting circled numbers near the atoms (writing + for +1 and - for -1). For the formulas given earlier for  $\text{COCl}_2$ , the formal charges are shown as follows:

Now we can discuss three rules that are useful in deciding which of several resonance formulas best approximates the electron distribution of a molecule or ion.

**RULE A** Whenever you can write several Lewis formulas for a molecule, choose the one having the lowest magnitudes of formal charges.

**RULE B** When two proposed Lewis formulas for a molecule have the same magnitudes of formal charges, choose the one having the negative formal charge on the more electronegative atom.

**RULE C** When possible, choose Lewis formulas that do not have like charges on adjacent atoms.

The second and third formulas for  $\text{COCl}_2$  have formal charges on the Cl and O atoms. The first formula, however, has zero formal charges for all atoms. So by Rule A, this formula most closely approximates the actual electron distribution. You would write it as the best description by a single Lewis formula. (To be more precise, you could consider a resonance description involving all three Lewis formulas. However, the Lewis formulas would not participate equally in the resonance description; the first one would predominate.)

You can also use formal charges to help you choose the most likely skeleton structure from several possibilities. Consider thionyl chloride,  $\text{SOCl}_2$ . Which of the following Lewis formulas is most plausible? Note that these Lewis formulas have quite different atomic arrangements, so they should not be considered as simply different resonance formulas of the same molecule.

You can verify these formal charges using the method we have outlined here. The last formula has a +2 formal charge on the Cl atom, which is larger in magnitude than the formal charges on any atoms in the other two formulas. Therefore, using Rule A, you would not consider the last formula a plausible structure. To choose between the first and second structures, you apply Rule B. According to this rule, you would choose the first structure over the second, because the first one associates a negative formal charge with the more electronegative atom (O), whereas the second structure associates a positive charge with the more electronegative atom. Note that this application of formal charge gives the same result that you would obtain by assuming that the least electronegative atom is the central atom.

So one possible Lewis formula for thionyl chloride, SOCl<sub>2</sub>, is

Now that you have one Lewis formula with the appropriate skeleton structure for SOCl<sub>2</sub>, you should explore the possibility of other Lewis formulas with this skeleton structure. You can write a Lewis formula that has a sulfur–oxygen double bond. This formula has formal charges of zero for each atom; so according to Rule A, it should be closer to the actual electron distribution than the formula having nonzero formal charges.

### Example 9.11 Using Formal Charges to Determine the Best Lewis Formula

#### Gaining Mastery Toolbox

##### Critical Concept 9.11

Given several resonance formulas for a molecule, decide the most important contributor by applying one or more of the following rules: (a) choose the formula with the lowest magnitudes of formal charges, (b) choose the formula with a negative formal charge on the more electronegative atom, and (c) when possible, choose the formula not having like charges on adjacent atoms.

##### Solution Essentials:

- Formal charge
- Resonance
- Skeleton structure of a molecule
- Lewis representation of multiple bonds
- Octet rule
- Number of valence electrons in a main-group atom

Write the Lewis formula that best describes the charge distribution in the sulfuric acid molecule, H<sub>2</sub>SO<sub>4</sub>, according to the rules of formal charge.

**Problem Strategy** Draw the skeleton structure of the molecule or ion, and then follow the steps for writing electron-dot formulas. Note that you can move electron pairs into bonding regions to obtain additional formulas (having multiple bonds). The formal charge of an atom in a formula equals the group number of the atom minus the number of electrons assigned to the atom by the rules of formal charge (half of the electrons of connecting bonds plus all of the lone-pair electrons on the atom). Apply Rules A, B, and C given before this example to decide which Lewis formula is best.

**Solution** Assume a skeleton structure in which the S atom is surrounded by the more electronegative O atoms; the H atoms are then attached to two of the O atoms. The following is a possible Lewis formula having single bonds:

You calculate the formal charge of each O atom bonded to an H atom as follows: You assign the O atom 2 electrons from the two single bonds and 4 electrons from the two lone pairs, for a total of 6 electrons. Because the number of valence electrons on the O atom is 6, the formal charge is 6 – 6 = 0. For each of the other two O atoms, you assign 1 electron from the one single bond and 6 electrons from the three lone pairs, for a total of 7. The formal charge is 6 – 7 = –1. For the S atom, you assign 4 electrons from the four single bonds, for a total of 4. Because the number of valence electrons is 6, the formal charge is 6 – 4 = +2. The formal charge of each of the H atoms is 1 – 1 = 0. The Lewis formula with formal charges is

(continued)

**Example 9.11** (continued)

You can also write a Lewis formula that has zero formal charges for atoms, if you form sulfur–oxygen double bonds:

To the top O atom, you assign 2 electrons from the double bond and 4 electrons from the two lone pairs, for a total of 6 electrons. The formal charge is  $6 - 6 = 0$ . To the S atom, you assign a total of 6 electrons from bonds. The formal charge is  $6 - 6 = 0$ . The formal charges of the other atoms are also 0. Thus, this Lewis formula should be a better representation of the electron distribution in the  $\text{H}_2\text{SO}_4$  molecule.

**Answer Check** The sum of the formal charges in any formula should equal the charge on the species, which is zero for a neutral molecule.

**Exercise 9.15** Write the Lewis formula that best describes the phosphoric acid molecule,  $\text{H}_3\text{PO}_4$ .

See Problems 9.77 and 9.78

**CONCEPT CHECK 9.3**

Which of the models shown below most accurately represents the hydrogen cyanide molecule, HCN? Write the electron-dot formula that most closely agrees with this model. State any concept or rule you used in arriving at your answer.

**9.10 Bond Length and Bond Order**

**Bond length** (or **bond distance**) is the distance between the nuclei in a bond. Bond lengths are determined experimentally using X-ray diffraction or the analysis of molecular spectra. Knowing the bond length in a particular molecule can sometimes provide a clue to the type of bonding present.

Bond lengths for a given bonding situation can often be predicted within a few picometers from a set of covalent radii. The **covalent radius** of an atom is the value for that atom in a set of covalent radii assigned to atoms in such a way that the sum of the covalent radii of atoms *A* and *B* predicts the approximate *A*–*B* bond length. A number of different sets of covalent radii have been derived for various bonding situations. Those given in Table 9.4 were obtained by a statistical analysis of known *single bond* lengths. To illustrate how we might use this table, let's suppose we would like to have an approximate C–Cl single bond length. Looking at Table 9.4, we see that the C and Cl covalent radii are 76 pm and 102 pm, respectively. The sum of these two radii ( $76 + 102 \text{ pm} = 178 \text{ pm}$ ) gives us an approximate value for the C–Cl single bond length. Here are actual C–Cl bond lengths in several compounds:

chloromethane,  $\text{CH}_3\text{Cl}$ , 178.4 pm;

tetrachloromethane,  $\text{CCl}_4$ , 176.6 pm;

hexachloroethane,  $\text{CCl}_3\text{CCl}_3$ , 174 pm.

The value predicted from Table 9.4 compares favorably with these known bond lengths.

Table 9.4 Single-Bond Covalent Radii

Atomic Number	Symbol	Name	Covalent Radius (pm)	Atomic Number	Symbol	Name	Covalent Radius (pm)
1	H	Hydrogen	31	44	Ru	Ruthenium	146
2	He	Helium	28	45	Rh	Rhodium	142
3	Li	Lithium	128	46	Pd	Palladium	139
4	Be	Beryllium	96	47	Ag	Silver	145
5	B	Boron	84	48	Cd	Cadmium	144
6	C	Carbon	76	49	In	Indium	142

Covalent radii are one type of atomic radii (recall the discussion in Section 8.6), and as such, the values for any given set of radii should follow the two major periodic trends for atomic radii:

1. Within a period, the covalent radius tends to decrease with increasing atomic number.
2. Within a group, the covalent radius tends to increase with period number.

Note that the radii in Table 9.4 do follow these trends rather well.

	<b>Exercise 9.16</b> Estimate the O—H bond length in H <sub>2</sub> O from the covalent radii listed in Table 9.4.	See Problems 9.79, 9.80, 9.81, and 9.82.
--	--	--

The **bond order**, defined in terms of the Lewis formula, is *the number of pairs of electrons in a bond*. For example, in C : C the bond order is 1 (single bond); in C : : C the bond order is 2 (double bond). Bond length depends on bond order. As the bond order increases, the bond strength increases and the nuclei are pulled inward, decreasing the bond length. Look at carbon–carbon bonds. The average C—C bond length is 154 pm, whereas C=C is 134 pm long and C≡C is 120 pm long. ▶

Although a double bond is stronger than a single bond, it is not necessarily less reactive. Ethylene, CH<sub>2</sub>=CH<sub>2</sub>, for example, is more reactive than ethane, CH<sub>3</sub>—CH<sub>3</sub>, where carbon atoms are linked through a single bond. ▶

### Example 9.12 Relating Bond Order and Bond Length

#### Gaining Mastery Toolbox

##### Critical Concept 9.12

As the bond order between two atoms increases, the bond length decreases.

##### Solution Essentials:

- Bond order
- Bond length

Consider the molecules N<sub>2</sub>H<sub>4</sub>, N<sub>2</sub>, and N<sub>2</sub>F<sub>2</sub>. Which molecule has the shortest nitrogen–nitrogen bond? Which has the longest nitrogen–nitrogen bond?

**Problem Strategy** First, write the electron-dot formulas for the molecules. Then note that the length of a bond between atoms decreases with bond order.

**Solution** First write the Lewis formulas:

**The nitrogen–nitrogen bond should be shortest in N<sub>2</sub>, where it is a triple bond, and longest in N<sub>2</sub>H<sub>4</sub>, where it is a single bond.** (Experimental values for the nitrogen–nitrogen bond lengths are 109 pm for N<sub>2</sub>, 122 pm for N<sub>2</sub>F<sub>2</sub>, and 147 pm for N<sub>2</sub>H<sub>4</sub>.)

**Answer Check** Check that you have written the electron-dot formulas correctly.

**Exercise 9.17** Formic acid, isolated in 1670, is the irritant in ant bites. The structure of formic acid is

One of the carbon–oxygen bonds has a length of 136 pm; the other is 123 pm long. What is the length of the C=O bond in formic acid?

See Problems 9.83 and 9.84.

## 9.11 Bond Enthalpy

In Section 9.4, when we described the formation of a covalent bond, we introduced the concept of bond dissociation energy, the energy required to break a particular bond in a molecule (see Figure 9.11). This bond dissociation energy is one measure of the strength of a bond. In this section, we want to look at a related idea, the *bond enthalpy*, which we can use as a measure of the average strength of a bond in its compounds. Bond enthalpies are often obtained from enthalpies of reaction,  $\Delta H$ , so the

term “bond enthalpies” is appropriate, but you will often see the term *bond energies* used for the same values. As a practical matter, the approximations made in arriving at average bond values tend to obscure the small differences between enthalpy changes and energy changes for bonds (which are small). So, for that reason, the terms “bond enthalpy” and “bond energy” are often used interchangeably. We will, however, continue to use the term bond enthalpy.

Let’s explore the possibility of assigning a value for the enthalpy change involved in breaking a particular type of bond, whatever the compound. Consider the experimentally determined enthalpy changes for the breaking, or dissociation, of a C–H bond in methane, CH<sub>4</sub>, and in ethane, C<sub>2</sub>H<sub>6</sub>, in the gas phase:

Note that the  $\Delta H$  values are approximately the same in the two cases. This suggests that the enthalpy change for the dissociation of a C–H bond may be about the same in other molecules. Comparisons of this sort lead to the conclusion that we can obtain approximate values of the enthalpy changes for given bond types.

We define the **A–B bond enthalpy** (denoted *BE*) as *the average enthalpy change for the breaking of an A–B bond in a molecule in the gas phase*. For example, to calculate a value for the C–H bond enthalpy, or *BE*(C–H), we might look at the experimentally determined enthalpy change for the breaking of all the C–H bonds in methane:

Because four C–H bonds are broken, we obtain an average value for breaking one C–H bond by dividing the enthalpy change for the reaction by 4:

$$BE(\text{C}-\text{H}) = \frac{1}{4} \times 1662 \text{ kJ} = 416 \text{ kJ}$$

Similar calculations with other molecules, such as ethane, would yield approximately the same values for the C–H bond enthalpy.

Table 9.5 lists values of some bond enthalpies, which are based on an approximate fit to known thermodynamic data. Note that the value given in this table for the C–H bond is 413 kJ/mol, which is in fair agreement with the value we just obtained (416 kJ/mol). Because it takes energy to break a bond, bond enthalpies are always positive numbers. When a bond is formed, the enthalpy change is equal to the negative of the bond enthalpy (heat is released).

Bond enthalpy is a measure of the strength of a bond: the larger the bond enthalpy, the stronger the chemical bond. Note from Table 9.5 that the bonds C–C, C=C, and C≡C have bond enthalpies of 348, 614, and 839 kJ/mol, respectively. These numbers indicate that the triple bond is stronger than the double bond, which in turn is stronger than the single bond.

You can use this table of bond enthalpies to estimate heats of reaction, or enthalpy changes,  $\Delta H$ , for gaseous reactions. To illustrate this, let’s find  $\Delta H$  for the following reaction (Figure 9.21):

**Figure 9.21** ▶

**Reaction of methane with chlorine** Molecular models illustrate the reaction  $\text{CH}_4 + \text{Cl}_2 \longrightarrow \text{CH}_3\text{Cl} + \text{HCl}$ .

Table 9.5 Bond Enthalpies (in kJ/mol)*									
Single Bonds									
	H	C	N	O	S	F	Cl	Br	I
H	436								
C	413	348							
N	391	393	163

Multiple Bonds									
C=C	614		C=N	615		C=O	804 (in CO <sub>2</sub> )		
C≡C	839		C≡N	891		C≡O	1076		
N=N	418		N=O	607		S=O	323		
N≡N	945		O=O	498		S=S	418		

\*Data are taken from [http://wiki.chemeddl.org/index.php/15.4\\_Bond\\_Enthalpies](http://wiki.chemeddl.org/index.php/15.4_Bond_Enthalpies).

You can *imagine* that the reaction takes place in steps involving the breaking and forming of bonds. Starting with the reactants, you suppose that one C—H bond and the Cl—Cl bond break.

The enthalpy change is  $BE(\text{C}-\text{H}) + BE(\text{Cl}-\text{Cl})$ . Now you reassemble the fragments to give the products.

In this case, C—Cl and H—Cl bonds are formed, and the enthalpy change equals the negative of the bond enthalpies:  $-BE(\text{C}-\text{Cl}) - BE(\text{H}-\text{Cl})$ . Substituting bond-enthalpy values from Table 9.5, you get the enthalpy of reaction.

$$\begin{aligned} \Delta H &\approx BE(\text{C}-\text{H}) + BE(\text{Cl}-\text{Cl}) - BE(\text{C}-\text{Cl}) - BE(\text{H}-\text{Cl}) \\ &= (413 + 242 - 328 - 431) \text{ kJ} \\ &= -104 \text{ kJ} \end{aligned}$$

The negative sign means that heat is released by the reaction. Because the bond-enthalpy concept is only approximate, this value is only approximate (the experimental value is  $-101 \text{ kJ}$ ).

In general, the enthalpy of reaction is (approximately) equal to the sum of the bond enthalpies for bonds broken minus the sum of the bond enthalpies for bonds formed.

Rather than calculating a heat of reaction from bond enthalpies, you usually obtain the heat of reaction from thermochemical data, because these are generally

Figure 9.22 ▲

**Explosion of nitrogen triiodide–ammonia complex** The red-brown complex of nitrogen triiodide and ammonia is so sensitive to explosion that it can be detonated with a feather. Nitrogen–iodine single bonds are replaced by very stable nitrogen–nitrogen triple bonds ( $N_2$ ) and iodine–iodine single bonds ( $I_2$ ).

known more accurately. If the thermochemical data are not known, however, bond enthalpies can give you a reasonable estimate of the heat of reaction.

Bond enthalpies are perhaps of greatest value when you try to explain heats of reaction or to understand the relative stabilities of compounds. In general, a reaction is exothermic (gives off heat) if weak bonds are replaced by strong bonds (see Figure 9.22). In the reaction we just discussed, two bonds were broken and replaced by two new, stronger bonds. In the following example, a strong bond ( $C=C$ ) is replaced by two weaker ones (two  $C-C$  bonds). Although the single bond is weaker than the double bond, as you would expect, two  $C-C$  bonds *together* create an energetically more stable situation than one  $C=C$  bond.

### Example 9.13 Estimating $\Delta H$ from Bond Enthalpies

#### Gaining Mastery Toolbox

##### Critical Concept 9.13

The enthalpy of a reaction equals approximately the sum of the bond enthalpies for bonds broken minus the sum of bond enthalpies formed.

##### Solution Essentials:

- Bond enthalpy
- Enthalpy of reaction

Polyethylene is formed by linking many ethylene molecules into long chains. Estimate the enthalpy change per mole of ethylene for this reaction (shown below), using bond enthalpies.

**Problem Strategy** Break bonds in the reactants, and then form new bonds to give the products. The approximate enthalpy change equals the sum of the bond enthalpies for the bonds broken minus the sum of the bond enthalpies for the bonds formed.

**Solution** Imagine the reaction to involve the breaking of the carbon–carbon double bonds and the formation of carbon–carbon single bonds. For a very long chain, the net result is that for every  $C=C$  bond broken, two  $C-C$  bonds are formed.

$$\Delta H \approx 614 - (2 \times 348) = -82 \text{ kJ}$$

**Answer Check** Note whether the sign of  $\Delta H$  agrees with what you would expect. Perhaps weak bonds have been replaced by strong bonds, in which case  $\Delta H$  should be negative. Here, every double bond is replaced by two single bonds, so  $\Delta H$  should be negative, as it is.

**Exercise 9.18** Use bond enthalpies to estimate the enthalpy change for the combustion of ethylene,  $C_2H_4$ , according to the equation

See Problems 9.85 and 9.86.

## Instrumental Methods

# Infrared Spectroscopy and Vibrations of Chemical Bonds

A chemical bond acts like a stiff spring connecting nuclei. As a result, the nuclei in a molecule vibrate, rather than maintaining fixed positions relative to each other. Nuclear vibration is depicted in Figure 9.23, which shows a spring model of HCl.

This vibration of molecules is revealed in their absorption of infrared radiation. (An instrument for observing the absorption of infrared radiation is shown in Figure 9.24.) The frequency of radiation absorbed equals the frequencies of nuclear vibrations. For example, the H—Cl bond vibrates at a frequency of  $8.652 \times 10^{13}$  vibrations per second. If radiation of this frequency falls on the molecule, it absorbs the radiation, which is in the infrared region, and begins vibrating more strongly.

The infrared absorption spectrum of a molecule of even moderate size can have a rather complicated appearance. Figure 9.25 shows the infrared (IR) spectrum of ethyl butyrate, a compound present in pineapple flavor. The complicated appearance of the IR spectrum is actually an advantage. Two different compounds are unlikely to have exactly the same IR spectrum. Therefore, the IR spectrum can act as a compound's "fingerprint."

The IR spectrum of a compound can also yield structural information. Suppose you would like to obtain the structural formula of ethyl butyrate. The molecular formula, determined from combustion analysis, is  $C_6H_{12}O_2$ . Important information about this structure can be obtained from Figure 9.25.

You first need to be able to read such a spectrum. Instead of plotting an IR spectrum in frequency units (since the frequencies are very large), you usually would give the frequencies in *wavenumbers*, which are proportional to frequency. To get the wavenumber, you divide

**Figure 9.23** ▲

**Vibration of the HCl molecule** The vibrating molecule is represented here by a spring model. The atoms in the molecule vibrate; that is, they move constantly back and forth.

Courtesy of ThermoFischer

**Figure 9.24** ▲

**A Fourier transform infrared (FTIR) spectrometer** A Fourier transform instrument collects data over a broad range simultaneously, using Fourier transform mathematics to obtain an infrared spectrum. The instrument shown is a Nicolet iS 50 FT-IR Spectrometer.

the frequency by the speed of light expressed in centimeters per second. For example, HCl absorbs at  $(8.652 \times 10^{13} \text{ s}^{-1}) / (2.998 \times 10^{10} \text{ cm/s}) = 2886 \text{ cm}^{-1}$  (wavenumbers). Wavenumber, or sometimes wavelength, is plotted along the horizontal axis.

*Percent transmittance*—that is, the percent of radiation that passes through a sample—is plotted on the vertical axis. When a molecule absorbs radiation of a given frequency or wavenumber, this is seen in the spectrum as an inverted spike (peak) at that wavenumber. Certain structural features of molecules appear as absorption peaks in definite regions of the infrared spectrum. For example, the absorption peak at  $1730 \text{ cm}^{-1}$  is characteristic of the C=O bond. With some knowledge of where various bonds absorb, one can identify other peaks, including that of C—O at  $1180 \text{ cm}^{-1}$ . (Generally, the IR peak for an A—B bond occurs at lower wavenumber than for an A=B bond.) The IR spectrum does not reveal the complete structure, but it provides important clues. Data from other instruments, such as the mass spectrometer (page 100), give additional clues.

(continued)

## Instrumental Methods Infrared Spectroscopy and Vibrations of Chemical Bonds *(continued)*

Figure 9.25 ▲

**Infrared spectrum of ethyl butyrate (gas phase)** Note the peaks corresponding to vibrations of C=O and C—O bonds. The molecular structure is shown at the bottom left. ## ✓ A Checklist for Review

### Summary of Facts and Concepts

An *ionic bond* is a strong attractive force holding ions together. An ionic bond can form between two atoms by the transfer of electrons from the valence shell of one atom to the valence shell of the other. Many similar ions attract one another to form a crystalline solid, in which positive ions are surrounded by negative ions and negative ions are surrounded by positive ions. As a result, ionic solids are typically high-melting solids. Monatomic cations of the main-group elements have charges equal to the group number (or in some cases, the group number minus two). Monatomic anions of the main-group elements have charges equal to the group number minus eight.

A *covalent bond* is a strong attractive force that holds two atoms together by their sharing of electrons. These bonding electrons are attracted simultaneously to both atomic nuclei, and they spend part of the time near one

atom and part of the time near the other. If an electron pair is not equally shared, the bond is *polar*. This polarity results from the difference in *electronegativities* of the atoms—that is, from the unequal abilities of the atoms to draw bonding electrons to themselves.

*Lewis electron-dot formulas* are simple representations of the valence-shell electrons of atoms in molecules and ions. You can apply simple rules to draw these formulas. In molecules with *delocalized bonding*, it is not possible to describe accurately the electron distribution with a single Lewis formula. For these molecules, you must use *resonance*. Although the atoms in Lewis formulas often satisfy the octet rule, *exceptions to the octet rule* are not uncommon. You can obtain the Lewis formulas for these exceptions by following the rules for writing Lewis formulas. The concept of *formal charge* will often help you decide which

of several Lewis formulas gives the best description of a molecule or ion.

*Bond lengths* can be estimated from the *covalent radii* of atoms. Bond length depends on *bond order*; as the bond

order increases, the bond length decreases. The *A—B bond enthalpy* is the average enthalpy change when an A—B bond is broken. You can use bond enthalpies to estimate  $\Delta H$  for gas-phase reactions.

## Learning Objectives

## Important Terms

### 9.1 Describing Ionic Bonds

- Define *ionic bond*.
- Explain the *Lewis electron-dot symbol* of an atom.
- Use Lewis symbols to represent ionic bond formation. **Example 9.1**
- Describe the energetics of ionic bonding.
- Define *lattice energy*.
- Describe the Born–Haber cycle to obtain a lattice energy from thermodynamic data.
- Describe some general properties of ionic substances.

**ionic bond**  
**Lewis electron-dot symbol**  
**Coulomb's law**  
**lattice energy**

### 9.2 Electron Configurations of Ions

- State the three categories of monatomic ions of the main-group elements.
- Write the electron configuration and Lewis symbol for a main-group ion. **Example 9.2**
- Note the polyatomic ions given earlier in Table 2.5.
- Note the formation of 2+ and 3+ transition-metal ions.
- Write electron configurations of transition-metal ions. **Example 9.3**

### 9.3 Ionic Radii

- Define *ionic radius*.
- Define *isoelectronic ions*.
- Use periodic trends to obtain relative ionic radii. **Example 9.4**

**ionic radius**  
**isoelectronic**

### 9.4 Describing Covalent Bonds

- Describe the formation of a covalent bond between two atoms.
- Define *Lewis electron-dot formula*.
- Define *bonding pair* and *lone (nonbonding) pair* of electrons.
- Define *coordinate covalent bond*.
- State the octet rule.
- Define *single bond*, *double bond*, and *triple bond*.

**covalent bond**  
**Lewis electron-dot formula**  
**bonding pair**  
**lone (nonbonding) pair**  
**coordinate covalent bond**  
**octet rule**  
**single bond**  
**double bond**  
**triple bond**

### 9.5 Polar Covalent Bonds; Electronegativity

- Define *polar covalent bond*.
- Define *electronegativity*.
- State the general periodic trends in electronegativities.
- Use electronegativity to obtain relative bond polarity. **Example 9.5**

**polar covalent bond**  
**electronegativity**

### 9.6 Writing Lewis Electron-Dot Formulas

- Write Lewis formulas with single bonds only. **Example 9.6**
- Write Lewis formulas having multiple bonds. **Example 9.7**
- Write Lewis formulas for ionic species. **Example 9.8**

<b>9.7 Delocalized Bonding; Resonance</b>	
<ul style="list-style-type: none"> <li>Define <i>delocalized bonding</i>.</li> <li>Define <i>resonance description</i>.</li> <li>Write resonance formulas. <b>Example 9.9</b></li> </ul>	<b>delocalized bonding</b> <b>resonance description</b>

## Questions and Problems

### Self-Assessment and Review Questions

**Key:** These questions test your understanding of the ideas you worked with in the chapter. These problems vary in difficulty and often can be used for the basis of discussion.

**9.1** Describe the formation of a sodium chloride crystal from atoms.

**9.2** Why does sodium chloride normally exist as a crystal rather than as a molecule composed of one cation and one anion?

**9.3** Explain what energy terms are involved in the formation of an ionic solid from atoms. In what way should these terms change (become larger or smaller) to give the lowest energy possible for the solid?

**9.4** Define lattice energy for potassium bromide.

**9.5** Why do most monatomic cations of the main-group elements have a charge equal to the group number? Why do most monatomic anions of these elements have a charge equal to the group number minus eight?

**9.6** The  $2+$  ions of transition elements are common. Explain why this might be expected.

**9.7** Explain how ionic radii are obtained from known distances between nuclei in crystals.

**9.8** Describe the trends shown by the radii of the monatomic ions for the main-group elements both across a period and down a column.

**9.9** Describe the formation of a covalent bond in  $H_2$  from atoms. What does it mean to say that the bonding electrons are shared by the two atoms?

**9.10** Draw a potential-energy diagram for a molecule such as  $Cl_2$ . Indicate the bond length (194 pm) and the bond dissociation energy (240 kJ/mol).

**9.11** Give an example of a molecule that has a coordinate covalent bond.

**9.12** The octet rule correctly predicts the Lewis formula of many molecules involving main-group elements. Explain why this is so.

**9.13** Describe the general trends in electronegativities of the elements in the periodic table both across a period and down a column.

**9.14** What is the qualitative relationship between bond polarity and electronegativity difference?

**9.15** What is a resonance description of a molecule? Why is this concept required if we wish to retain Lewis formulas as a description of the electron structure of molecules?

**9.16** Describe the kinds of exceptions to the octet rule that we encounter in compounds of the main-group elements. Give examples.

**9.17** What is the relationship between bond order and bond length? Use an example to illustrate it.

9.18 Define bond enthalpy. Explain how one can use bond enthalpies to estimate the heat of reaction.

9.19 Which of the following contains *both* ionic and covalent bonds in the same compound?

- a  $\text{CO}_3^{2-}$       b  $\text{BaSO}_3$   
 c SrO            d HI  
 e MgS

9.20 The radii of the species S,  $\text{S}^+$ , and  $\text{S}^-$  decrease in the following order:

- a  $\text{S}^+ > \text{S} > \text{S}^-$       b  $\text{S}^+ > \text{S} > \text{S}^-$   
 c  $\text{S} > \text{S}^- > \text{S}^+$       d  $\text{S} > \text{S}^+ > \text{S}^-$   
 e  $\text{S}^- > \text{S} > \text{S}^+$

9.21 Which of the following is the ground-state electron configuration of a  $\text{C}^{3-}$  ion?

- a  $1s^2 2s^2 2p^4$       b  $[\text{He}] 2s^2 2p^6$   
 c  $[\text{He}] 2s^1$         d  $1s^2 2s^2 2p^5$   
 e  $1s^2 2s^2 2p^6 3s^1$

9.22 The element X below could be

- a sulfur  
 b iodine  
 c aluminum  
 d phosphorus  
 e silicon

## Concept Explorations

**Key:** Concept explorations are comprehensive problems that provide a framework that will enable you to explore and learn many of the critical concepts and ideas in each chapter. If you master the concepts associated with these explorations, you will have a better understanding of many important chemistry ideas and will be more successful in solving all types of chemistry problems. These problems are well suited for group work and for use as in-class activities.

### 9.23 Forming Ionic Compounds

- a Consider a metal atom, which we will give the symbol M. Metal M can readily form the  $\text{M}^+$  cation. If the sphere on the left below represents the metal atom M, which of the other three spheres would probably represent the  $\text{M}^+$  cation? Explain your choice.

- b Consider a nonmetal atom, which we will give the symbol X. The element X is a gas at room temperature and can easily form the  $\text{X}^-$  anion. If atom X is represented by the sphere on the left below, which of the other three spheres would probably represent the  $\text{X}^-$  anion. Explain your choice.

- c On the basis of the information given previously, write a balanced chemical equation for the reaction that occurs when metal M reacts with nonmetal X. Include state symbols for the reactants and products.
- d Is the product of the reaction of M and X a molecule or an ionic compound? Provide justification for your answer.
- e Which of the representations below is the most appropriate to describe the compound of M and X, according to your answer for Part d? Explain how you arrived at your choice.

### 9.24 Bond Enthalpy

When atoms of the hypothetical element X are placed together, they rapidly undergo reaction to form the  $\text{X}_2$  molecule:

- a Would you predict that this reaction is exothermic or endothermic? Explain.
- b Is the bond enthalpy of  $\text{X}_2$  a positive or a negative quantity? Why?
- c Suppose  $\Delta H$  for the reaction is  $-500 \text{ kJ/mol}$ . Estimate the bond enthalpy of the  $\text{X}_2$  molecule.
- d Another hypothetical molecular compound,  $\text{Y}_2(g)$ , has a bond enthalpy of  $750 \text{ kJ/mol}$ , and the molecular compound  $\text{XY}(g)$  has a bond enthalpy of  $1500 \text{ kJ/mol}$ . Using bond enthalpy information, calculate  $\Delta H$  for the following reaction.

- e Given the following information, as well as the information previously presented, predict whether or not the hypothetical ionic compound AX is likely to form. In this compound, A forms the  $\text{A}^+$  cation, and X forms the  $\text{X}^-$  anion. Be sure to justify your answer.  
 Reaction:  $\text{A}(g) + \frac{1}{2}\text{X}_2(g) \longrightarrow \text{AX}(s)$   
 The first ionization energy of  $\text{A}(g)$  is  $400 \text{ kJ/mol}$ .  
 The electron affinity of  $\text{X}(g)$  is  $525 \text{ kJ/mol}$ .  
 The lattice energy of  $\text{AX}(s)$  is  $100 \text{ kJ/mol}$ .
- f If you predicted that no ionic compound would form from the reaction in Part e, what minimum amount of  $\text{AX}(s)$  lattice energy might lead to compound formation?

## Conceptual Problems

**Key:** These problems are designed to check your understanding of the concepts associated with some of the main topics presented in each chapter. A strong conceptual understanding of chemistry is the foundation for both applying chemical knowledge and solving chemical problems. These problems vary in level of difficulty and often can be used as a basis for group discussion.

**9.25** You land on a distant planet in another universe and find that the  $n = 1$  level can hold a maximum of 4 electrons, the  $n = 2$  level can hold a maximum of 5 electrons, and the  $n = 3$  level can hold a maximum of 3 electrons. Like our universe, protons have a charge of  $+1$ , electrons have a charge of  $-1$ , and opposite charges attract. Also, a filled shell results in greater stability of an atom, so the atom tends to gain or lose electrons to give a filled shell. Predict the formula of a compound that results from the reaction of a neutral metal atom X, which has 7 electrons, and a neutral nonmetal atom Y, which has 3 electrons.

**9.26** Which of the following represent configurations of indium ions in compounds? Explain your decision in each case.

- a**  $\text{In}^{4+} [\text{Kr}]4d^9$       **b**  $\text{In}^+ [\text{Kr}]4d^{10}5s^2$   
**c**  $\text{In}^{3+} [\text{Kr}]4d^{10}$       **d**  $\text{In} [\text{Kr}]4d^{10}5s^1$

**9.27** Below on the left side are models of two atoms, one from a metal, the other from a nonmetal. On the right side are corresponding monatomic ions of those atoms. Decide which of these ions is the cation and which is the anion. Label atoms as “metal” or “nonmetal,” as appropriate.

**9.28** Predict a possible monatomic ion for Element 117, Uus. Given the spherical models below, which should be labeled “atom” and which should be labeled “ion”?

**9.29** Examine each of the following electron-dot formulas and decide whether the formula is correct, or whether you could write a formula that better approximates the electron structure of the molecule. State which concepts or rules you use in each case to arrive at your conclusion.

**9.30** For each of the following molecular models, write an appropriate Lewis formula.

**9.31** For each of the following molecular formulas, draw the most reasonable skeleton structure.

- a**  $\text{CH}_2\text{Cl}_2$     **b**  $\text{HNO}_2$     **c**  $\text{NOF}$     **d**  $\text{N}_2\text{O}_4$

What rule or concept did you use to obtain each structure?

**9.32** Below are three resonance formulas for  $\text{N}_2\text{O}$  (nitrous oxide). Rank these in terms of how closely you think each one represents the true electron structure of the molecule. State the rules and concepts you use to do this ranking.

**9.33** Lithium, Li, reacts with element X to form an ionic compound with the formula  $\text{Li}_2\text{X}$ .

- a** What is the formula of the compound you expect to form when aluminum, Al, reacts with element X?  
**b** Would you expect this compound to be ionic or molecular?

**9.34** The enthalpy change for each of the following reactions was calculated using bond enthalpies. The bond enthalpies of  $\text{X}-\text{O}$ ,  $\text{Y}-\text{O}$ , and  $\text{Z}-\text{O}$  are all equal.

- a** Rank the bonds  $\text{X}-\text{X}$ ,  $\text{Y}-\text{Y}$ , and  $\text{Z}-\text{Z}$  from strongest to weakest.  
**b** Compare the enthalpies required to completely dissociate each of the products to atoms.  
**c** If  $\text{O}_2$  molecules were  $\text{O}-\text{O}$  instead of  $\text{O}=\text{O}$ , how would this change  $\Delta H$  for each reaction?

## Practice Problems

**Key:** These problems are for practice in applying problem-solving skills. They are divided by topic, and some are keyed to exercises (see the ends of the exercises). The problems are arranged in matching pairs; the odd-numbered problem of each pair is listed first, and its answer is given in the back of the book.

### Ionic Bonding

**9.35** Write Lewis symbols for the following:

- a** Br    **b**  $\text{Br}^-$     **c** Ga    **d**  $\text{Ga}^{3+}$

**9.36** Write Lewis symbols for the following:

- a** O    **b**  $\text{O}^{2-}$     **c** Ca    **d**  $\text{Ca}^{2+}$

**9.37** Use Lewis symbols to represent the transfer of electrons between the following atoms to form ions with noble-gas configurations:

- a** Ca and Br      **b** K and I

**9.38** Use Lewis symbols to represent the electron transfer between the following atoms to give ions with noble-gas configurations:

- a** Ba and I      **b** Sr and O

**9.39** For each of the following, write the electron configuration and Lewis symbol:

- a** As    **b**  $\text{As}^{3+}$     **c** Se    **d**  $\text{Se}^{2-}$

**9.40** For each of the following, write the electron configuration and Lewis symbol:

- a** Ge    **b**  $\text{Ge}^{2+}$     **c**  $\text{K}^+$     **d**  $\text{I}^-$

**9.41** Write the electron configurations of Bi and  $\text{Bi}^{3+}$ .

**9.42** Write the electron configurations of Sn and  $\text{Sn}^{2+}$ .

**9.43** Give the electron configurations of  $\text{Ni}^{2+}$  and  $\text{Ni}^{3+}$ .

**9.44** Give the electron configurations of  $\text{Cu}^+$  and  $\text{Cu}^{2+}$ .

### Ionic Radii

**9.45** Arrange the members of each of the following pairs in order of increasing radius and explain the order:

- a** Ca,  $\text{Ca}^{2+}$       **b** P,  $\text{P}^{3-}$

**9.46** Arrange the members of each of the following pairs in order of increasing radius and explain the order:

- a** Te,  $\text{Te}^{2-}$       **b** Al,  $\text{Al}^{3+}$

**9.47** Without looking at Table 9.3, arrange the following in order of increasing ionic radius:  $\text{As}^{3-}$ ,  $\text{Se}^{2-}$ ,  $\text{Br}^-$ . Explain how you arrived at this order. (You may use a periodic table.)

**9.48** Which has the larger radius,  $\text{N}^{3-}$  or  $\text{P}^{3-}$ ? Explain. (You may use a periodic table.)

**9.49** Arrange the following in order of increasing ionic radius:  $\text{F}^-$ ,  $\text{Na}^+$ , and  $\text{N}^{3-}$ . Explain this order. (You may use a periodic table.)

**9.50** Arrange the following in order of increasing ionic radius:  $\text{I}^-$ ,  $\text{Cs}^+$ , and  $\text{Te}^{2+}$ . Explain this order. (You may use a periodic table.)

### Covalent Bonding

**9.51** Use Lewis symbols to show the reaction of atoms to form hydrogen selenide,  $\text{H}_2\text{Se}$ . Indicate bonding pairs and lone pairs in the electron-dot formula of this compound.

**9.52** Use Lewis symbols to show the reaction of atoms to form arsine,  $\text{AsH}_3$ . Indicate which electron pairs in the Lewis formula of  $\text{AsH}_3$  are bonding and which are lone pairs.

**9.53** Assuming that the atoms form the normal number of covalent bonds, give the molecular formula of the simplest compound of arsenic and bromine atoms.

**9.54** Assuming that the atoms form the normal number of covalent bonds, give the molecular formula of the simplest compound of germanium and fluorine atoms.

### Polar Covalent Bonds; Electronegativity

**9.55** Using a periodic table (not Figure 9.15), arrange the following in order of increasing electronegativity:

- a** P, O, N      **b** Na, Al, Mg      **c** C, Al, Si

**9.56** With the aid of a periodic table (not Figure 9.15), arrange the following in order of increasing electronegativity:

- a** Li, Na, Cs      **b** B, Be, Li      **c** S, Se, Cl

**9.57** Arrange the following bonds in order of increasing polarity using electronegativities of atoms: P—O, C—Cl, As—Br.

**9.58** Decide which of the following bonds is least polar on the basis of electronegativities of atoms: Cl—H, S—Si, Br—As.

**9.59** Indicate the partial charges for the bonds given in Problem 9.57, using the symbols  $\delta^+$  and  $\delta^-$ .

**9.60** Indicate the partial charges for the bonds given in Problem 9.58, using the symbols  $\delta^+$  and  $\delta^-$ .

### Writing Lewis Formulas

**9.61** Write Lewis formulas for the following molecules:

- a**  $\text{Br}_2$       **b**  $\text{H}_2\text{S}$       **c**  $\text{NF}_3$

**9.62** Write Lewis formulas for the following molecules:

- a**  $\text{BrF}$       **b**  $\text{PBr}_3$       **c**  $\text{NOF}$

**9.63** Write Lewis formulas for the following molecules:

- a**  $\text{P}_2$       **b**  $\text{COBr}_2$       **c**  $\text{HNO}_2$

**9.64** Write Lewis formulas for the following molecules:

- a**  $\text{CO}$       **b**  $\text{BrCN}$       **c**  $\text{N}_2\text{F}_2$

**9.65** Write Lewis formulas for the following ions:

- a**  $\text{ClO}^-$       **b**  $\text{SnCl}_3^-$       **c**  $\text{S}_2^{2-}$

**9.66** Write Lewis formulas for the following ions:

- a**  $\text{IBr}_2^+$       **b**  $\text{ClF}_2^+$       **c**  $\text{CN}^-$

### Resonance

**9.67** Write resonance descriptions for the following:

- a**  $\text{HNO}_3$       **b**  $\text{SO}_3$

**9.68** Write resonance descriptions for the following:

- a**  $\text{ClNO}_2$       **b**  $\text{NO}_2^-$

**9.69** Use resonance to describe the electron structure of nitromethane,  $\text{CH}_3\text{NO}_2$ . The skeleton structure is

**9.70** Give the resonance description of the formate ion. The skeleton structure is

### Exceptions to the Octet Rule

**9.71** Write Lewis formulas for the following:

- a**  $\text{XeF}_2$       **b**  $\text{SeF}_4$       **c**  $\text{TeF}_6$       **d**  $\text{XeF}_5^+$

9.72 Write Lewis formulas for the following:

- a  $I_3^-$    b  $ClF_3$    c  $IF_4^-$    d  $BrF_5$

9.73 Write Lewis formulas for the following:

- a  $BCl_3$    b  $TiCl_2^+$    c  $BeBr_2$

9.74 Write Lewis formulas for the following:

- a  $BeF_2$    b  $BeF_3^-$    c  $AlBr_3$

### Formal Charge and Lewis Formulas

9.75 Write a Lewis formula for each of the following, assuming that the octet rule holds for the atoms. Then obtain the formal charges of the atoms.

- a  $O_3$    b  $CO$    c  $HNO_3$

9.76 Write a Lewis formula for each of the following, assuming that the octet rule holds for the atoms. Then obtain the formal charges of the atoms.

- a  $CINO$    b  $POCl_3$    c  $N_2O$  (NNO)

9.77 For each of the following, use formal charges to choose the Lewis formula that gives the best description of the electron distribution:

- a  $SOF_2$   
b  $H_2SO_3$   
c  $HClO_2$

9.78 For each of the following, use formal charges to choose the Lewis formula that gives the best description of the electron distribution:

- a  $ClO_2F$   
b  $SO_2$   
c  $ClO_3^-$

### Bond Length, Bond Order, and Bond Enthalpy

9.79 Use covalent radii (Table 9.4) to estimate the length of the P—F bond in phosphorus trifluoride,  $PF_3$ .

9.80 What do you expect for the B—Cl bond length in boron trichloride,  $BCl_3$ , on the basis of covalent radii (Table 9.4)?

9.81 Calculate the bond length for each of the following single bonds, using covalent radii (Table 9.4):

- a C—H  
b S—Cl  
c Br—Cl  
d Si—O

9.82 Calculate the C—Cl and C—C bond lengths in ethyl chloride,  $C_2H_5Cl$ , using values for the covalent radii from Table 9.4. How do these values compare with the experimental values: C—Cl, 177; C—C, 155 pm?

9.83 One of the following compounds has a carbon–nitrogen bond length of 116 pm; the other has a carbon–nitrogen bond length of 147 pm. Match a bond length with each compound.

9.84 Which of the following two compounds has the shorter carbon–oxygen bond?

9.85 Use bond enthalpies (Table 9.5) to estimate  $\Delta H$  for the following gas-phase reaction.

This is called an “addition” reaction, because a compound (HBr) is added across the double bond.

9.86 A commercial process for preparing ethanol (ethyl alcohol),  $C_2H_5OH$ , consists of passing ethylene gas,  $C_2H_4$ , and steam over an acid catalyst (to speed up the reaction). The gas-phase reaction is

Use bond enthalpies (Table 9.5) to estimate the enthalpy change for this reaction when 37.0 g of ethyl alcohol is produced.

## General Problems

**Key:** These problems provide more practice but are not divided by topic or keyed to exercises. Each section ends with essay questions, each of which is color coded to refer to the *A Chemist Looks at Frontiers* (purple), *A Chemist Looks at Daily Life* (orange), and *Instrumental Methods* (brown) chapter essay on which it is based. Odd-numbered problems and the even-numbered problems that follow are similar; answers to all odd-numbered problems except the essay questions are given in the back of the book.

9.87 For each of the following pairs of elements, state whether the binary compound formed is likely to be

ionic or covalent. Give the formula and name of the compound.

- a Sr, O   b C, Br   c Ga, F   d N, Br

9.88 For each of the following pairs of elements, state whether the binary compound formed is likely to be ionic or covalent. Give the formula and name of the compound.

- a K, Se   b Al, F   c Ba, Br   d Si, Cl

9.89 Give the Lewis formula for the selenite ion,  $SeO_3^{2-}$ . Write the formula of aluminum selenite.

9.90 Give the Lewis formula for the arsenate ion,  $AsO_4^{3-}$ . Write the formula of lead(II) arsenate.

**9.91** Iodic acid,  $\text{HIO}_3$ , is a colorless, crystalline compound. What is the electron-dot formula of iodic acid?

**9.92** Selenic acid,  $\text{H}_2\text{SeO}_4$ , is a crystalline substance and a strong acid. Write the electron-dot formula of selenic acid.

**9.93** Sodium amide, known commercially as sodamide, is used in preparing indigo, the dye used to color blue jeans. It is an ionic compound with the formula  $\text{NaNH}_2$ . What is the electron-dot formula of the amide anion,  $\text{NH}_2^-$ ?

**9.94** Lithium aluminum hydride,  $\text{LiAlH}_4$ , is an important reducing agent (an element or compound that generally has a strong tendency to give up electrons in its chemical reactions). Write the electron-dot formula of the  $\text{AlH}_4^-$  ion.

**9.95** Nitronium perchlorate,  $\text{NO}_2\text{ClO}_4$ , is a reactive salt of the nitronium ion  $\text{NO}_2^+$ . Write the electron-dot formula of  $\text{NO}_2^+$ .

**9.96** Solid phosphorus pentabromide,  $\text{PBr}_5$ , has been shown to have the ionic structure  $[\text{PBr}_4^+][\text{Br}^-]$ . Write the electron-dot formula of the  $\text{PBr}_4^+$  cation.

**9.97** Write electron-dot formulas for the following:

- a**  $\text{SeOCl}_2$     **b**  $\text{CSe}_2$     **c**  $\text{GaCl}_4^-$     **d**  $\text{C}_2^{2-}$

**9.98** Write electron-dot formulas for the following:

- a**  $\text{NO}^+$     **b**  $\text{IF}_2^+$     **c**  $\text{Si}_2\text{H}_6$     **d**  $\text{POBr}_3$

**9.99** Write Lewis formulas for the following:

- a**  $\text{SbCl}_3$     **b**  $\text{ICN}$     **c**  $\text{ICl}_3$     **d**  $\text{IF}_5$

**9.100** Write Lewis formulas for the following:

- a**  $\text{AlCl}_4^-$     **b**  $\text{AlF}_6^{3-}$     **c**  $\text{BrF}_3$     **d**  $\text{IF}_6^+$

**9.101** Give resonance descriptions for the following:

- a**  $\text{SeO}_2$     **b**  $\text{N}_2\text{O}_4$

**9.102** Give resonance descriptions for the following:

- a**  $\text{C}_2\text{O}_4^{2-}$     **b**  $\text{CH}_3\text{NO}_2$

**9.103** The compound  $\text{S}_2\text{N}_2$  has a cyclic structure with alternating sulfur and nitrogen atoms. Draw all resonance formulas in which the atoms obey the octet rule. Of these, select those in which the formal charges of all atoms are closest to zero.

**9.104** Acetic acid has the structure  $\text{CH}_3\text{CO}(\text{OH})$ , in which the OH group is bonded to a C atom. The two carbon-oxygen bonds have different lengths. When an acetic acid molecule loses the H from the OH group to form the acetate ion, the two carbon-oxygen bonds become equal in length. Explain.

**9.105** The atoms in  $\text{N}_2\text{O}_5$  are connected as follows:

No attempt has been made here to indicate whether a bond is single or double or whether there is resonance. Obtain the Lewis formula (or formulas). The N—O bond lengths are 118 pm and 136 pm. Indicate the lengths of the bonds in the compound.

**9.106** Methyl nitrite has the structure

No attempt has been made here to indicate whether a bond is single or double or whether there is resonance. Obtain the Lewis formula (or formulas). The N—O bond lengths are 122 pm and 137 pm. Indicate the lengths of the N—O bonds in the compound.

**9.107** Use bond enthalpies to estimate  $\Delta H$  for the reaction

**9.108** Use bond enthalpies to estimate  $\Delta H$  for the reaction

**9.109** Use bond enthalpies to estimate  $\Delta H$  for the reaction

**9.110** Use bond enthalpies to estimate  $\Delta H$  for the reaction

**9.111** Compare the properties of an ionic material such as sodium chloride with a room-temperature ionic liquid. Explain this difference.

**9.112** What advantages does using an ionic liquid as a solvent have over using an organic solvent?

**9.113** Explain the decomposition of nitroglycerin in terms of relative bond enthalpies.

**9.114** How did the Swedish chemist Alfred Nobel manage to tame the decomposition of nitroglycerin?

**9.115** What property of a chemical bond gives rise to the infrared spectrum of a compound?

**9.116** What kind of information can be obtained about a compound from its infrared spectrum?

## Strategy Problems

**Key:** As noted earlier, all of the practice and general problems are matched pairs. This section is a selection of problems that are not in matched-pair format. These challenging problems require that you employ many of the concepts and strategies that were developed in the chapter. In some cases, you will have to integrate several concepts and operational skills in order to solve the problem successfully.

**9.117** Which of the following Lewis symbols is (or are) *not* correct?

- a**  $[\text{Al}]^{3+}$     **b**  $[\text{F}]^-$     **c**  $[\text{O}]^{2-}$     **d**  $\cdot\text{Mg}$     **e**  $\cdot\text{Si}$

**9.118** Calculate the lattice energy of potassium fluoride, KF, using the Born–Haber cycle. Use thermodynamic data from Appendix C to obtain the enthalpy changes for each step. (Note: You will obtain a slightly different answer if you use values given in Chapter 8 for the ionization energy and electron affinity, which are energy values at 0 K rather than the enthalpy changes at 298 K.)

**9.119** Draw a figure similar to Figure 9.2 but for the energetics of ionic bonding in KF. Use the ionization energy and electron affinity from values given in Tables 8.3 and

8.4 in Chapter 8. Calculate the sublimation energy from thermodynamic data (Appendix C). For the lattice energy, see Problem 9.118.

**9.120** Consider the following ions:  $\text{Al}^{3+}$ ,  $\text{Mg}^{2+}$ ,  $\text{Na}^+$ ,  $\text{S}^{2-}$ ,  $\text{Cl}^-$ . Write down all possible formulas of ionic compounds between each of the oppositely charged ions. Of these compounds, note the ones with a metal-to-nonmetal ratio of one-to-one. Which compound do you expect has the highest melting point? Why?

**9.121** Which of the following are isoelectronic with the potassium ion,  $\text{K}^+$ ? What are the electron configurations of these species?

- a Ar    b  $\text{Cl}^+$     c Kr    d  $\text{Cl}^-$     e  $\text{Ca}^+$

**9.122** An ion  $\text{M}^{2+}$  has the configuration  $[\text{Ar}]3d^2$ , and an atom has the configuration  $[\text{Ar}]4s^2$ . Identify the ion and the atom.

**9.123** Give the symbol of an atomic ion for each of the following electron configurations:

- a  $1s^2 2s^2 2p^6 3s^2 3p^6$   
 b  $1s^2 2s^2 2p^6 3s^2 3p^6 4s^1$   
 c  $1s^2 2s^2 2p^6 3s^2 3p^6 3d^8$   
 d  $1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10} 4s^2$   
 e  $1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10} 4s^2 4p^6$

**9.124** Using the ionic radii given in Table 9.3, estimate the energy to form a mole of  $\text{Na}^+\text{F}^-$  ion pairs from the corresponding atomic ions.

**9.125** Calculate the difference in electronegativities between the atoms in  $\text{SrF}_2$  and between the atoms in  $\text{SnF}_2$ . Which substance would you expect to be more ionic in character? One of these compounds melts at  $213^\circ\text{C}$ , the other one at about  $1400^\circ\text{C}$ . What is the melting point of tin(II) fluoride?

**9.126** Which of the following molecules possesses a double bond? If none do, so state. Which species has an atom with a nonzero formal charge?

- a  $\text{I}_2$     b  $\text{SF}_4$     c  $\text{COCl}_2$     d  $\text{C}_2\text{H}_4$     e  $\text{CN}^-$

**9.127** Which of the following molecules contains *only* double bonds? If none do, so state.

- a  $\text{NCCN}$     b  $\text{CO}_2$     c  $\text{C}_2\text{H}_4$     d  $\text{O}_3$     e  $\text{N}_2$

**9.128** Draw resonance formulas for the azide ion,  $\text{N}_3^-$ , and for the nitronium ion,  $\text{NO}_2^+$ . Decide which resonance formula is the best description of each ion.

**9.129** Two fourth-period atoms, one of a transition metal, M, and the other of a main-group nonmetal, X, form a compound with the formula  $\text{M}_2\text{X}_3$ . What is the electron configuration of atom X if M is Fe? What is the configuration of X if M is Co?

**9.130** In Section 9.8, several resonance formulas of  $\text{BF}_3$  were discussed. Which of these would be favored based on the concept of formal charge? Explain how you arrived at this answer. Does this answer agree with the chemistry described in the text?

**9.131** Draw resonance formulas of the phosphoric acid molecule,  $(\text{HO})_3\text{PO}$ . Obtain formal charges for the atoms in these resonance formulas. From this result, which resonance formula would you expect to most closely approximate the actual electron distribution?

**9.132** Consider all A—B bonds that can be formed between any two of the four elements germanium (Ge) to bromine (Br) in Period 4. Which bond should be the most polar? What is the covalent single bond length for this bond? What is the likely molecular formula of a binary compound of these two elements? Draw an electron-dot formula for the molecule.

**9.133** Consider hypothetical elements X and Y. Suppose the enthalpy of formation of the compound XY is  $-336 \text{ kJ/mol}$ , the bond enthalpy for  $\text{X}_2$  is  $414 \text{ kJ/mol}$ , and the bond enthalpy for  $\text{Y}_2$  is  $159 \text{ kJ/mol}$ . Estimate the XY bond enthalpy in units of  $\text{kJ/mol}$ .

**9.134** Nitrous oxide,  $\text{N}_2\text{O}$ , has a linear structure  $\text{NNO}$ . Write resonance formulas for this molecule and from them estimate the NN bond length in the molecule. Use the data in Example 9.12.

**9.135** Write the electron-dot formula for the nitrous acid molecule,  $\text{H—O—N—O}$  (bond lines are drawn only to show how the atoms are bonded, not the multiplicity of the bonds). The experimental values for the nitrogen-oxygen bonds in this molecule are  $120 \text{ pm}$  and  $146 \text{ pm}$ . Assign these values to the N—O bonds in the nitrous acid molecule. Explain how you arrived at your answer.

**9.136** Using bond enthalpies, estimate the heat obtained in burning  $10.0 \text{ g}$  of methane gas,  $\text{CH}_4$ , in oxygen gas,  $\text{O}_2$ , to obtain carbon dioxide gas and water vapor.

## Capstone Problems

**Key:** The problems under this heading combine skills, strategies, and concepts learned in previous chapters with those introduced in the current one.

**9.137** Phosphorous acid,  $\text{H}_3\text{PO}_3$ , has the structure  $(\text{HO})_2\text{PHO}$ , in which one H atom is bonded to the P atom, and two H atoms are bonded to O atoms. For each bond to an H atom, decide whether it is polar or nonpolar. Assume that only polar-bonded H atoms are acidic. Write the balanced equation for the complete neutralization of phosphorous acid with sodium hydroxide. A  $200.0\text{-mL}$  sample of  $\text{H}_3\text{PO}_3$  requires  $22.50 \text{ mL}$  of  $0.1250 \text{ M}$   $\text{NaOH}$  for complete neutralization. What is the molarity of the  $\text{H}_3\text{PO}_3$  solution?

**9.138** Hypophosphorous acid,  $\text{H}_3\text{PO}_2$ , has the structure  $(\text{HO})\text{PH}_2\text{O}$ , in which two H atoms are bonded to the P atom, and one H atom is bonded to an O atom. For each bond to an H atom, decide whether it is polar or nonpolar. Assume that only polar-bonded H atoms are acidic.

Write the balanced equation for the complete neutralization of hypophosphorous acid with sodium hydroxide. An 800.0-mL sample of  $\text{H}_3\text{PO}_2$  requires 22.00 mL of 0.7850 M NaOH for complete neutralization. What is the molarity of the  $\text{H}_3\text{PO}_2$  solution?

**9.139** An ionic compound has the following composition (by mass): Mg, 10.9%; Cl, 31.8%; O, 57.3%. What are the formula and name of the compound? Write the Lewis formulas for the ions.

**9.140** An ionic compound has the following composition (by mass): Ca, 30.3%; N, 21.2%; O, 48.5%. What are the formula and name of the compound? Write the Lewis formulas for the ions.

**9.141** A gaseous compound has the following composition by mass: C, 25.0%; H, 2.1%; F, 39.6%; O, 33.3%. Its molecular mass is 96.0 amu. Write the Lewis formula for the molecule.

**9.142** A liquid compound used in dry cleaning contains 14.5% C and 85.5% Cl by mass and has a molecular mass of 166 amu. Write the Lewis formula for the molecule.

**9.143** A compound of tin and chlorine is a colorless liquid. The vapor has a density of 7.49 g/L at 151°C and 1.00 atm. What is the molecular mass of the compound? Why do you think the compound is molecular and not ionic? Write the Lewis formula for the molecule.

**9.144** A compound of arsenic and fluorine is a gas. A sample weighing 0.100 g occupies 14.2 mL at 23°C and 765 mmHg. What is the molecular mass of the compound? Write the Lewis formula for the molecule.

**9.145** Calculate the enthalpy of reaction for

from enthalpies of formation (see Appendix C). Given that the C—H bond enthalpy is 411 kJ/mol, obtain a value for the C≡N bond enthalpy. Compare your result with the value given in Table 9.5.

**9.146** Assume the values of the C—H and C—C bond enthalpies given in Table 9.5. Then, using data given in Appendix C, calculate the C=O bond enthalpy in acetaldehyde,

Compare your result with the value given in Table 9.5.

**9.147** According to Pauling, the A—B bond enthalpy is equal to the average of the A—A and B—B bond enthalpies plus an enthalpy contribution from the polar character of the bond:

$$BE(\text{A}-\text{B}) = \frac{1}{2} [BE(\text{A}-\text{A}) + BE(\text{B}-\text{B})] + k(X_{\text{A}} - X_{\text{B}})^2]$$

Here  $X_{\text{A}}$  and  $X_{\text{B}}$  are the electronegativities of atoms A and B, and  $k$  is a constant equal to 98.6 kJ. Assume that the electronegativity of H is 2.1. Use the formula to calculate the electronegativity of oxygen.

**9.148** Because known compounds with N—I bonds tend to be unstable, there are no thermodynamic data available with which to calculate the N—I bond enthalpy. However, we can estimate a value from Pauling's formula relating electronegativities and bond enthalpies (see Problem 9.147). Using Pauling's electronegativities and the bond enthalpies given in Table 9.5, calculate the N—I bond enthalpy.

**9.149** Using Mulliken's formula, calculate a value for the electronegativity of chlorine. Use values of the ionization energy from Figure 8.18 and values of the electron affinity from Table 8.4. Divide this result (in kJ/mol) by 230 to get a value comparable to Pauling's scale.

**9.150** Using Mulliken's formula, calculate a value for the electronegativity of oxygen. Convert the result to a value on Pauling's scale. See Problem 9.149.

## CONTENTS AND CONCEPTS

### Molecular Geometry and Directional Bonding

We can predict the *molecular geometry* of a molecule, its general shape as determined by the relative positions of atomic nuclei, with a simple model: the valence-shell electron-pair repulsion model. After exploring molecular geometry, we explain chemical bonding by means of *valence bond theory*, which gives us insight into why

bonds form and why they have definite directions in space, giving particular molecular geometries.

**10.1** The Valence-Shell Electron-Pair Repulsion (VSEPR) Model

**10.2** Dipole Moment and Molecular Geometry

**10.3** Valence Bond Theory

**10.4** Description of Multiple Bonding

### Molecular Orbital Theory

Although valence bond theory satisfactorily describes most molecules, it has trouble explaining the bonding in a molecule such as oxygen,  $O_2$ , which has even numbers of electrons but is paramagnetic. *Molecular orbital theory* is an alternative theory that views the electronic structure of molecules much the way we

think of atoms: in terms of orbitals that are successively occupied by electrons.

**10.7** Molecular Orbitals and Delocalized Bonding

Figure 10.1 ▲

**Molecular models of  $\text{BF}_3$  and  $\text{PF}_3$**  Although both molecules have the general formula  $\text{AX}_3$ , boron trifluoride is planar (flat), whereas phosphorus trifluoride is pyramidal (pyramid shaped).

We know from various experiments that molecules have definite structures; that is, the atoms of a molecule have definite positions relative to one another in three-dimensional space. Consider two molecules: boron trifluoride,  $\text{BF}_3$ , and phosphorus trifluoride,  $\text{PF}_3$ . Both have the same general formula,  $\text{AX}_3$ , but their molecular structures are very different (Figure 10.1). Boron trifluoride is a planar, or flat, molecule. The angle between any two B—F bonds is  $120^\circ$ . The geometry or general shape of the  $\text{BF}_3$  molecule is said to be *trigonal planar* (trigonal because the figure described by imaginary lines connecting the F atoms has three sides). Phosphorus trifluoride is nonplanar, and the angle between any two P—F bonds is  $96^\circ$ . If you imagine lines connecting the fluorine atoms, these lines and those of the P—F bonds describe a pyramid with the phosphorus atom at its apex. The geometry of the  $\text{PF}_3$  molecule is said to be *trigonal pyramidal*. How do you explain such different molecular geometries?

Subtle differences in structure are also possible. Consider the following molecular structures, which differ only in the arrangement of the atoms about the  $\text{C}=\text{C}$  bond; such molecules are referred to as *isomers*.

In the *cis* compound, both H atoms are on the same side of the  $\text{C}=\text{C}$  bond; in the *trans* compound, they are on opposite sides. These structural formulas represent entirely different compounds, as their boiling points clearly demonstrate. *Cis*-1,2-dichloroethene boils at  $60^\circ\text{C}$ ; *trans*-1,2-dichloroethene boils at  $48^\circ\text{C}$ . The differences between such *cis* and *trans* compounds can be quite important. The central molecular event in the detection of light by the human eye involves the transformation of a *cis* compound to its corresponding *trans* compound after the absorption of a photon of light. How do you explain the existence of *cis* and *trans* compounds?

In this chapter, we discuss how to explain the geometries of molecules in terms of their electronic structures. We also explore two theories of chemical bonding: valence bond theory and molecular orbital theory.

## ► Molecular Geometry and Directional Bonding

**Molecular geometry** is the general shape of a molecule, as determined by the relative positions of the atomic nuclei. There is a simple model that allows you to predict molecular geometries, or shapes, from Lewis formulas. This valence-shell electron-pair model usually predicts the correct general shape of a molecule. It does not explain chemical bonding, however. For this you must look at a theory, such as valence bond theory, that is based on quantum mechanics. Valence bond theory provides further insight into why bonds form and, at the same time, reveals that bonds have definite directions in space, resulting in particular molecular geometries.

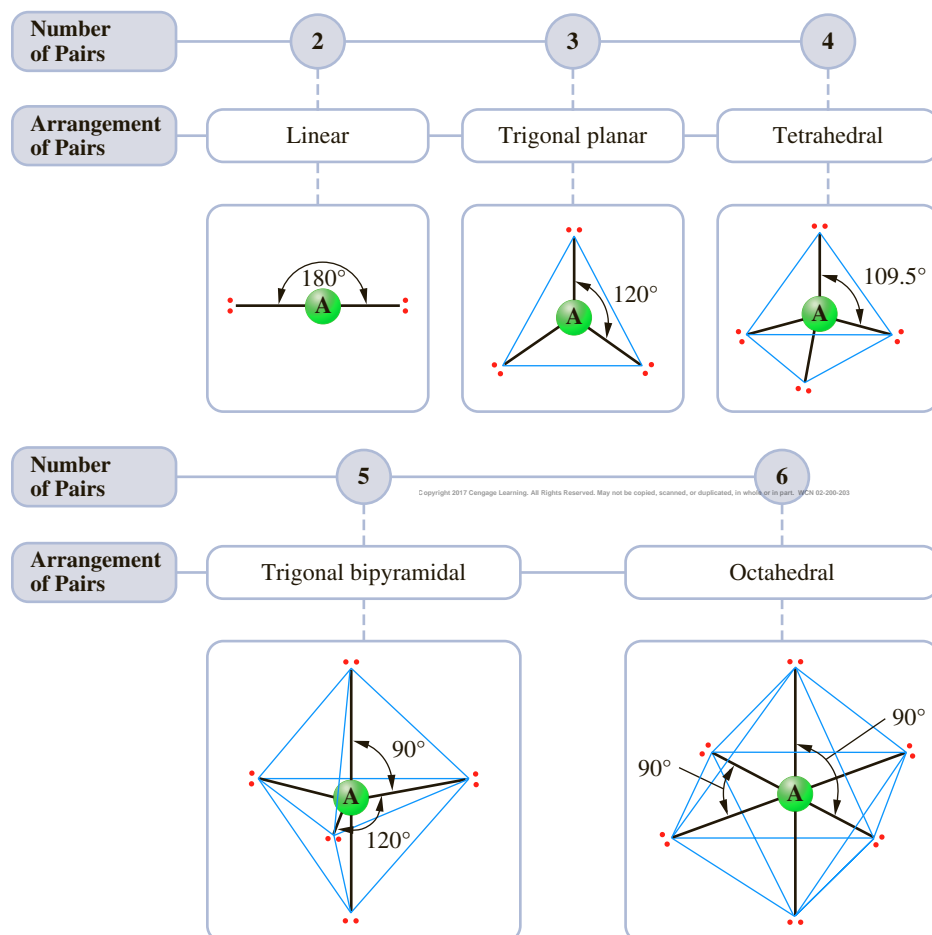

### 10.1 The Valence-Shell Electron-Pair Repulsion (VSEPR) Model

The **valence-shell electron-pair repulsion (VSEPR) model** predicts the shapes of molecules and ions by assuming that the valence-shell electron pairs are arranged about each atom so that electron pairs are kept as far away from one another as possible, thus minimizing electron-pair repulsions. ► The possible arrangements assumed by different numbers of electron pairs about an atom are shown in Figure 10.2. (If you tie various numbers of similar balloons together, they assume these same arrangements; see Figure 10.3.)

For example, if there are only two electron pairs in the valence shell of an atom, these pairs tend to be at opposite sides of the nucleus, so that repulsion is minimized. This gives a *linear* arrangement of electron pairs; that is, the electron pairs mainly occupy regions of space at an angle of  $180^\circ$  to one another (Figure 10.2).

If three electron pairs are in the valence shell of an atom, they tend to be arranged in a plane directed toward the corners of a triangle of equal sides (equilateral

The acronym VSEPR is pronounced "vesper."

**Figure 10.2** ◀ **Arrangement of electron pairs about an atom** Black lines give the directions of electron pairs about atom A. The blue lines merely help depict the geometric arrangement of electron pairs.

© Cengage Learning

Figure 10.3 ▲

**Balloon models of electron-pair arrangements** When you tie similar balloons together, they assume the arrangements shown. These arrangements are the same as those assumed by valence electron pairs about an atom, as in the examples.

triangle). This arrangement is *trigonal planar*, in which the regions of space occupied by electron pairs are directed at  $120^\circ$  angles to one another (Figure 10.2).

Four electron pairs in the valence shell of an atom tend to have a *tetrahedral* arrangement. That is, if you imagine the atom at the center of a regular tetrahedron, each region of space in which an electron pair mainly lies extends toward a corner, or vertex (Figure 10.2). (A regular tetrahedron is a geometrical shape with four faces, each an equilateral triangle. Thus, it has the form of a triangular pyramid.) The regions of space mainly occupied by electron pairs are directed at approximately  $109.5^\circ$  angles to one another.

When you determine the geometry of a molecule experimentally, you locate the positions of the atoms, not the electron pairs. To predict the relative positions of atoms around a given atom using the VSEPR model, you first note the arrangement of valence-shell electron pairs around that central atom. Some of these electron pairs are bonding pairs and some are lone pairs. *The direction in space of the bonding pairs gives you the molecular geometry.* To consider examples of the method, we will first look at molecules AX<sub>n</sub> in which the central atom A is surrounded by two, three, or four valence-shell electron pairs. Later we will look at molecules in which A is surrounded by five or six valence-shell electron pairs.

### Central Atom with Two, Three, or Four Valence-Shell Electron Pairs

Examples of geometries in which two, three, or four valence-shell electron pairs surround a central atom are shown in Figure 10.4.

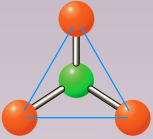

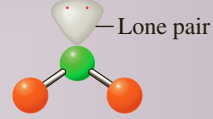

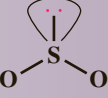

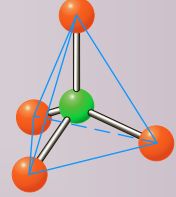

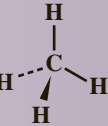

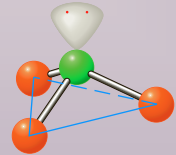

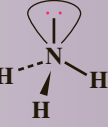

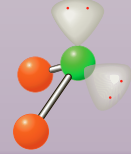

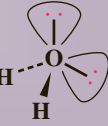

**Two Electron Pairs (Linear Arrangement)** To find the geometry of the molecule AX<sub>n</sub>, you first determine the number of valence-shell electron pairs around atom A. You can get this information from the electron-dot formula. For example, following the rules given in Section 9.6, you can find the electron-dot formula for the BeF<sub>2</sub> molecule. ◀

There are two electron pairs in the valence shell for beryllium, and the VSEPR model predicts that they will have a linear arrangement (see Figure 10.2). Fluorine atoms are bonded in the same direction as the electron pairs. Hence, the geometry of the BeF<sub>2</sub> molecule is *linear*—that is, the atoms are arranged in a straight line (see Figure 10.4).

Beryllium fluoride, BeF<sub>2</sub>, is normally a solid. The BeF<sub>2</sub> molecule exists in the vapor phase at high temperature.

Electron Pairs			Arrangement of Pairs	Molecular Geometry	Example
Total	Bonding	Lone			
2	2	0	Linear	Linear $AX_2$	 $BeF_2$ $F—Be—F$
3	3	0	Trigonal planar	Trigonal planar $AX_3$	 $BF_3$ 
	2	1		Bent (or angular) $AX_2$	 $SO_2$ 
4	4	0	Tetrahedral	Tetrahedral $AX_4$	 $CH_4$ 
	3	1		Trigonal pyramidal $AX_3$	 $NH_3$ 
	2	2		Bent (or angular) $AX_2$	 $H_2O$ 

The VSEPR model can also be applied to molecules with multiple bonds. In this case, each multiple bond is treated as though it were a single electron pair. (All pairs of a multiple bond are required to be in approximately the same region.) To predict the geometry of carbon dioxide, for example, you first write the electron-dot formula.

You have two double bonds, or two electron groups, about the carbon atom, and these are treated as though there were two pairs on carbon. Thus, according to the VSEPR model, the bonds are arranged linearly and the geometry of carbon dioxide is linear.

**Three Electron Pairs (Trigonal Planar Arrangement)** Let us now predict the geometry of the boron trifluoride molecule,  $BF_3$ , introduced in the chapter opening. The electron-dot formula is

The three electron pairs on boron have a trigonal planar arrangement, and the molecular geometry, which is determined by the directions of the bonding pairs, is also *trigonal planar* (Figures 10.1 and 10.4).

Figure 10.4 ▲

**Molecular geometries** Central atom with two, three, or four valence-shell electron pairs. The notation in the column at the right provides a convenient way to represent the shape of a molecule drawn on a flat surface. A straight line represents a bond or electron pair in the plane of the page. A dashed line represents a bond or electron pair extending behind the page. A wedge represents a bond or electron pair extending above (in front of) the page.

Sulfur dioxide, SO<sub>2</sub>, provides an example of a molecule with three electron groups about the S atom; one group is a lone pair. This molecule requires a resonance description, so it gives us a chance to see how the VSEPR model can be applied in such cases. The resonance description can be written

Whichever formula you consider, sulfur has three groups of electrons about it. These groups have a trigonal planar arrangement, so sulfur dioxide is a *bent*, or *angular*, molecule (Figure 10.4). In general, whenever you consider a resonance description, you can use any of the resonance formulas to predict the molecular geometry with the VSEPR model.

Note the difference between the *arrangement of electron pairs* and the *molecular geometry*, or the arrangement of nuclei. What you usually “see” by means of X-ray diffraction and similar methods are the nuclear positions—that is, the molecular geometry. Unseen, but nevertheless important, are the lone pairs, which occupy definite positions about an atom according to the VSEPR model.

**Four Electron Pairs (Tetrahedral Arrangement)** The common and most important case of four electron pairs about the central atom (the octet rule) leads to three different molecular geometries, depending on the number of bonds formed. Note the following examples.

In each of these examples, the electron pairs are arranged tetrahedrally, and two or more atoms are bonded in these tetrahedral directions to give the different geometries (Figure 10.4).

When all electron pairs are bonding, as in methane, CH<sub>4</sub>, the molecular geometry is *tetrahedral* (Figure 10.5). When three of the pairs are bonding and one pair is nonbonding, as in ammonia, NH<sub>3</sub>, the molecular geometry is *trigonal pyramidal*. Note that the nitrogen atom is at the apex of the pyramid, and the three hydrogen atoms extend downward to form the triangular base of the pyramid.

Now you can answer the question raised in the chapter opening: Why is the BF<sub>3</sub> molecule trigonal planar and the PF<sub>3</sub> molecule trigonal pyramidal? The difference occurs because in BF<sub>3</sub> there are three pairs of electrons around boron, and in PF<sub>3</sub> there are four pairs of electrons around phosphorus. As in NH<sub>3</sub>, there are three bonding pairs and one lone pair in PF<sub>3</sub>, which give rise to the trigonal pyramidal geometry.

**Steps in the Prediction of Geometry by the VSEPR Model** Let us summarize the steps to follow in order to predict the geometry of an AX<sub>n</sub> molecule or ion by the VSEPR method. (All X atoms of AX<sub>n</sub> need not be identical.)

- Step 1:** Write the electron-dot formula from the molecular formula.
- Step 2:** Determine from the electron-dot formula the number of electron pairs around the central atom, including bonding and nonbonding pairs. (Count a multiple bond as one pair. If resonance occurs, use one resonance formula to determine this number.)
- Step 3:** Determine the arrangement of these electron pairs about the central atom (see Figure 10.2).
- Step 4:** Obtain the molecular geometry from the directions of the bonding pairs for this arrangement (see Figure 10.4).

**Figure 10.5** ▲

**The methane molecule** A ball-and-stick model shows the tetrahedral arrangement of bonds. This model is within an electrostatic-potential map, showing the electron density about the molecule by gradations of color. Thus, the red color means high density, which occurs in the C—H bonding regions.

**CONCEPT CHECK 10.1**

An atom in a molecule is surrounded by four pairs of electrons: one lone pair and three bonding pairs. Describe how the four electron pairs are arranged about the atom. How are any three of these pairs arranged in space? What is the geometry about this central atom, taking into account just the bonded atoms?

**Example 10.1 Predicting Molecular Geometries (Two, Three, or Four Electron Pairs)****Gaining Mastery Toolbox****Critical Concept 10.1**

The arrangement of electron groups about a central atom depends on the number of electron groups: two electron groups have a linear arrangement, three electron groups a trigonal planar arrangement, and four electron groups a tetrahedral arrangement.

**Solution Essentials:**

- Molecular geometries for a given arrangement of electrons
- Arrangement of electron groups about an atom
- Electron-dot formulas

Predict the geometry of the following molecules or ions, using the VSEPR method:  
a. BeCl<sub>2</sub>; b. NO<sub>2</sub><sup>-</sup>; c. SiCl<sub>4</sub>.

**Problem Strategy** After drawing the Lewis formula for a molecule, determine the number of electron groups about the central atom. This number determines the arrangement of the electron groups (Figure 10.2). The geometry is determined by the arrangement of bonds to the central atom (Figure 10.4).

**Solution**

a. Following the steps outlined in Sections 9.6 and 9.8 for writing Lewis formulas, you distribute the valence electrons to the skeleton structure of BeCl<sub>2</sub> as follows:

The two pairs on Be have a linear arrangement, indicating a **linear** molecular geometry for BeCl<sub>2</sub>. (See Figure 10.4; 2 electron pairs, 0 lone pairs.)

b. The nitrite ion, NO<sub>2</sub><sup>-</sup>, has the following resonance description:

The N atom has three electron groups (one single bond, one double bond, and one lone pair) about it. Therefore the molecular geometry of the NO<sub>2</sub><sup>-</sup> ion is **bent**. (See Figure 10.4; 2 bonding pairs, 1 lone pair.)

c. The electron-dot formula of SiCl<sub>4</sub> is

The molecular geometry is **tetrahedral**. (See Figure 10.4; 4 bonding pairs, 0 lone pairs.)

**Answer Check** Be careful not to confuse the name for the arrangement of valence electron pairs with the name for the molecular geometry. The geometry refers only to the arrangement of bonds. In this example, the nitrite ion, NO<sub>2</sub><sup>-</sup>, has a trigonal planar arrangement of valence electron pairs and a bent geometry (arrangement of the bonds).

**Exercise 10.1** Use the VSEPR method to predict the geometry of the following ion and molecules: a. ClO<sub>3</sub><sup>-</sup>; b. OF<sub>2</sub>; c. SiF<sub>4</sub>.

See Problems 10.33, 10.34, 10.35, and 10.36.

**Bond Angles and the Effect of Lone Pairs**

The VSEPR model allows you to predict the approximate angles between bonds in molecules. For example, it tells you that CH<sub>4</sub> should have a tetrahedral geometry and that the H—C—H bond angles should be 109.5° (see Figure 10.2). Because all of the

Figure 10.6 ▶

**H—A—H bond angles in some molecules** Experimentally determined bond angles are shown for  $\text{CH}_4$ ,  $\text{CH}_3\text{Cl}$ ,  $\text{NH}_3$ , and  $\text{H}_2\text{O}$ , represented here by models.

valence-shell electron pairs about the carbon atom are bonding and all of the bonds are alike, you expect the  $\text{CH}_4$  molecule to have an exact tetrahedral geometry. However, if one or more of the electron pairs is nonbonding or if there are dissimilar bonds, all four valence-shell electron pairs will not be alike. Then you expect the bond angles to deviate from the  $109.5^\circ$  predicted by an exact tetrahedral geometry. This is indeed what you see. Experimentally determined H—A—H bond angles (A is the central atom) in  $\text{CH}_4$ ,  $\text{CH}_3\text{Cl}$ ,  $\text{NH}_3$ , and  $\text{H}_2\text{O}$  are shown in Figure 10.6.

The increase or decrease of bond angles from the ideal values is often predictable. *A lone pair tends to require more space than a corresponding bonding pair.* You can explain this as follows: A lone pair of electrons is attracted to only one atomic core, whereas a bonding pair is attracted to two. As a result, the lone pair is spatially more diffuse, while the bonding pair is drawn more tightly to the nuclei. Consider the trigonal pyramidal molecule  $\text{NH}_3$ . The lone pair on the nitrogen atom requires more space than the bonding pairs. Therefore, the N—H bonds are effectively pushed away from the lone pair, and the H—N—H bond angles become smaller than the tetrahedral value of  $109.5^\circ$ . How much smaller, the VSEPR model cannot tell you. The experimental value of an H—N—H bond angle is a few degrees smaller ( $107^\circ$ ). But the trigonal pyramidal molecule  $\text{PF}_3$ , mentioned in the chapter opening, has an F—P—F bond angle of  $96^\circ$ , which is significantly smaller than the exact tetrahedral value.

*Multiple bonds require more space than single bonds because of the greater number of electrons.* You therefore expect the C=O bond in the formaldehyde molecule,  $\text{CH}_2\text{O}$ , to require more space than the C—H bonds. You predict that the H—C—H bond angle will be smaller than the  $120^\circ$  seen in an exact trigonal planar geometry, such as the F—B—F angle in  $\text{BF}_3$ . Similarly, you expect the H—C—H bond angles in the ethylene molecule,  $\text{CH}_2\text{CH}_2$ , to be smaller than the trigonal planar value.

Experimental values are shown in Figure 10.7.

Figure 10.7 ▲

**H—C—H bond angles in molecules with a carbon double bond** Bond angles are shown for formaldehyde,  $\text{CH}_2\text{O}$ , and ethylene,  $\text{CH}_2\text{CH}_2$ , represented here by models.

### Central Atom with Five or Six Valence-Shell Electron Pairs

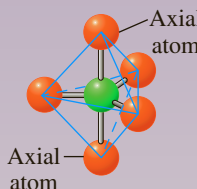

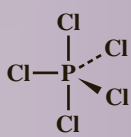

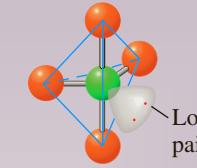

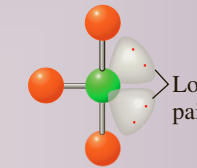

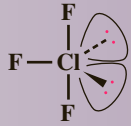

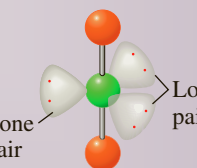

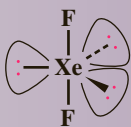

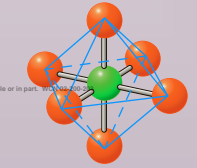

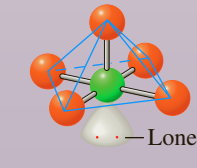

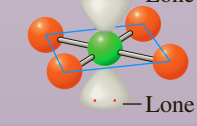

Five electron pairs tend to have a *trigonal bipyramidal arrangement*. The electron pairs tend to be directed to the corners of a trigonal bipyramid, a figure formed by placing the face of one tetrahedron onto the face of another tetrahedron (see Figure 10.2).

Six electron pairs tend to have an *octahedral arrangement*. The electron pairs tend to be directed to the corners of a regular octahedron, a figure that has eight triangular faces and six vertexes, or corners (see Figure 10.2).

**Five Electron Pairs (Trigonal Bipyramidal Arrangement)** Large atoms like phosphorus can accommodate more than eight valence electrons. The phosphorus atom in phosphorus pentachloride,  $\text{PCl}_5$ , has five electron pairs in its valence shell. With five electron pairs around phosphorus, all bonding,  $\text{PCl}_5$  should have a *trigonal bipyramidal geometry* (Figure 10.8). Note, however, that the vertices of the trigonal bipyramid are not all equivalent (that is, the angles between the electron pairs are not all the same). Thus, the directions to which the electron pairs point are not equivalent. Two of the directions, called *axial directions*, form an axis through the

Figure 10.8 ▼

**Molecular geometries**  
Central atom with five or six valence-shell electron pairs.

Electron Pairs			Arrangement of Pairs	Molecular Geometry	Example
Total	Bonding	Lone			
5	5	0	Trigonal bipyramidal	Trigonal bipyramidal $\text{AX}_5$ 	$\text{PCl}_5$

	2	3		Linear $\text{AX}_2$ 	$\text{XeF}_2$ 
6	6	0	Octahedral	Octahedral $\text{AX}_6$ 	$\text{SF}_6$ 
	5	1		Square pyramidal $\text{AX}_5$ 	$\text{IF}_5$ 
	4	2		Square planar $\text{AX}_4$ 	$\text{XeF}_4$ 

Figure 10.9 ▲

**Trigonal bipyramidal arrangement of electron pairs** Electron pairs are directed along the black lines to the vertices of a trigonal bipyramid. Equatorial directions are labeled *E*, and axial directions are labeled *A*.

central atom (see Figure 10.9). They are  $180^\circ$  apart. The other three directions are called *equatorial directions*. These point toward the corners of the equilateral triangle that lies on a plane through the central atom, perpendicular (at  $90^\circ$ ) to the axial directions. The equatorial directions are  $120^\circ$  from each other.

Molecular geometries other than trigonal bipyramidal are possible when one or more of the five electron pairs are lone pairs. Consider the sulfur tetrafluoride molecule,  $\text{SF}_4$ . The Lewis electron-dot formula is

The five electron pairs about sulfur should have a trigonal bipyramidal arrangement. Because the axial and equatorial positions of the electron pairs are not equivalent, you must decide in which of these positions the lone pair appears.

The lone pair acts as though it is somewhat “larger” than a bonding pair. Therefore, the total repulsion between all pairs should be lower if the lone pair is in a position that puts it directly adjacent to the smallest number of other pairs.

An electron pair in an equatorial position is directly adjacent to only *two* other pairs—the two axial pairs at  $90^\circ$ . The other two equatorial pairs are farther away at  $120^\circ$ . An electron pair in an axial position is directly adjacent to *three* other pairs—the three equatorial pairs at  $90^\circ$ . The other axial pair is much farther away at  $180^\circ$ .

Thus you expect lone pairs to occupy equatorial positions in the trigonal bipyramidal arrangement. For sulfur tetrafluoride, this gives a *seesaw* (or *distorted tetrahedral*) geometry (Figure 10.10; see also Figure 10.8).

Chlorine trifluoride,  $\text{ClF}_3$ , has the electron-dot formula

Figure 10.10 ▲

**The sulfur tetrafluoride molecule**  
Molecular model.

The lone pairs on chlorine occupy two of the equatorial positions of the trigonal bipyramidal arrangement, giving a *T-shaped geometry* (Figure 10.11; see also Figure 10.8). The four atoms of the molecule all lie in one plane, with the chlorine nucleus at the intersection of the “T.”

Xenon difluoride,  $\text{XeF}_2$ , has the electron-dot formula

The three lone pairs on xenon occupy the equatorial positions of the trigonal bipyramidal arrangement, giving a *linear geometry* (Figure 10.12; see also Figure 10.8).

**Six Electron Pairs (Octahedral Arrangement)** There are six electron pairs (all bonding pairs) about sulfur in sulfur hexafluoride,  $\text{SF}_6$ . Thus, it has an *octahedral geometry*, with sulfur at the center of the octahedron and fluorine atoms at the vertices (Figure 10.8).

Figure 10.11 ▲

**The chlorine trifluoride molecule**  
Molecular model.

Figure 10.12 ▲

**The xenon difluoride molecule**  
Molecular model.

Iodine pentafluoride,  $\text{IF}_5$ , has the electron-dot formula

The lone pair on iodine occupies one of the six equivalent positions in the octahedral arrangement, giving a *square pyramidal geometry* (Figure 10.13; see also Figure 10.8). The name derives from the shape formed by drawing lines between atoms.

Xenon tetrafluoride,  $\text{XeF}_4$ , has the electron-dot formula

The two lone pairs on xenon occupy opposing positions in the octahedral arrangement to minimize their repulsion. The result is a *square planar geometry* (Figure 10.14; see also Figure 10.8).

Molecular model.

### Example 10.2 Predicting Molecular Geometries (Five or Six Electron Pairs)

#### Gaining Mastery Toolbox

##### Critical Concept 10.2

The arrangement of electron groups about a central atom depends on the number of electron groups: five electron groups have a trigonal bipyramidal arrangement and six electron groups an octahedral arrangement.

##### Solution Essentials:

- Molecular geometries for a given arrangement of electrons
- Arrangement of electron groups about an atom
- Electron-dot formulas

What do you expect for the geometry of tellurium tetrachloride,  $\text{TeCl}_4$ ?

**Problem Strategy** After drawing the Lewis formula for a molecule, determine the number of electron groups about the central atom. This number determines the arrangement of the electron groups (Figure 10.2). The geometry is determined by the arrangement of bonds to the central atom (Figure 10.8).

**Solution** First you distribute the valence electrons to the Cl atoms to satisfy the octet rule. Then you allocate the remaining valence electrons to the central atom, Te (following the steps outlined in Section 9.6). The electron-dot formula is

There are five electron pairs in the valence shell of Te in  $\text{TeCl}_4$ . Of these, four are bonding pairs and one is a lone pair. The arrangement of electron pairs is trigonal bipyramidal. You expect the lone pair to occupy an equatorial position, so  $\text{TeCl}_4$  has a **seesaw** molecular geometry. (See Figure 10.8; 4 bonding pairs, 1 lone pair.)

**Answer Check** Again, be careful to distinguish the name for the arrangement of valence electron pairs from the name for the molecular geometry.

**Exercise 10.1** According to the VSEPR model, what molecular geometry would you predict for iodine trichloride,  $\text{ICl}_3$ ?

See Problems 10.39, 10.40, 10.41, and 10.42.

### Applying the VSEPR Model to Larger Molecules

In the preceding discussion, we looked at the geometry of molecules having a single central atom with other atoms or groups attached to that central atom. We can also apply what we have learned there to more complicated molecules. What we need to

Daily Life

A CHEMIST Looks at . . .

## Left-Handed and Right-Handed Molecules

This morning, half asleep, I (D. E.) tried to put my left glove on my right hand. Silly mistake, of course. A person's two hands are similar but not identical. If I look at my hands, say, with both palms toward me, the thumbs point in opposite directions. But, if I now hold the palm of my right hand toward a mirror and compare that image with my actual left hand, I see that the thumbs point in the same direction. A person's left hand looks like the mirror image of his or her right hand, and vice versa. You can mentally superimpose one hand onto the mirror image of the other hand. Yet the two hands are themselves non-superimposable. Many molecules have this "handedness" property too, and this possibility gives rise to a subtle kind of isomerism.

The presence of handedness in molecules depends on the fact that the atoms in the molecules occupy specific places in three-dimensional space. In most organic molecules, this property depends on the tetrahedral bonding of the carbon atom. Consider a carbon atom bonded to four different kinds of groups, say,  $\text{—H}$ ,  $\text{—OH}$ ,  $\text{—CH}_3$ , and  $\text{—COOH}$ . (The resulting molecule is called lactic acid.) Two isomers are possible in which one isomer is the mirror image of the other, but the two isomers are themselves not identical (they are nonsuperimposable; see Figure 10.15). However, all four

groups bonded to this carbon atom must be different to have this isomerism. If you replace the  $\text{—OH}$  group of lactic acid by, say, an H atom, the molecule and its mirror image become identical. There are no isomers; there is just one kind of molecule.

The two lactic acid isomers shown in Figure 10.15 are labeled *D*-lactic acid and *L*-lactic acid (*D* is for *dextro*, meaning right; *L* is for *levo*, meaning left). They might be expected to have quite similar properties, and they do. They have identical melting points, boiling points, and solubilities, for instance. And if we try to prepare lactic acid in the laboratory, we almost always get an equal molar mixture of the *D* and *L* isomers. But the biological origins of the molecules are different. Only *D*-lactic acid occurs in sour milk, whereas only *L*-lactic acid forms in muscle tissue after exercising.

Biological molecules frequently have the handedness character. The chemical substance responsible for the flavor of spearmint is *L*-carvone. The substance responsible for the flavor of caraway seeds, which you see in some rye bread, is *D*-carvone (see Figure 10.16). Here are two substances whose molecules differ only in being mirror images of one another. Yet, they have strikingly different flavors: one is minty; the other is pungent aromatic.

*(continued)*

do is to imagine a large molecule broken into pieces to which we can apply the VSEPR model. As an example, let's consider the lactic acid molecule.

Lactic acid has the following electron-dot formula:

We have divided this formula into several "central atoms," each surrounded by a number of bonding or lone pairs of electrons. Note that the carbon atom at the far left is surrounded by bonds to three hydrogen atoms plus a bond to another carbon atom. These four bonds would be expected to have a tetrahedral arrangement about this carbon atom. Similarly, the next carbon atom is surrounded by four bonds and would also be expected to have a tetrahedral arrangement of bonds about it. The carbon atom on the right, though, has a single bond to the carbon atom on its left and a single bond to the oxygen atom on its right plus a double bond to the oxygen atom above it. We would expect these three groups of electrons to have a trigonal

planar arrangement about that carbon atom. Then, there are two —O—H groups, with each oxygen atom having a tetrahedral arrangement of electron pairs and a bent or angular geometry of bonds. Here is a molecular model of lactic acid.

You might find it instructive to use a molecular model kit to build this structure. The essay on the preceding page describes a subtle type of isomerism that arises in lactic acid.

## 10.2 Dipole Moment and Molecular Geometry

The VSEPR model provides a simple procedure for predicting the geometry of a molecule. However, predictions must be verified by experiment. Information about the geometry of a molecule can sometimes be obtained from an experimental quantity called the dipole moment, which is related to the polarity of the bonds in a molecule.

Figure 10.17 ►

Alignment of polar molecules by an electric field

The **dipole moment** is a quantitative measure of the degree of charge separation in a molecule and is therefore an indicator of the polarity of the molecule. In general, a positive charge  $q$  and a negative charge  $-q$ , separated by a distance  $d$  has a dipole moment,  $\mu$ , equal to

$$\mu = q \times d$$

Consider the bond in the H—Cl molecule. Because the Cl atom is more electronegative than the H atom, the electrons of the bond are pulled toward it, giving this atom a partial negative charge, which we indicate as  $\delta^-$ . The H atom then has an equal but positive charge,  $\delta^+$ :

So, the dipole moment in HCl is  $\delta d$ . Dipole moments are usually measured in units of *debyes* (D); the dipole moment of HCl is 1.08 D. In SI units, dipole moments are measured in coulomb-meters (C·m), and  $1 \text{ D} = 3.34 \times 10^{-30} \text{ C}\cdot\text{m}$ .

Measurements of dipole moments are based on the fact that polar molecules (molecules having a dipole moment) can be oriented by an electric field. Figure 10.17 shows an electric field generated by charged plates. Note that the polar molecules tend to align themselves so that the negative ends of the molecules point toward the positive plate, and the positive ends point toward the negative plate. This orientation of the molecules affects the *capacitance* of the charged plates (the capacity of the plates to hold a charge). Consequently, measurements of the capacitance of plates separated by different substances can be used to obtain the dipole moments of those substances. Figure 10.18 shows a simple demonstration that distinguishes between a polar liquid (one whose molecules have a dipole moment) and a nonpolar liquid. The polar liquid, but not the nonpolar one, is attracted to a charged rod.

You can sometimes relate the presence or absence of a dipole moment in a molecule to its molecular geometry. For example, consider the carbon dioxide molecule. Each carbon–oxygen bond has a polarity in which the more electronegative oxygen atom has a partial negative charge.

**left** Water is a polar liquid; it is attracted to the electrically charged rod. The capacitance of the polar liquid (due to the alignment of polar molecules) stabilizes a charge separation induced in the column of liquid surface near the rod, resulting in a net attraction.

**right** Carbon tetrachloride,  $\text{CCl}_4$ , is a nonpolar liquid; it is not attracted to the glass rod.

Figure 10.18 ▲

Attraction of a polar liquid to an electrified rod

We will denote the dipole-moment contribution from each bond (the bond dipole) by an arrow with a positive sign at one end ( $\rightarrow$ ). The dipole-moment arrow points

from the positive partial charge toward the negative partial charge. Thus, you can rewrite the formula for carbon dioxide as

Each bond dipole, like a force, is a *vector* quantity; that is, it has both magnitude and direction. Like forces, two bond dipoles of equal magnitude but opposite direction cancel each other. (Think of two groups of people in a tug of war. As long as each group pulls on the rope with the same force but in the opposite direction, there is no movement—the net force is zero.) Because the two carbon–oxygen bond dipoles in  $\text{CO}_2$  are equal but point in opposite directions, they give a net dipole moment of zero for the molecule.

For comparison, consider the water molecule. The bond dipoles point from the hydrogen atoms toward the more electronegative oxygen.

Here, the two bond dipoles do not point directly toward or away from each other. As a result, they add together to give a nonzero dipole moment for the molecule.

The dipole moment of  $\text{H}_2\text{O}$  has been observed to be 1.94 D.

The fact that the water molecule has a dipole moment is excellent experimental evidence for a bent geometry. If the  $\text{H}_2\text{O}$  molecule were linear, the dipole moment would be zero.

The analysis we have just made for two different geometries of  $\text{AX}_2$  molecules can be extended to other  $\text{AX}_n$  molecules (in which all X atoms are identical). Table 10.1 summarizes the relationship between molecular geometry and dipole moment. Those geometries in which A—X bonds are directed symmetrically about the central atom (for example, linear, trigonal planar, and tetrahedral) give molecules of zero dipole moment; that is, the molecules are *nonpolar*. Those geometries in which the X atoms tend to be on one side of the molecule (for example, bent and trigonal pyramidal) can have nonzero dipole moments; that is, they can give *polar* molecules.

**Table 10.1** Relationship Between Molecular Geometry and Dipole Moment

Formula	Molecular Geometry	Dipole Moment*
$\text{AX}$	Linear	Can be nonzero
$\text{AX}_2$	Linear	Zero
	Bent	Can be nonzero
$\text{AX}_3$	Trigonal planar	Zero
	Trigonal pyramidal	Can be nonzero
	T-shaped	Can be nonzero
$\text{AX}_4$	Tetrahedral	Zero
	Square planar	Zero
	Seesaw	Can be nonzero
$\text{AX}_5$	Trigonal bipyramidal	Zero
	Square pyramidal	Can be nonzero
$\text{AX}_6$	Octahedral	Zero

\*All X atoms are assumed to be identical.

**Example 10.3** Relating Dipole Moment and Molecular Geometry**Gaining Mastery Toolbox****Critical Concept 10.3**

The dipole moment is a vector quantity; it is possible for similar bond dipoles that are arranged symmetrically to cancel one another in order to give an overall zero dipole moment.

**Solution Essential:**

- Relationship between molecular geometry and dipole moment

Each of the following molecules has a nonzero dipole moment. Select the molecular geometry that is consistent with this information. Explain your reasoning.

- a.  $\text{SO}_2$  linear, bent  
b.  $\text{PH}_3$  trigonal planar, trigonal pyramidal

**Problem Strategy** Because the dipole moment is a *vector* quantity, it can happen that nonzero bond dipoles cancel one another to give a molecule with zero dipole moment. Look for bonds that are symmetrically arranged to oppose one another (think of a tug of war between bonds). Table 10.1 summarizes the relationship between geometry and dipole moment.

**Solution** a. In the linear geometry, the S—O bond contributions to the dipole moment would cancel, giving a zero dipole moment. That would not happen in the **bent** geometry; hence, this must be the geometry for the  $\text{SO}_2$  molecule. b. In the trigonal planar geometry, the bond contributions to the dipole moment would cancel, giving a zero dipole moment. That would not occur in the **trigonal pyramidal** geometry; hence, this is a possible molecular geometry for  $\text{PH}_3$ .

**Answer Check** Make sure that you have the correct geometry for the molecule, and note how the bonds either oppose one another, to give zero dipole moment, or else do not oppose and so give a dipole moment.

**Exercise 10.3** Bromine trifluoride,  $\text{BrF}_3$ , has a nonzero dipole moment. Indicate which of the following geometries are consistent with this information: a. trigonal planar; b. trigonal pyramidal; c. T-shaped.

See Problems 10.43 and 10.44.

**Exercise 10.4** Which of the following would be expected to have a dipole moment of zero on the basis of symmetry? Explain. a.  $\text{SOCl}_2$ ; b.  $\text{SiF}_4$ ; c.  $\text{OF}_2$ .

See Problems 10.45 and 10.46.

In Example 10.3, the fact that certain molecular geometries necessarily imply a zero dipole moment allowed us to eliminate these geometries when considering a molecule with a nonzero dipole moment. The reverse argument does not follow, however. For example, suppose a molecule of the type  $\text{AX}_3$  is found to have no measurable dipole moment. It may be that the geometry is trigonal planar. Another possibility, however, is that the geometry is trigonal pyramidal or T-shaped, but the lone pairs on the central atom offset the polarity of the bonds.

You can see this effect of lone pairs on the dipole moment of nitrogen trifluoride,  $\text{NF}_3$ . Judging by the electronegativity difference, you would expect each N—F bond to be quite polar. Yet the dipole moment of nitrogen trifluoride is only 0.2 D. (By contrast, ammonia has a dipole moment of 1.47 D.) The explanation for the small dipole moment in  $\text{NF}_3$  appears in Figure 10.19. The lone pair on nitrogen has a dipole-moment contribution that is directed outward from the nucleus, because the electrons are offset from the nuclear center. This dipole-moment contribution thus opposes the N—F bond moments. ◀

Can you explain why  $\text{NH}_3$  has such a large dipole moment compared with  $\text{NF}_3$ ?

**Effect of Polarity on Molecular Properties**

Whether a molecule has a dipole moment (that is, whether it is polar or nonpolar) can affect its properties. We will explore this issue in detail in the next chapter (Section 11.5). Briefly, though, we can see why *cis*- and *trans*-1,2-dichloroethene, mentioned in the chapter opening, have different boiling points. The C—Cl bonds are quite polar, because of the relatively large electronegativity difference between C and Cl atoms (0.9); the H—C bonds have moderate polarity (electronegativity difference of 0.4). The bond dipoles (light arrows) add together in *cis*-1,2-dichloroethene to give a polar

**a** The lone-pair and bond contributions to the dipole moment of  $\text{NF}_3$  tend to offset one another.

**b** The electrostatic-potential model of  $\text{NF}_3$  shows the electron density, which increases as the color changes from blue to yellow to red.

**Figure 10.19** ◀

**Explanation of the small dipole moment of  $\text{NF}_3$**

molecule (the total dipole moment is indicated by the heavy arrow). (Note that the electronegative Cl atoms are on the same side in the *cis* molecule.) In the *trans* molecule, the bond dipoles subtract to give a nonpolar molecule.

In a liquid, polar molecules tend to orient so that positive ends of molecules are attracted to negative ends. This results in an attractive force between molecules (an *intermolecular* force), which increases the energy required for the liquid to boil, and therefore increases the boiling point. Recall that the *trans* compound boils at  $48^\circ\text{C}$ , whereas the *cis* compound boils at a higher temperature,  $60^\circ\text{C}$ .

### CONCEPT CHECK 10.2

Two molecules, each with the general formula  $\text{AX}_3$ , have different dipole moments. Molecule Y has a dipole moment of zero, whereas molecule Z has a nonzero dipole moment. From this information, what can you say about the geometries of Y and Z?

## 10.3 Valence Bond Theory

The VSEPR model is usually a satisfactory method for predicting molecular geometries. To understand bonding and electronic structure, however, you must look to quantum mechanics. We will consider two theories stemming from quantum mechanics: valence bond theory and molecular orbital theory. Both use the methods of quantum mechanics but make different simplifying assumptions. In this section, we will look in a qualitative way at the basic ideas involved in **valence bond theory**, an *approximate theory to explain the electron pair or covalent bond by quantum mechanics*.

Figure 10.20 ▲

**Formation of  $H_2$**  The H—H bond forms when the  $1s$  orbitals, one from each atom, overlap.

Figure 10.21 ▲

**Bonding in HCl** The bond forms by the overlap of a hydrogen  $1s$  orbital (blue) along the axis of a chlorine  $3p$  orbital (green).

### Basic Theory

According to valence bond theory, a bond forms between two atoms when the following conditions are met:

1. An orbital on one atom comes to occupy a portion of the same region of space as an orbital on the other atom. The two orbitals are said to *overlap*.
2. The sum of the electrons in both orbitals is no more than two.

As the orbital of one atom overlaps the orbital of another, the electrons in the orbitals begin to move about both atoms. Because the electrons are attracted to both nuclei at once, they pull the atoms together. Strength of bonding depends on the amount of overlap; the greater the overlap, the greater the bond strength. The two orbitals cannot contain more than two electrons because a given region of space can hold only two electrons with opposite spin.

For example, consider the formation of the  $H_2$  molecule from atoms. Each atom has the electron configuration  $1s^1$ . As the H atoms approach each other, their  $1s$  orbitals begin to overlap and a covalent bond forms (Figure 10.20). Valence bond theory also explains why two He atoms (each with electron configuration  $1s^2$ ) do not bond. Suppose two He atoms approach one another and their  $1s$  orbitals begin to overlap. Each orbital is doubly occupied, so the sharing of electrons between atoms would place the four valence electrons from the two atoms in the same region. This, of course, could not happen. As the orbitals begin to overlap, each electron pair strongly repels the other. The atoms come together, then fly apart.

Because the strength of bonding depends on orbital overlap, orbitals other than  $s$  orbitals bond only in given directions. *Orbitals bond in the directions in which they protrude or point, to obtain maximum overlap.* Consider the bonding between a hydrogen atom and a chlorine atom to give the HCl molecule. A chlorine atom has the electron configuration  $[Ne]3s^23p^5$ . Of the orbitals in the valence shell of the chlorine atom, three are doubly occupied by electrons and one (a  $3p$  orbital) is singly occupied. The bonding of the hydrogen atom has to occur with the singly occupied  $3p$  orbital of chlorine. For the strongest bonding to occur, the maximum overlap of orbitals is required. The  $1s$  orbital of hydrogen must overlap along the axis of the singly occupied  $3p$  orbital of chlorine (see Figure 10.21).

### Hybrid Orbitals

From what has been said, you might expect the number of bonds formed by a given atom to equal the number of unpaired electrons in its valence shell. Chlorine, whose orbital diagram is

has one unpaired electron and forms one bond. Oxygen, whose orbital diagram is

has two unpaired electrons and forms two bonds, as in  $H_2O$ .

However, consider the carbon atom, whose orbital diagram is

You might expect this atom to bond to two hydrogen atoms to form the  $\text{CH}_2$  molecule. Although this molecule is known to be present momentarily during some reactions, it is very reactive and cannot be isolated. But methane,  $\text{CH}_4$ , in which the carbon atom bonds to four hydrogen atoms, is well known. In fact, a carbon atom usually forms four bonds.

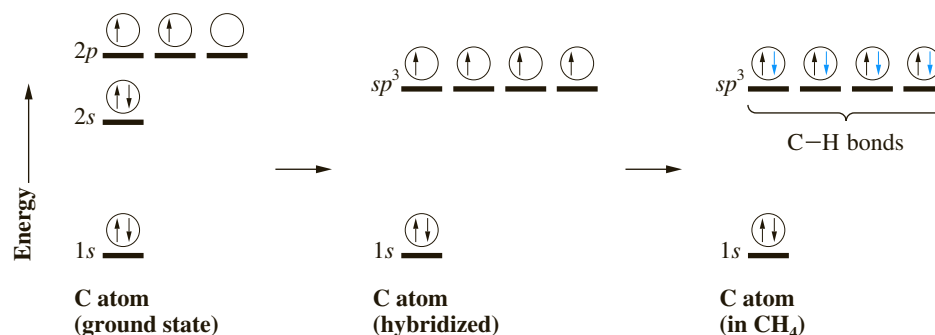

You might explain this as follows: Four unpaired electrons are formed when an electron from the  $2s$  orbital of the carbon atom is *promoted* (excited) to the vacant  $2p$  orbital.

It would require energy to promote the carbon atom this way, but more than enough energy would be obtained from the formation of two additional covalent bonds. One bond would form from the overlap of the carbon  $2s$  orbital with a hydrogen  $1s$  orbital. Each of the other three bonds would form from a carbon  $2p$  orbital and a hydrogen  $1s$  orbital.

Experiment shows, however, that the four C—H bonds in methane are identical. ▶ This implies that the carbon orbitals involved in bonding are also equivalent. For this reason, valence bond theory assumes that the four valence orbitals of the carbon atom combine during the bonding process to form four new, but equivalent, hybrid orbitals. **Hybrid orbitals** are *orbitals used to describe bonding that are obtained by taking combinations of atomic orbitals of the isolated atoms*. In this case, a set of hybrid orbitals is constructed from one  $s$  orbital and three  $p$  orbitals, so they are called  $sp^3$  hybrid orbitals. Calculations from theory show that each  $sp^3$  hybrid orbital has a large lobe pointing in one direction and a small lobe pointing in the opposite direction. The four  $sp^3$  hybrid orbitals point in tetrahedral directions. Figure 10.22a shows the shape of a single  $sp^3$  orbital; Figure 10.22b shows a stylized set of four orbitals pointing in tetrahedral directions.

The C—H bonds in methane,  $\text{CH}_4$ , are described by valence bond theory as the overlapping of each  $sp^3$  hybrid orbital of the carbon atom with  $1s$  orbitals of hydrogen atoms (see Figure 10.22c). Thus, the bonds are arranged tetrahedrally, which is predicted by the VSEPR model. You can represent the hybridization of carbon and the bonding of hydrogen to the carbon atom in methane as follows:

Nuclear magnetic resonance (page 242) and infrared spectroscopy (page 305) both show that  $\text{CH}_4$  has four equivalent C—H bonds.

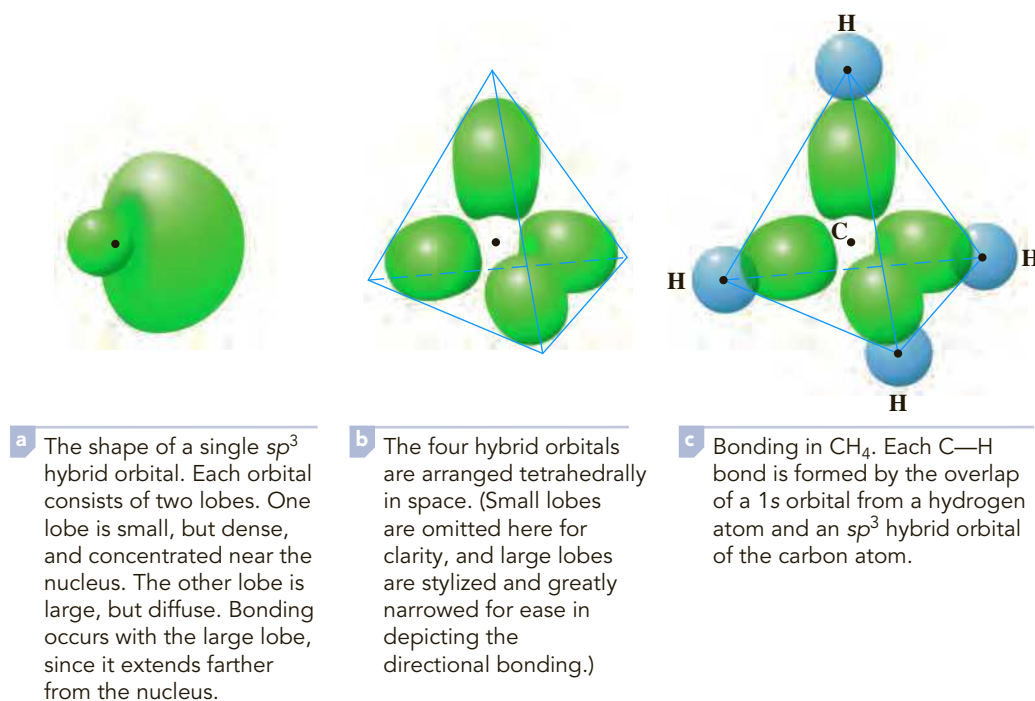

Figure 10.22 ▲

**Spatial arrangement of  $sp^3$  hybrid orbitals**

Here the blue arrows represent electrons originally belonging to hydrogen atoms.

Hybrid orbitals can be formed from various numbers of atomic orbitals. *The number of hybrid orbitals formed always equals the number of atomic orbitals used.* For example, if you combine an  $s$  orbital and two  $p$  orbitals to get a set of equivalent orbitals, you get three hybrid orbitals (called  $sp^2$  hybrid orbitals). A set of hybrid orbitals always has definite directional characteristics. Here, all three  $sp^2$  hybrid orbitals lie in a plane and are directed at  $120^\circ$  angles to one another; that is, they have a trigonal planar arrangement. Some possible hybrid orbitals and their geometric arrangements are listed in Table 10.2 and shown in Figure 10.23. Note that the geometric arrangements of hybrid orbitals are the same as those for electron pairs in the VSEPR model.

Only two of the three  $p$  orbitals are used to form  $sp^2$  hybrid orbitals. The unhybridized  $p$  orbital is perpendicular to the plane of the  $sp^2$  hybrid orbitals. Similarly, only one of the three  $p$  orbitals is used to form  $sp$  hybrid orbitals. The two unhybridized  $p$  orbitals are perpendicular to the axis of the  $sp$  hybrid orbitals and perpendicular to each other. We will use these facts when we discuss multiple bonding in the next section.

Now that you know something about hybrid orbitals, let us develop a general scheme for describing the bonding about any atom (we will call this the central atom). First, notice from Table 10.2 that there is a relationship between the type of hybrid orbitals on an atom and the geometric arrangement of those orbitals. If you know one, you can infer the other. Thus, if you know the geometric arrangement, you know what hybrid orbitals to use in the bond description of the central atom. Your first task in describing the bonding, then, is to obtain the geometric arrangement about the central atom. In lieu of experimental information about the geometry, you can use the VSEPR model, since it proves to be a fairly good predictor of molecular geometry. To obtain the bonding description about any atom in a molecule, you proceed as follows:

Hybrid Orbitals	Geometric Arrangement	Number of Orbitals	Example
$sp$	Linear	2	Be in $\text{BeF}_2$
$sp^2$	Trigonal planar	3	B in $\text{BF}_3$
$sp^3$	Tetrahedral	4	C in $\text{CH}_4$

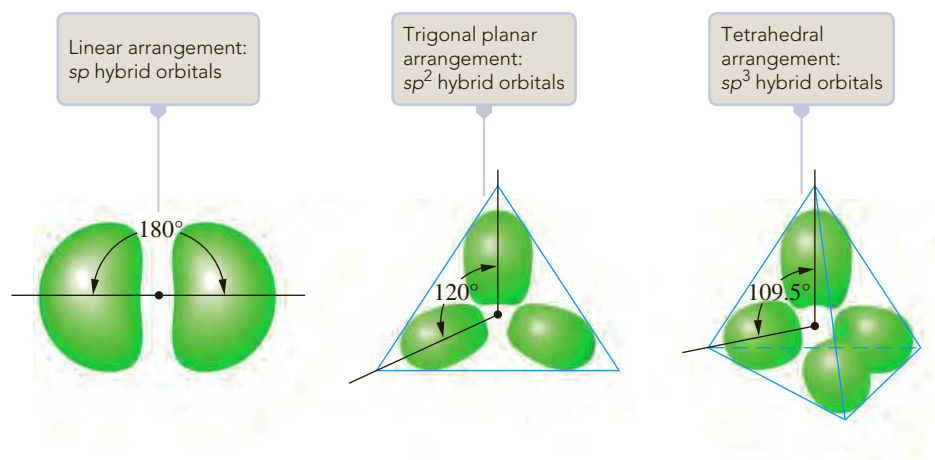

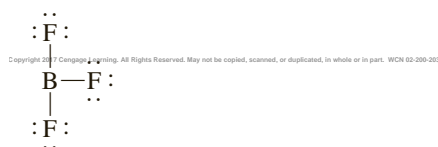

Figure 10.23 ◀

**Diagrams of hybrid orbitals showing their spatial arrangements** Each lobe shown is one hybrid orbital (small lobes are omitted for clarity).

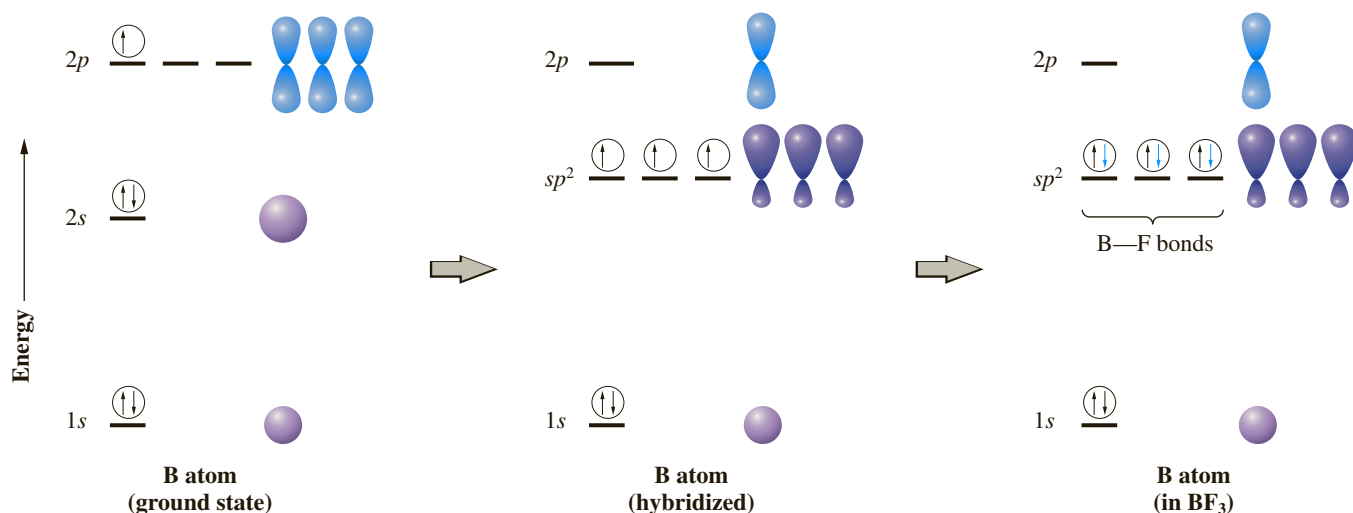

- Step 1:** Write the Lewis electron-dot formula of the molecule.
- Step 2:** From the Lewis formula, use the VSEPR model to obtain the arrangement of electron pairs about this atom.
- Step 3:** From the geometric arrangement of the electron pairs, deduce the type of hybrid orbitals on this atom required for the bonding description (see Table 10.2).
- Step 4:** Assign valence electrons to the hybrid orbitals of this atom one at a time, pairing them only when necessary.
- Step 5:** Form bonds to this atom by overlapping singly occupied orbitals of other atoms with the singly occupied hybrid orbitals of this atom.

As an application of this scheme, let us look at the  $\text{BF}_3$  molecule and obtain the bond description of the boron atom. Following Step 1, you write the Lewis formula of  $\text{BF}_3$ :

Now you apply the VSEPR model to the boron atom (Step 2). There are three electron pairs about the boron atom, so they are expected to have a planar trigonal arrangement. Looking at Table 10.2 (Step 3), you note that three  $sp^2$  hybrid orbitals have a trigonal planar arrangement. In Step 4, you assign the valence electrons of the boron atom to the hybrid orbitals. Finally, in Step 5, you imagine three fluorine atoms approaching the boron atom. The singly occupied  $2p$  orbital on a fluorine atom overlaps one of the  $sp^2$  hybrid orbitals on boron, forming a covalent bond. Three such B—F bonds form. Note that one of the  $2p$  orbitals of boron remains unhybridized and is unoccupied by electrons. It is oriented

perpendicular to the molecular plane. You can summarize these steps using orbital diagrams as follows:

The next example further illustrates how to describe the bonding about an atom in a molecule. To solve problems of this type, you need to know the geometric arrangements of the hybrid orbitals listed in Table 10.2.

### Example 10.4 Applying Valence Bond Theory (Two, Three, or Four Electron Pairs)

#### Gaining Mastery Toolbox

##### Critical Concept 10.4

Using the VSEPR model, determine the geometry about the central atom and then the hybrid orbitals of the atom. Now form bonds by overlapping these hybrid orbitals with orbitals from bonding atoms; use nonbonded hybrid orbitals for the lone pairs.

##### Solution Essentials:

- Bond formation by orbital overlap
- Kinds of hybrid orbitals
- VSEPR model
- Electron-dot formulas

Figure 10.24 ▲

**Bonding in  $H_2O$**  Orbitals on oxygen are  $sp^3$  hybridized; bonding is tetrahedral.

Describe the bonding in  $H_2O$  according to valence bond theory. Assume that the molecular geometry is the same as given by the VSEPR model.

**Problem Strategy** From the Lewis formula for a molecule, determine its geometry about the central atom using the VSEPR model. From this geometry, determine the hybrid orbitals on this atom, assigning its valence electrons to these orbitals one at a time. Finally, form bonds by overlapping these hybrid orbitals with orbitals of the other atoms.

**Solution** The Lewis formula for  $H_2O$  is

Note that there are four pairs of electrons about the oxygen atom. According to the VSEPR model, these are directed tetrahedrally, and from Table 10.2 you see that you should use  $sp^3$  hybrid orbitals. Each O—H bond is formed by the overlap of a 1s orbital of a hydrogen atom with one of the singly occupied  $sp^3$  hybrid orbitals of the oxygen atom. You can represent the bonding to the oxygen atom in  $H_2O$  as follows (see also Figure 10.24):

(continued)

**Example 10.4** (continued)

**Answer Check** Check that you have the correct Lewis formula for the molecule and that you have the correct geometry about the central atom and the correct hybrid orbitals (Table 10.2).

**Exercise 10.5** Using hybrid orbitals, describe the bonding in  $\text{NH}_3$  according to valence bond theory.

See Problems 10.47, 10.48, 10.49, and 10.50.

The actual angle between O—H bonds in  $\text{H}_2\text{O}$  has been experimentally determined to be  $104.5^\circ$ . Because this is close to the tetrahedral angle ( $109.5^\circ$ ), the description of bonding given in Example 10.4 is essentially correct. To be more precise, you should note that the hybrid orbitals for bonds and lone pairs are not exactly equivalent. The lone pairs are somewhat larger than bonding pairs. Because they take up more space, the lone pairs push the bonding pairs closer together than they are in the exact tetrahedral case.

### More Than Eight Electrons About a Central Atom

In the original discussion of  $sp$ ,  $sp^2$ , and  $sp^3$  hybrid orbitals by Linus Pauling, he also described hybrid orbitals involving  $d$  atomic orbitals. For example,  $sp^3d$  orbitals yield 5 orbitals in a trigonal bipyramidal arrangement, and  $sp^3d^2$  orbitals yield 6 orbitals in an octahedral arrangement. They have been used to describe molecules such as  $\text{PF}_5$ , which has a trigonal bipyramidal geometry, and  $\text{SF}_6$ , which has an octahedral geometry, and the descriptions have appeared in many textbooks (including earlier editions of this one). However, as recent quantum mechanical calculations have shown, this description with  $d$  orbitals does not appear tenable. This doesn't mean that valence bond theory cannot be applied to these molecules. Valence bond calculations for the electronic structure of  $\text{SF}_6$ , for example, have been made, but they are much more complicated to describe than we want to get involved in here.

This is a good time to pause to discuss again how science proceeds. (You may want to review this topic in Section 1.2.) A tentative explanation or hypothesis of an experimental phenomenon is proposed. Further work may either agree with this explanation or not. If it agrees, that is fine for the moment. But if it doesn't agree, either the explanation is altered or it is replaced by an improved explanation. In this way, science continues to progress. You may learn an explanation here or in another area (say, in what is good for your health) that one day may become obsolete. As disconcerting as this may appear, it is in the nature of science. No explanation can be said to be absolute. There is always a tentative aspect to it.

Both valence bond theory and molecular orbital theory (which we will describe later in this chapter) are approximate ways of approaching quantum mechanical calculations. They each start with a different view of bonding, but they both can be refined so that they approach one another in accuracy. Earlier in this section, we described the hybrid orbital approach to valence bond theory, and we did that because this is an accessible way to describe bonding. What we have found though is that fairly accurate quantum-mechanical calculations do not substantiate this simple view in the case of hybrid orbitals involving  $d$  atomic orbitals. Of course, quantum mechanics is also a theory that is subject to experimental verification. At the moment, however, it is regarded as one of the most solid theories available to science.

## 10.4 Description of Multiple Bonding

In the previous section, we described bonding as the overlap of *one* orbital from each of the bonding atoms. Now we consider the possibility that *more than one* orbital from each bonding atom might overlap, resulting in a multiple bond.

As an example, consider the ethylene molecule.

One hybrid orbital is needed for each bond (whether a single or a multiple bond) and for each lone pair. Because each carbon atom is bonded to three other atoms and there are no lone pairs, three hybrid orbitals are needed. This suggests the use of  $sp^2$  hybrid orbitals on each carbon atom (there are three  $sp^2$  hybrid orbitals; see Table 10.2). Thus, during bonding, the  $2s$  orbital and two of the  $2p$  orbitals of each carbon atom form three hybrid orbitals having trigonal planar orientation. A third  $2p$  orbital on each carbon atom remains unhybridized and is perpendicular to the plane of the three  $sp^2$  hybrid orbitals.

To describe the multiple bonding in ethylene, we must distinguish between two kinds of bonds. A  $\sigma$  (sigma) bond has a cylindrical shape about the bond axis. It is formed either when two  $s$  orbitals overlap, as in  $\text{H}_2$  (Figure 10.25a), or when an orbital with directional character, such as a  $p$  orbital or a hybrid orbital, overlaps another orbital along their axis (Figure 10.25b). The bonds we discussed in the previous section are  $\sigma$  bonds.

A  $\pi$  (pi) bond has an electron distribution above and below the bond axis. It is formed by the sideways overlap of two parallel  $p$  orbitals (see Figure 10.25c). A sideways overlap will not give so strong a bond as an along-the-axis overlap of two

Figure 10.25 ▼  
Sigma and pi bonds

Figure 10.26 ◀  
Bonding in ethylene

a The  $\sigma$ -bond framework in ethylene, formed by the overlap of  $sp^2$  hybrid orbitals on C atoms and  $1s$  orbitals on H atoms.

b The formation of the  $\pi$  bond in ethylene. When the  $2p$  orbitals are perpendicular to one another, there is no overlap and no bond formation. When the two  $-\text{CH}_2$  groups rotate so that the  $2p$  orbitals are parallel, a  $\pi$  bond forms.

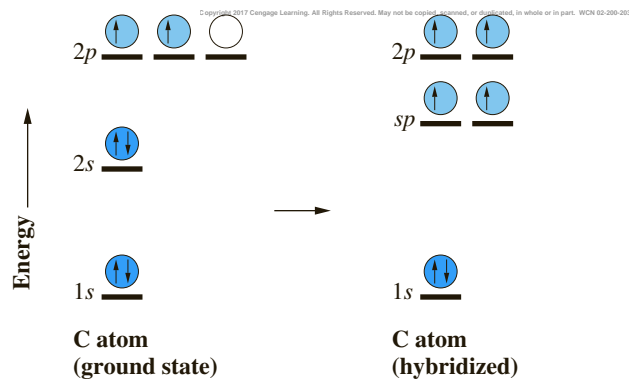

$p$  orbitals. A  $\pi$  bond occurs when two parallel orbitals are still available after strong  $\sigma$  bonds have formed.

Now imagine that the separate atoms of ethylene move into their normal molecular positions. Each  $sp^2$  hybrid carbon orbital overlaps a  $1s$  orbital of a hydrogen atom or an  $sp^2$  hybrid orbital of another carbon atom to form a  $\sigma$  bond (Figure 10.26a). Together, the  $\sigma$  bonds give the molecular framework of ethylene.

As you see from the orbital diagram for the hybridized C atom, a single  $2p$  orbital still remains on each carbon atom. These orbitals are perpendicular to the plane of the hybrid orbitals; that is, they are perpendicular to the  $-\text{CH}_2$  plane. Note that the two  $-\text{CH}_2$  planes can rotate about the carbon-carbon axis without affecting the overlap of the hybrid orbitals. As these planes rotate, the  $2p$  orbitals also rotate. When the  $-\text{CH}_2$  planes rotate so that the  $2p$  orbitals become parallel, the orbitals overlap to give a  $\pi$  bond (Figure 10.26b).

You therefore describe the carbon-carbon double bond as one  $\sigma$  bond and one  $\pi$  bond. Note that when the two  $2p$  orbitals are parallel, the two  $-\text{CH}_2$  ends of the molecule lie in the same plane. Thus, the formation of a  $\pi$  bond “locks” the two ends into a flat, rigid molecule.

You can describe the triple bonding in acetylene,  $\text{H}-\text{C}\equiv\text{C}-\text{H}$ , in similar fashion. Because each carbon atom is bonded to two other atoms and there are no lone pairs, two hybrid orbitals are needed. This suggests  $sp$  hybridization (see Table 10.2).

These  $sp$  hybrid orbitals have a linear arrangement, so the  $\text{H}-\text{C}-\text{C}-\text{H}$  geometry is linear. Bonds formed by the overlap of these hybrid orbitals are  $\sigma$  bonds. The two  $2p$

Figure 10.27 ▶

## Bonding in acetylene

**b** Two  $2p$  orbitals on each carbon atom begin to overlap (symbolized by lines) to form two  $\pi$  bonds.

orbitals not used to construct hybrid orbitals are perpendicular to the bond axis and to each other. They are used to form two  $\pi$  bonds. Thus, the carbon–carbon triple bond consists of one  $\sigma$  bond and two  $\pi$  bonds (see Figure 10.27).

### Example 10.5 Applying Valence Bond Theory (Multiple Bonding)

#### Gaining Mastery Toolbox

##### Critical Concept 10.5

A double bond is described as a  $\pi$  bond plus a  $\sigma$  bond. To describe the bonding, first determine the number of hybrid orbitals on the central atom (equal to the number of electron groups about the atom). Use these orbitals to form sigma bonds and lone pairs. Finally, use unhybridized  $p$  orbitals to form  $\pi$  bonds.

##### Solution Essentials:

- $\sigma$ - and  $\pi$ -bond formation by orbital overlap
- Kinds of hybrid orbitals
- VSEPR model
- Electron-dot formulas

Describe the bonding on a given N atom in dinitrogen difluoride,  $N_2F_2$ , using valence bond theory.

**Problem Strategy** From the Lewis formula, determine the hybrid orbitals on the double-bonded atoms. Do this by counting the number of electron groups about each atom, and from this determine the kind of hybrid orbitals used. Form a  $\sigma$  bond between the double-bonded atoms by overlapping a hybrid orbital of one atom with a hybrid orbital of the other atom. Also, form  $\sigma$  bonds from these atoms to other atoms. Use any unhybridized  $p$  orbitals on the central atoms to form  $\pi$  bonds between them.

**Solution** The electron-dot formula of  $N_2F_2$  is

Note that a double bond is described as a  $\pi$  bond plus a  $\sigma$  bond. Hybrid orbitals are needed to describe each  $\sigma$  bond and each lone pair (a total of three hybrid orbitals for each N atom). This suggests  $sp^2$  hybridization (see Table 10.2). According to this description, one of the  $sp^2$  hybrid orbitals is used to form the N–F bond, another to form the  $\sigma$  bond of N=N, and the third to hold the lone pair on the N atom. The  $2p$  orbitals on each N atom overlap to form the  $\pi$  bond of N=N. Hybridization and bonding of the N atoms are shown as follows:

(continued)

**Example 10.5** (continued)

**Answer Check** Check that the number of hybrid orbitals on an atom of a multiple bond equals the number of sigma bonds plus lone pairs on that atom.

**Exercise 10.6** Describe the bonding on the carbon atom in carbon dioxide,  $\text{CO}_2$ , using valence bond theory. See Problems 10.53 and 10.54.

The  $\pi$ -bond description of the double bond agrees well with experiment. The *geometric*, or *cis-trans*, *isomers* of the compound 1,2-dichloroethene (described in the chapter opening) illustrate this. *Isomers* are compounds of the same molecular formula but with different arrangements of the atoms. (The numbers in the name 1,2-dichloroethene refer to the positions of the chlorine atoms; one chlorine atom is attached to carbon atom 1 and the other to carbon atom 2.) The structures of these isomers of 1,2-dichloroethene are

*cis*-1,2-Dichloroethene    *trans*-1,2-Dichloroethene

To transform one isomer into the other, one end of the molecule must be rotated as the other remains fixed. For this to happen, the  $\pi$  bond must be broken. Breaking the  $\pi$  bond requires considerable energy, so the *cis* and *trans* compounds are not easily interconverted. Contrast this with 1,2-dichloroethane (Figure 10.28), in which the two ends of the molecule can rotate without breaking any bonds. Here isomers corresponding to different spatial orientations of the two chlorine atoms cannot be prepared, because the two ends rotate freely with respect to one another. There is only one compound.

As we noted in the chapter opening, *cis* and *trans* isomers have different properties. The *cis* isomer of 1,2-dichloroethene boils at  $60^\circ\text{C}$ , the *trans* compound at  $48^\circ\text{C}$ . These isomers can also be differentiated on the basis of dipole moment. The *trans* compound has no dipole moment because it is symmetrical (the polar C—Cl bonds point in opposite directions and so cancel). However, the *cis* compound has a dipole moment of 1.85 D.

**Figure 10.28** ◀  
Lack of geometric isomers in 1,2-dichloroethane

It is possible to convert one isomer to another if sufficient energy is supplied—say by chemical reaction. The role of the conversion of a *cis* isomer to its *trans* isomer in human vision is discussed in the essay at the end of Section 10.7.

**Exercise 10.7** Dinitrogen difluoride (see Example 10.5) exists as *cis* and *trans* isomers. Write structural formulas for these isomers and explain (in terms of the valence bond theory of the double bond) why they exist.

See Problems 10.55 and 10.56.

### CONCEPT CHECK 10.3

An atom in a molecule has one single bond and one triple bond to other atoms. What hybrid orbitals do you expect for this atom? Describe how you arrive at your answer.

## ► Molecular Orbital Theory

In the preceding sections, we looked at a simple version of valence bond theory. Although simple valence bond theory satisfactorily describes most of the molecules we encounter, it does not apply to all molecules. For example, according to this theory any molecule with an even number of electrons should be diamagnetic (not attracted to a magnet), because we assume the electrons to be paired and to have opposite spins. In fact, a few molecules with an even number of electrons are paramagnetic (attracted to a magnet), indicating that some of the electrons are not paired. The best-known example of such a paramagnetic molecule is  $O_2$ . Because of the paramagnetism of  $O_2$ , liquid oxygen sticks to a magnet when poured over it (Figure 10.29). Although valence bond theory can be extended to explain the electronic structure of  $O_2$ , molecular orbital theory (an alternative bonding theory) provides a straightforward explanation of the paramagnetism of  $O_2$ .

**Molecular orbital theory** is a theory of the electronic structure of molecules in terms of molecular orbitals, which may spread over several atoms or the entire molecule. This theory views the electronic structure of molecules to be much like the electronic structure of atoms. Each molecular orbital has a definite energy. To obtain the ground state of a molecule, electrons are put into orbitals of lowest energy, consistent with the Pauli exclusion principle, just as in atoms.

### 10.5 Principles of Molecular Orbital Theory

You can think of a molecular orbital as being formed from a combination of atomic orbitals. As atoms approach each other and their atomic orbitals overlap, molecular orbitals are formed.

#### Bonding and Antibonding Orbitals

Consider the  $H_2$  molecule. As the atoms approach to form the molecule, their  $1s$  orbitals overlap. One molecular orbital is obtained by adding the two  $1s$  orbitals (see Figure 10.30). Note that where the atomic orbitals overlap, their values sum to give a larger result. This means that in this molecular orbital, electrons are often found in the region between the two nuclei where the electrons can hold the nuclei together. *Molecular orbitals that are concentrated in regions between nuclei* are called **bonding orbitals**. The bonding orbital in  $H_2$ , which we have just described, is denoted  $\sigma_{1s}$ . The  $\sigma$  (sigma) means that the molecular orbital has a cylindrical shape about the bond axis. The subscript  $1s$  tells us that the molecular orbital was obtained from  $1s$  atomic orbitals.

© Yoav Levy/Phototake

**Figure 10.29** ▲

**Paramagnetism of oxygen,  $O_2$**  Liquid oxygen is poured between the poles of a strong magnet. Oxygen adheres to the poles, showing that it is paramagnetic.

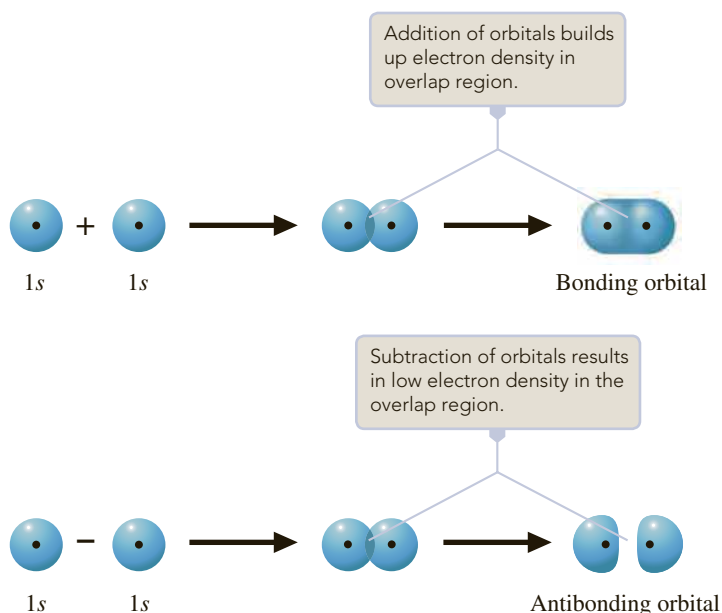

Figure 10.30 ◀

**Formation of bonding and antibonding orbitals from 1s orbitals of hydrogen atoms** When the two 1s orbitals overlap, they can either add to give a bonding molecular orbital or subtract to give an antibonding molecular orbital.

Another molecular orbital is obtained by subtracting the 1s orbital on one atom from the 1s orbital on the other (Figure 10.30). When the orbitals are subtracted, the resulting values in the region of the overlap are close to zero. This means that in this molecular orbital, the electrons spend little time between the nuclei. *Molecular orbitals having zero values in the region between two nuclei and therefore concentrated in other regions* are called **antibonding orbitals**. The antibonding orbital in  $\text{H}_2$ , which we have just described, is denoted  $\sigma_{1s}^*$ . The asterisk, which you read as “star,” tells us that the molecular orbital is antibonding.

Figure 10.31 shows the energies of the molecular orbitals  $\sigma_{1s}$  and  $\sigma_{1s}^*$  relative to the atomic orbitals. Energies of the separate atomic orbitals are represented by heavy black lines at the far left and right. The energies of the molecular orbitals are shown by heavy black lines in the center. (These are connected by dashed lines to show which atomic orbitals were used to obtain the molecular orbitals.) Note that the energy of a bonding orbital is less than that of the separate atomic orbitals, whereas the energy of an antibonding orbital is higher.

You obtain the electron configuration for the ground state of  $\text{H}_2$  by placing the two electrons (one from each atom) into the lower-energy orbital (see Figure 10.31). The orbital diagram is

Copyright 2011 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. WCH 02-200-203

and the electron configuration is  $(\sigma_{1s})^2$ . Because the energy of the two electrons is lower than their energies in the isolated atoms, the  $\text{H}_2$  molecule is stable.

Configurations involving the  $\sigma_{1s}^*$  orbital describe excited states of the molecule. As an example of an excited state, you can write the orbital diagram

The corresponding electron configuration is  $(\sigma_{1s})^1(\sigma_{1s}^*)^1$ .

You obtain a similar set of orbitals when you consider the approach of two helium atoms. To obtain the ground state of  $\text{He}_2$ , you note that there are four electrons, two from each atom, that would fill the molecular orbitals.

Figure 10.31 ▲

**Relative energies of the 1s orbital of the H atom and the  $\sigma_{1s}$  and  $\sigma_{1s}^*$  molecular orbitals of  $\text{H}_2$**  Arrows denote occupation of the  $\sigma_{1s}$  orbital by electrons in the ground state of  $\text{H}_2$ .

Two electrons go into the  $\sigma_{1s}$  orbital and two go into the  $\sigma_{1s}^*$  orbital. The orbital diagram is

and the configuration is  $(\sigma_{1s})^2(\sigma_{1s}^*)^2$ . The energy decrease from the bonding electrons is offset by the energy increase from the antibonding electrons. Hence,  $\text{He}_2$  is not a stable molecule. Molecular orbital theory therefore explains why the element helium exists as a monatomic gas, whereas hydrogen is diatomic.

### Bond Order

The term *bond order* refers to the number of bonds that exist between two atoms. In molecular orbital theory, the bond order of a diatomic molecule is defined as one-half the difference between the number of electrons in bonding orbitals,  $n_b$ , and the number of electrons in antibonding orbitals,  $n_a$ . ◀

$$\text{Bond order} = \frac{1}{2}(n_b - n_a)$$

For  $\text{H}_2$ , which has two bonding electrons,

$$\text{Bond order} = \frac{1}{2}(2 - 0) = 1$$

That is,  $\text{H}_2$  has a single bond. For  $\text{He}_2$ , which has two bonding and two antibonding electrons,

$$\text{Bond order} = \frac{1}{2}(2 - 2) = 0$$

Bond orders need not be whole numbers; half-integral bond orders of  $\frac{1}{2}$ ,  $\frac{3}{2}$ , and so forth are also possible. For example, the  $\text{H}_2^+$  molecular ion, which is formed in mass spectrometers, has the configuration  $(\sigma_{1s})^1$  and a bond order of  $\frac{1}{2}(1 - 0) = \frac{1}{2}$ .

### Factors That Determine Orbital Interaction

The  $\text{H}_2$  and  $\text{He}_2$  molecules are relatively simple. A  $1s$  orbital on one atom interacts with the  $1s$  orbital on the other atom. But now let us consider the  $\text{Li}_2$  molecule. Each Li atom has  $1s$  and  $2s$  orbitals. Which orbitals interact to form molecular orbitals? To find out, you need to understand the factors that determine orbital interaction.

The strength of the interaction between two atomic orbitals to form molecular orbitals is determined by two factors: (1) the energy difference between the interacting orbitals and (2) the magnitude of their overlap. *For the interaction to be strong, the energies of the two orbitals must be approximately equal and the overlap must be large.*

From this last statement, you see that when two Li atoms approach one another to form  $\text{Li}_2$ , only like orbitals on the two atoms interact appreciably. The  $2s$  orbital of one lithium atom interacts with the  $2s$  orbital of the other atom, but the  $2s$  orbital from one atom does not interact with the  $1s$  orbital of the other atom, because their energies are quite different. Also, because the  $2s$  orbitals are outer orbitals, they are able to overlap and interact strongly when the atoms approach. As in  $\text{H}_2$ , these atomic orbitals interact to give a bonding orbital (denoted  $\sigma_{2s}$ ) and an antibonding orbital (denoted  $\sigma_{2s}^*$ ). However, even though the  $1s$  orbitals of the two atoms have the same energy, they do not overlap appreciably and so interact weakly. (The difference in energy between  $\sigma_{1s}$  and  $\sigma_{1s}^*$  is very small.) Figure 10.32 gives the relative energies of the orbitals.

You obtain the ground-state configuration of  $\text{Li}_2$  by putting six electrons (three from each atom) into the molecular orbitals of lowest energy. The configuration of the diatomic molecule  $\text{Li}_2$  is

Figure 10.32 ▲

The energies of the molecular orbitals of  $\text{Li}_2$ . Arrows indicate the occupation of these orbitals by electrons in the ground state.

The  $(\sigma_{1s})^2(\sigma_{1s}^*)^2$  part of the configuration is often abbreviated KK (which denotes the K shells, or inner shells, of the two atoms). These electrons do not have a significant effect on bonding. ▶

In calculating bond order, we can ignore KK (it includes two bonding and two antibonding electrons). Thus, the bond order is 1, as in  $\text{H}_2$ .

In  $\text{Be}_2$ , the energy diagram is similar to that in Figure 10.32. You have eight electrons to distribute (four from each Be atom). The ground-state configuration of  $\text{Be}_2$  is

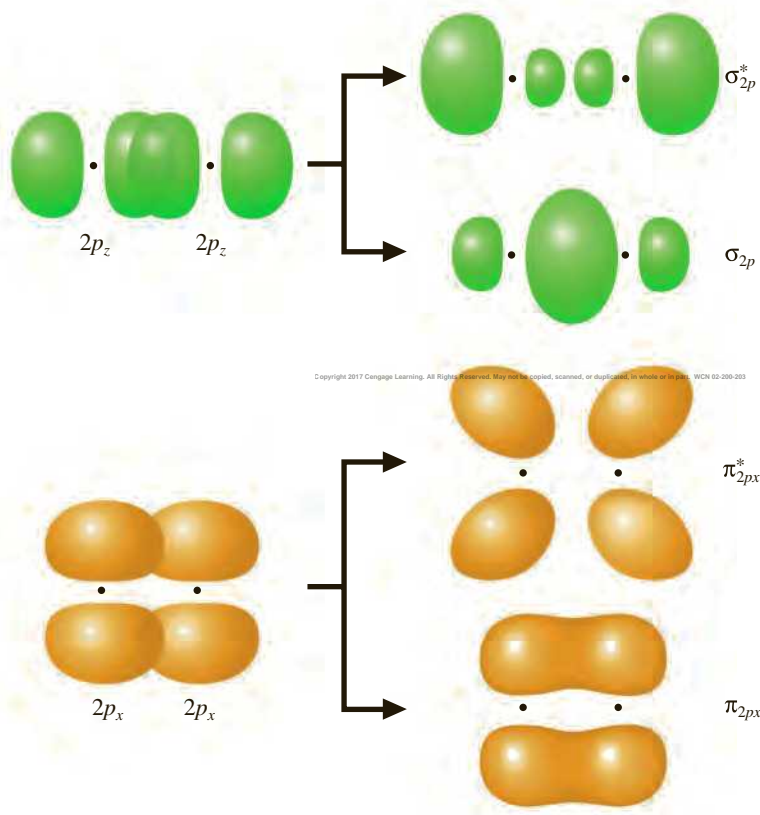

Note that the configuration has two bonding and two antibonding electrons outside the K shells. Thus, the bond order is  $\frac{1}{2}(2 - 2) = 0$ . No bond is formed, so the  $\text{Be}_2$  molecule, like the  $\text{He}_2$  molecule, is unstable.

## 10.6 Electron Configurations of Diatomic Molecules of the Second-Period Elements

The previous section looked at the electron configurations of some simple molecules:  $\text{H}_2$ ,  $\text{He}_2$ ,  $\text{Li}_2$ , and  $\text{Be}_2$ . These are **homonuclear diatomic molecules**—that is, *molecules composed of two like nuclei*. (**Heteronuclear diatomic molecules** are *molecules composed of two different nuclei*—for example, CO and NO.) To find the electron configurations of other homonuclear diatomic molecules, we need to have additional molecular orbitals.

We have already looked at the formation of molecular orbitals from  $s$  atomic orbitals. Now we need to consider the formation of molecular orbitals from  $p$  atomic orbitals. There are two different ways in which  $2p$  atomic orbitals can interact. One set of  $2p$  orbitals can overlap along their axes to give one bonding and one antibonding  $\sigma$  orbital ( $\sigma_{2p}$  and  $\sigma_{2p}^*$ ). The other two sets of  $2p$  orbitals then overlap sideways to give two bonding and two antibonding  $\pi$  orbitals ( $\pi_{2p}$  and  $\pi_{2p}^*$ ). (See Figure 10.33.)

However, small shifts in the energy of the core electrons due to bonding can be measured by X-ray photoelectron spectroscopy (page 250).

Figure 10.33 ◀

**The different ways in which  $2p$  orbitals can interact** Let the  $z$  axis be the bond axis between two atoms. When a  $2p_z$  orbital (lying along the bond axis) on one atom overlaps with a similar  $2p_z$  orbital on the other atom, they interact to form  $\sigma_{2p}$  (bonding sigma orbital) and  $\sigma_{2p}^*$  (antibonding sigma orbital). See at the top of the figure. When a  $2p_x$  orbital (which is perpendicular to the bond axis) overlaps a  $2p_x$  on the other atom, they interact to form  $\pi_{2p_x}$  (bonding pi orbital) and  $\pi_{2p_x}^*$  (antibonding pi orbital). These are shown at the bottom of the figure. Similar pi orbitals ( $\pi_{2p_y}$  and  $\pi_{2p_y}^*$ ) are formed by overlap of the  $2p_y$  orbitals on the two atoms. (The  $2p_y$  orbital is perpendicular to the bond axis and perpendicular to the  $2p_x$  orbital.)

Figure 10.34 ►

**Relative energies of molecular orbitals of homonuclear diatomic molecules (excluding K shells)** The arrows show the occupation of molecular orbitals by the valence electrons of  $N_2$ .

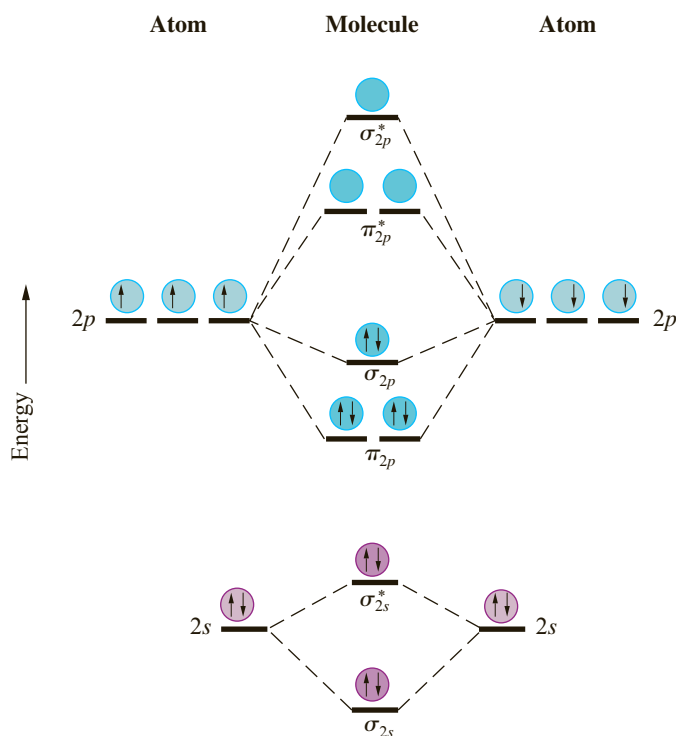

Figure 10.34 shows the relative energies of the molecular orbitals obtained from  $2s$  and  $2p$  atomic orbitals. This order of molecular orbitals reproduces the known electron configurations of homonuclear diatomic molecules composed of elements in the second row of the periodic table. ◀ The order of filling is

Note that there are two orbitals in the  $\pi$  subshell and two orbitals in the  $\pi^*$  subshell. Because each orbital can hold two electrons, a  $\pi$  or  $\pi^*$  subshell can hold four electrons. The next example shows how you can use the order of filling to obtain the orbital diagram, magnetic character, electron configuration, and bond order of a homonuclear diatomic molecule.

This order gives the correct number of electrons in subshells, even though in  $O_2$  and  $F_2$  the energy of  $\sigma_{2p}$  is below  $\pi_{2p}^*$ .

### Example 10.6 Describing Molecular Orbital Configurations (Homonuclear Diatomic Molecules)

#### Gaining Mastery Toolbox

##### Critical Concept 10.6

Place the electrons of a homonuclear diatomic molecule into the molecular orbitals. As in an atom, observe the order of filling of the orbitals, the Pauli exclusion principle, and Hund's rule.

##### Solution Essentials:

- Order of filling of molecular orbitals
- Hund's rule
- Pauli exclusion principle

Give the orbital diagram of the  $O_2$  molecule. Is the molecular substance diamagnetic or paramagnetic? What is the electron configuration? What is the bond order of  $O_2$ ?

**Problem Strategy** Note the order of filling of molecular orbitals for the second-row homonuclear diatomic molecules (given just before this example). Now assign the valence electrons to these orbitals in this order. Pay attention to both the Pauli exclusion principle (no more than two electrons to an orbital, and then only with opposed spins) and Hund's rule (fill all orbitals of a subshell with one electron each—and with the same spins—before pairing electrons in any orbital). Decide whether the substance is diamagnetic (all electrons paired) or paramagnetic (unpaired electrons). Then calculate the bond order equal to  $\frac{1}{2}(\text{number of bonding electrons} - \text{number of antibonding electrons})$ .

(continued)

**Example 10.6** (continued)

**Solution** There are 12 valence electrons in  $O_2$  (six from each atom), which occupy the molecular orbitals as shown in the following orbital diagram:

Note that the two electrons in the  $\pi_{2p}^*$  subshell must go into different orbitals with their spins in the same direction (Hund's rule). Because there are two unpaired electrons, the molecular substance is **paramagnetic**. The electron configuration is

There are eight bonding electrons and four antibonding electrons. Therefore,

$$\text{Bond order} = \frac{1}{2}(8 - 4) = 2$$

**Answer Check** Check that the number of electrons assigned to orbitals equals the number of valence electrons of the two atoms. Make sure that the Pauli exclusion principle and Hund's rule have been properly applied.

**Exercise 10.8** The  $C_2$  molecule exists in the vapor phase over carbon at high temperature. Describe the molecular orbital structure of this molecule; that is, give the orbital diagram and electron configuration. Would you expect the molecular substance to be diamagnetic or paramagnetic? What is the bond order for  $C_2$ ?

See Problems 10.57 and 10.58.

Table 10.3 compares experimentally determined bond lengths, bond dissociation energies, and magnetic character of the second-period homonuclear diatomic molecules with the bond order calculated from molecular orbital theory, as in the preceding example. Note that as the bond order increases, bond length tends to decrease and bond dissociation energy tends to increase. You should be able to verify that the experimentally determined magnetic character of the molecule, given in the last column of the table, is correctly predicted by molecular orbital theory.

When the atoms in a heteronuclear diatomic molecule are close to one another in a row of the periodic table, the molecular orbitals have the same relative order of energies as those for homonuclear diatomic molecules. In this case, you can obtain the electron configurations in the same way, as the next example illustrates.

**Table 10.3** Theoretical Bond Orders and Experimental Data for the Second-Period Homonuclear Diatomic Molecules

Molecule	Bond Order	Bond Length (pm)	Bond Dissociation Energy (kJ/mol)	Magnetic Character
$Li_2$	1	267	110	Diamagnetic
$Be_2$	0	*	*	*
$B_2$	1	159	290	Paramagnetic
$C_2$	2	124	602	Diamagnetic
$N_2$	3	110	942	Diamagnetic
$O_2$	2	121	494	Paramagnetic
$F_2$	1	142	155	Diamagnetic
$Ne_2$	0	*	*	*

The symbol \* means that no stable molecule has been observed.

**Example 10.7 Describing Molecular Orbital Configurations (Heteronuclear Diatomic Molecules)****Gaining Mastery Toolbox****Critical Concept 10.7**

If the two different atoms of a heteronuclear diatomic molecule are close to one another in the periodic table, you can use the same order of the filling of orbitals that you used for homonuclear diatomic molecules.

**Solution Essentials:**

- Order of filling of molecular orbitals
- Hund's rule
- Pauli exclusion principle

Write the molecular orbital diagram for nitrogen monoxide (nitric oxide), NO. What is the bond order of NO?

**Problem Strategy** If the two different atoms of the molecule are close to one another in the periodic table, then you can assume that the order of filling is the same as that for homonuclear diatomic molecules. After that, the procedure is similar to that for a homonuclear molecule (see Example 10.6).

**Solution** You assume that the order of filling of orbitals is the same as for homonuclear diatomic molecules. There are 11 valence electrons in NO. Thus, the orbital diagram is

Because there are eight bonding and three antibonding electrons,

$$\text{Bond order} = \frac{1}{2}(8 - 3) = \frac{5}{2}$$

**Answer Check** Check that the number of electrons assigned to orbitals equals the number of valence electrons of the two atoms. Make sure that the Pauli exclusion principle and Hund's rule have been properly applied.

**Exercise 10.9** Give the orbital diagram and electron configuration for the carbon monoxide molecule, CO. What is the bond order of CO? Is the molecule diamagnetic or paramagnetic?

See Problems 10.59 and 10.60.

When the two atoms in a heteronuclear diatomic molecule differ appreciably, you can no longer use the scheme appropriate for homonuclear diatomic molecules. The HF molecule is an example. Figure 10.35 shows the relative energies of the molecular orbitals that form. Sigma bonding and antibonding orbitals are formed by combining the  $1s$  orbital on the H atom with the  $2p$  orbital on the F atom that lies along the bond axis. The  $2s$  orbital and the other  $2p$  orbitals on fluorine remain as *nonbonding* orbitals (neither bonding nor antibonding). Note that the energy of the  $2p$  subshell in fluorine is lower than the energy of the  $1s$  orbital in hydrogen, because the fluorine electrons are more tightly held. As a result, the bonding orbital is made up of a greater percentage of the  $2p$  fluorine orbital than of the  $1s$  hydrogen orbital. This means that electrons in the bonding molecular orbital spend more time in the vicinity of the fluorine atom; that is, the H—F bond is polar, with the F atom having a small negative charge.

**10.7 Molecular Orbitals and Delocalized Bonding**

One of the advantages of using molecular orbital theory is the simple way in which it describes molecules with delocalized bonding. Whereas valence bond theory requires two or more resonance formulas, molecular orbital theory describes the bonding in terms of a single electron configuration.

Consider the ozone molecule as an example. In the previous chapter, we described this molecule in terms of resonance as follows:

Some of these electrons are localized either on one atom or between an oxygen–oxygen bond (these are printed in black). The other electrons are delocalized (these

are printed in blue). They are the electron pairs that change position in going from one resonance formula to the other.

Each O atom has three localized electron pairs about it, which suggests that each atom uses  $sp^2$  hybrid orbitals (see Table 10.2). The overlap of one hybrid orbital on the center O atom with a hybrid orbital on the end O atom at the left forms the left O—O bond (Figure 10.36). The overlap of another hybrid orbital on the center O atom with a hybrid orbital on the end O atom at the right forms the other O—O bond. This leaves one hybrid orbital on the center O atom and two on each of the end O atoms for lone pairs.

After the hybrid orbitals are formed, one unhybridized  $p$  orbital remains on each O atom. These three  $p$  orbitals are perpendicular to the plane of the molecule and parallel to one another. They can overlap sideways to give three  $\pi$  molecular orbitals. (Three interacting atomic orbitals produce three molecular orbitals.) All three will span the entire molecule (Figure 10.37). One of these orbitals turns out to be antibonding; one is nonbonding (that is, it has an energy equal to that of the isolated atoms); and the third is bonding.

The bonding and nonbonding  $\pi$  orbitals are both doubly occupied. This agrees with the resonance description, in which one delocalized pair is bonding and the other is a lone (nonbonding) pair on the end oxygen atoms.

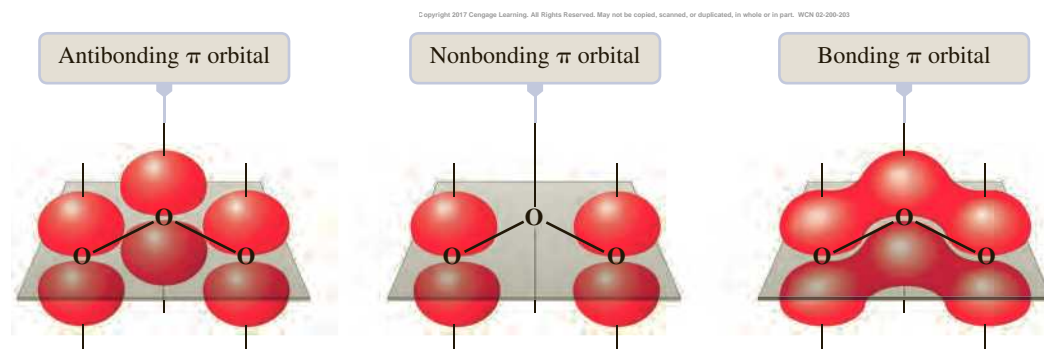

Figure 10.37 ▲

**The electron distributions of the  $\pi$  molecular orbitals of  $O_3$**  Note that one molecular orbital is nonbonding. It describes a lone pair of electrons that can be on either of the end-oxygen atoms.

Figure 10.35 ▲

**Relative energies of molecular orbitals in the valence shell of HF** Arrows show the occupation of orbitals by electrons.

Figure 10.36 ◀

**Hybrid orbitals on oxygen atoms of ozone,  $O_3$**  Each oxygen atom has  $sp^2$  hybrid orbitals. One hybrid orbital on the center atom and one hybrid orbital on the left atom overlap to form a single bond at the left. Similar orbitals at the right form another single bond. Each atom has a  $\pi$  orbital perpendicular to the plane of these hybrid orbitals.

## Human Vision

Life Science

Human vision, as well as the detection of light by other organisms, is known to involve a compound called 11-*cis*-retinal. The structural formula is shown on the left side of Figure 10.38. This compound, which is derived from vitamin A, is contained in two kinds of cells—rod cells and cone cells—located in the retina of the eye. Rod cells are responsible for vision in dim light. They give the sensation of light or dark but no sensation of color. Cone cells are responsible for color vision, but they require bright light. Color vision is possible because three types of cone cells exist: one type absorbs light in the red region of the spectrum, another absorbs in the green region, and a third absorbs in the blue region. In each of these different cells, 11-*cis*-retinal is attached to a different protein molecule, which affects the region of light that is absorbed by retinal.

When a photon of light is absorbed by 11-*cis*-retinal, it is transformed to 11-*trans*-retinal (see Figure 10.38). This small change at one carbon-carbon double bond results in a large movement of one end of the molecule with respect to the other. In other words, the absorption of a single photon results in a significant change in molecular geometry. This change in shape of retinal also affects the shape of the protein molecule to which it is attached, and *this* change results in a sequence of events, not completely understood, in which an electrical signal is generated.

To understand the *cis-trans* conversion when a photon is absorbed, consider the similar, but simpler, molecule *cis*-1,2-dichloroethene (see structural formula on page 310). The double bond consists of  $\sigma$  bond and a  $\pi$  bond. The  $\pi$  bond results from two electrons in a  $\pi$ -type molecular orbital. A corresponding antibonding orbital,  $\pi^*$ , has higher

energy than the  $\pi$  orbital and is unoccupied in the ground state. When a photon of light in the ultraviolet region (near 180 nm) is absorbed by *cis*-1,2-dichloroethene, an electron in the  $\pi$  orbital undergoes a transition to the  $\pi^*$  orbital. Whereas there were previously two electrons in the bonding  $\pi$  orbital (contributing one bond), there is now one electron in the bonding orbital and one in the antibonding orbital (with zero net bonding). As a result of the absorption of a photon, the double bond becomes a single bond and rotation about the bond is now possible. The *cis* isomer tends to rotate to the *trans* isomer, which is more stable. Then energy is lost as heat, and the electron in the  $\pi^*$  orbital undergoes a transition back to the  $\pi$  orbital; the single bond becomes a double bond again. The net result is the conversion of the *cis* isomer to the *trans* isomer.

Retinal differs from dichloroethene in having six double bonds alternating with single bonds instead of only one double bond. The alternating double and single bonds give a rigid structure, and when the middle double bond undergoes the *cis*-to-*trans* change, a large movement of atoms occurs. Another result of a long chain of alternating double and single bonds is a change in the wavelength of light absorbed in the  $\pi$ -to- $\pi^*$  transition. Dichloroethene absorbs in the ultraviolet region, but retinal attached to its protein absorbs in the visible region. (The attached protein also alters the wavelength of absorbed light.) Many biological compounds that are colored consist of long chains of alternating double and single bonds.  $\beta$ -Carotene, a yellow pigment in carrots, has this structure. It is broken down in the body to give vitamin A, from which retinal is derived.

Figure 10.38 ▲

The *cis-trans* conversion of retinal on absorption of light Note the large movement of atoms caused by the rotation about the double bond between carbon atoms 11 and 12.

## Environment

A CHEMIST Looks at . . .

# Stratospheric Ozone (An Absorber of Ultraviolet Rays)

Ozone (also known as trioxygen,  $O_3$ ) is a reactive form of oxygen having a bent molecular geometry, as you would predict from its resonance formulas:

Ozone forms in the atmosphere whenever  $O_2$  is irradiated by ultraviolet light or subjected to electrical discharges. On bright sunny days, you might notice the fresh-air smell of dilute ozone (trioxygen,  $O_3$ ). Around electrical equipment, however, ozone often occurs in higher concentrations and has a disagreeable odor.

Although ozone occurs at ground level and is an ingredient of *photochemical smog*, it is an essential component of the *stratosphere*, which occurs at about 10 to 15 km above ground level. Ozone in the stratosphere absorbs ultraviolet radiation between 200 and 300 nm, which is vitally important to life on earth. Radiation from the sun contains ultraviolet rays that are harmful to the DNA of biological organisms. Oxygen,  $O_2$ , absorbs the most energetic of these ultraviolet rays in the earth's upper atmosphere, but only ozone in the stratosphere absorbs the remaining ultraviolet radiation that is destructive to life on earth (Figure 10.39).

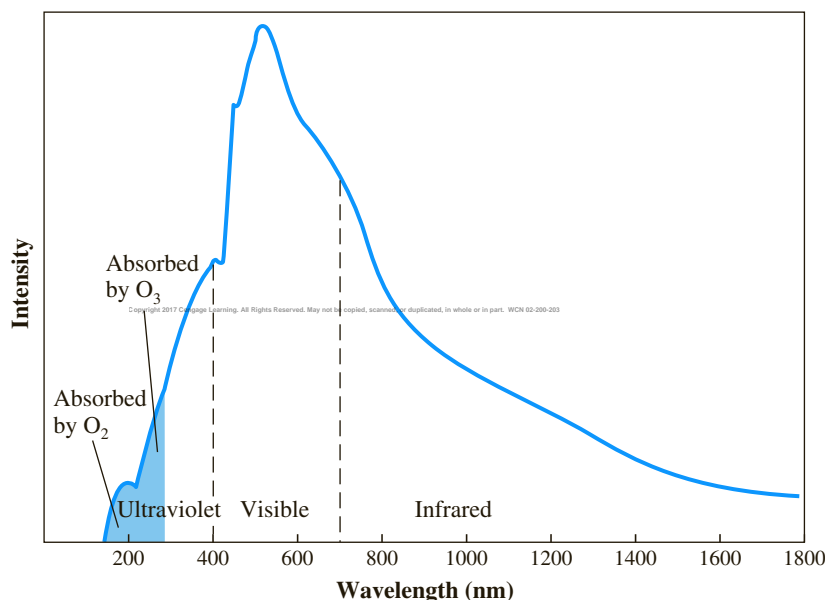

In 1974, Mario J. Molina and F. Sherwood Rowland expressed concern that chlorofluorocarbons (CFCs), such as

$CClF_3$  and  $CCl_2F_2$ , would be a source of chlorine atoms that could catalyze the decomposition of ozone in the stratosphere, so that the ozone would be destroyed faster than it could be produced. The chlorofluorocarbons are relatively inert compounds that were used as refrigerants, spray-can propellants, and blowing agents (substances used to produce plastic foams). As a result of their inertness, however, CFCs concentrate in the atmosphere, where they steadily rise into the stratosphere. Once they are in the stratosphere, ultraviolet light decomposes them to form chlorine atoms, which react with ozone to form  $ClO$  and  $O_2$ . The  $ClO$  molecules react with oxygen atoms in the stratosphere to regenerate  $Cl$  atoms.

The net result is the decomposition of ozone to dioxygen. Chlorine atoms are consumed in the first step but regenerated in the second. Thus, chlorine atoms are not used up, so they function as a catalyst.

In 1985, British researchers reported that the ozone over the Antarctic had been declining precipitously each spring for several years, although it returned the following winter. Then in August 1987, an expedition was assembled

**Figure 10.39** ▲

**The solar spectrum** Radiation below 200 nm is absorbed in the upper atmosphere by  $O_2$ . Ultraviolet radiation between 200 and 300 nm is absorbed by  $O_3$  in the stratosphere.

(continued)

## A CHEMIST Looks at . . . Stratospheric Ozone (An Absorber of Ultraviolet Rays) *(continued)*

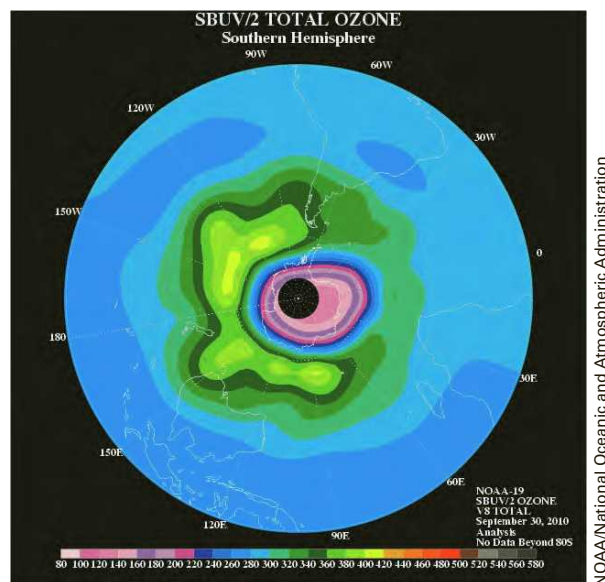

to begin flights through the “ozone hole” with instruments (Figure 10.40). Researchers found that wherever ozone is depleted in the stratosphere, chlorine monoxide (ClO) appears, as expected if chlorine atoms are catalyzing the depletion (see the previous reactions). The chlorofluorocarbons are the suspected source of these chlorine atoms, and by international treaty they are being phased out of production. Refrigerators and air conditioners, for example, now use hydrofluorocarbons (HFCs), such as R410A, which is

a mixture of  $\text{CH}_2\text{F}_2$  and  $\text{CF}_3\text{CHF}_2$ . The ozone layer is expected to recover by about 2070.

In October 1995, Sherwood Rowland (University of California, Irvine), Mario Molina (Massachusetts Institute of Technology), and Paul Crutzen (Max Planck Institute, Mainz, Germany) were awarded the Nobel Prize in chemistry for their work on stratospheric ozone depletion. Crutzen studied the effect of nitrogen oxides in catalyzing the decomposition of ozone.

### Figure 10.40 ►

**Total stratospheric ozone over the Southern Hemisphere** This computer image shows the total quantity of ozone over the Southern Hemisphere in Dobson units (equivalent to the thickness, in units of  $10^{-2}$  mm, of total ozone, assuming it to be compressed to 1 atm at  $0^\circ\text{C}$ ). The ozone depletion is shown near the South Pole (pink color; black color indicates no data). The data are from the SBUV/2 instrument on board the National Oceanic and Atmospheric Administration’s polar orbiting satellite.

### Summary of Facts and Concepts

*Molecular geometry* refers to the spatial arrangement of atoms in a molecule. The *valence-shell electron-pair repulsion (VSEPR) model* is a simple model for predicting molecular geometries. It is based on the idea that the valence-shell electron pairs are arranged symmetrically about an atom to minimize electron-pair repulsion. The geometry about an atom is then determined by the directions of the bonding pairs. Information about the geometry of a molecule can sometimes be obtained from the experimentally determined presence or absence of a *dipole moment*.

The bonding and geometry in a molecule can be described in terms of *valence bond theory*. In this theory, a

bond is formed by the overlap of orbitals from two atoms. *Hybrid orbitals*, a set of equivalent orbitals formed by combining atomic orbitals, are often needed to describe this bond. Multiple bonds occur via the overlap of atomic orbitals to give  $\sigma$  bonds and  $\pi$  bonds. *Cis-trans* isomers result from the molecular rigidity imposed by a  $\pi$  bond.

*Molecular orbital theory* can also be used to explain bonding in molecules. According to this theory, electrons in a molecule occupy orbitals that may spread over the entire molecule. You can think of these molecular orbitals as constructed from atomic orbitals. Thus, when two atoms approach to form a diatomic molecule, the atomic orbitals

interact to form *bonding* and *antibonding* molecular orbitals. The electron configuration of a diatomic molecule such as  $O_2$  can be predicted from the order of filling of the mo-

lecular orbitals. From this configuration, you can predict the bond order and whether the molecular substance is diamagnetic or paramagnetic.

## Learning Objectives

## Important Terms

### 10.1 The Valence-Shell Electron-Pair Repulsion (VSEPR) Model

- Define *molecular geometry*.
- Define *valence-shell electron-pair repulsion model*.
- Note the difference between the arrangement of electron pairs about a central atom and molecular geometry.
- Note the four steps in the prediction of geometry by the VSEPR model.
- Predict the molecular geometry (two, three, or four electron pairs). **Example 10.1**
- Note that a lone pair tends to require more space than a corresponding bonding pair and that a multiple bond requires more space than a single bond.
- Predict the molecular geometry (five or six electron pairs). **Example 10.2**

**molecular geometry**  
**valence-shell electron-pair repulsion (VSEPR) model**

### 10.2 Dipole Moment and Molecular Geometry

- Define *dipole moment*.
- Explain the relationship between dipole moment and molecular geometry. **Example 10.3**
- Note that the polarity of a molecule can affect certain properties, such as a boiling point.

**dipole moment**

### 10.3 Valence Bond Theory

- Define *valence bond theory*.
- State the two conditions needed for bond formation, according to valence bond theory.
- Define *hybrid orbitals*.
- State the five steps in describing bonding, following the valence bond theory.
- Apply valence bond theory (two, three, or four electron pairs). **Example 10.4**

**valence bond theory**  
**hybrid orbitals**

### 10.4 Description of Multiple Bonding

- Define  $\sigma$  (*sigma*) *bond*.
- Define  $\pi$  (*pi*) *bond*.
- Apply valence bond theory (multiple bonding). **Example 10.5**
- Explain geometric, or *cis-trans*, isomers in terms of the  $\pi$ -bond description of a double bond.

**$\sigma$  (sigma) bond**  
 **$\pi$  (pi) bond**

### 10.5 Principles of Molecular Orbital Theory

- Define *molecular orbital theory*.
- Define *bonding orbitals* and *antibonding orbitals*.
- Define *bond order*.
- State the two factors that determine the strength of interaction between two atomic orbitals.
- Describe the electron configurations of  $H_2$ ,  $He_2$ ,  $Li_2$ , and  $Be_2$ .

**molecular orbital theory**  
**bonding orbitals**  
**antibonding orbitals**

### 10.6 Electron Configurations of Diatomic Molecules of the Second-Period Elements

- Define *homonuclear diatomic molecules* and *heteronuclear diatomic molecules*.
- Describe molecular orbital configurations (homonuclear diatomic molecules). **Example 10.6**
- Describe molecular orbital configurations (heteronuclear diatomic molecules). **Example 10.7**

**homonuclear diatomic molecules**  
**heteronuclear diatomic molecules**

### 10.7 Molecular Orbitals and Delocalized Bonding

- Describe the delocalized bonding in molecules such as  $O_3$ .

## Questions and Problems

### Self-Assessment and Review Questions

**Key:** These questions test your understanding of the ideas you worked with in the chapter. These problems vary in difficulty and often can be used for the basis of discussion.

- 10.1** Describe the main features of the VSEPR model.
- 10.2** According to the VSEPR model, what are the arrangements of two, three, four, five, and six valence-shell electron pairs about an atom?
- 10.3** Why is a lone pair expected to occupy an equatorial position instead of an axial position in the trigonal bipyramidal arrangement?
- 10.4** Why is it possible for a molecule to have polar bonds, yet have a dipole moment of zero?
- 10.5** Explain why nitrogen trifluoride has a small dipole moment even though it has polar bonds in a trigonal pyramidal arrangement.
- 10.6** Explain in terms of valence bond theory why the orbitals used on an atom give rise to a particular geometry about that atom.
- 10.7** What is the angle between two  $sp^3$  hybrid orbitals?
- 10.8** What is the difference between a sigma bond and a pi bond?
- 10.9** Describe the bonding in ethylene,  $C_2H_4$ , in terms of valence bond theory.
- 10.10** How does the valence bond description of a carbon-carbon double bond account for *cis-trans* isomers?
- 10.11** What are the differences between a bonding and an antibonding molecular orbital of a diatomic molecule?

**10.12** What factors determine the strength of interaction between two atomic orbitals to form a molecular orbital?

**10.13** Describe the formation of bonding and antibonding molecular orbitals resulting from the interaction of two  $2s$  orbitals.

**10.14** Describe the formation of molecular orbitals resulting from the interaction of two  $2p$  orbitals.

**10.15** How does molecular orbital theory describe the bonding in the HF molecule?

**10.16** Describe the bonding in  $O_3$ , using molecular orbital theory. Compare this with the resonance description.

**10.17** According to the VSEPR model, the H—P—H bond angle in  $PH_3$  is

- a**  $120^\circ$     **b**  $109.5^\circ$     **c**  $90^\circ$   
**d** a little less than  $120^\circ$     **e** a little less than  $109.5^\circ$

**10.18** Which of the following molecular geometries does the  $XeF_5^+$  cation exhibit?

- a** tetradral  
**b** T-shaped  
**c** octahedral  
**d** square pyramidal  
**e** trigonal bipyramidal

**10.19** Which of the following would be a polar molecule?

- a**  $CO_2$     **b**  $H_2S$     **c**  $CH_4$     **d**  $SF_6$     **e**  $BeF_2$

**10.20** What is the bond order of NO?

- a**  $\frac{1}{2}$     **b** 1    **c**  $\frac{3}{2}$     **d** 3    **e**  $\frac{5}{2}$

### Concept Explorations

**Key:** Concept explorations are comprehensive problems that provide a framework that will enable you to explore and learn many of the critical concepts and ideas in each chapter. If you master the concepts associated with these

explorations, you will have a better understanding of many important chemistry ideas and will be more successful in solving all types of chemistry problems. These problems are well suited for group work and for use as in-class activities.

### 10.21 Best Lewis Formula and Molecular Geometry

A student writes the Lewis electron-dot formula for the carbonate anion,  $\text{CO}_3^{2-}$ , as

- Does this Lewis formula obey the octet rule? Explain. What are the formal charges on the atoms? Try describing the bonding for this formula in valence bond terms. Do you have any difficulty doing this?
- Does this Lewis formula give a reasonable description of the electron structure, or is there a better one? If there is a better Lewis formula, write it down and explain why it is better.
- The same student writes the following resonance description for  $\text{CO}_2$ :

Is there something wrong with this description? (What would you predict as the geometries of these formulas?)

- Is one or the other formula a better description? Could a value for the dipole moment help you decide?
- Can you write a Lewis formula that gives an even better description of  $\text{CO}_2$ ? Explain your answer.

### 10.22 Molecular Geometry and Bonding

- Shown here are several potential Lewis electron-dot formulas for the  $\text{SeO}_2$  molecule.

Are there any electron-dot formulas that you expect to give the best description? How would you describe the bonding in terms of electron-dot formulas?

- Describe the bonding in  $\text{SeO}_2$  in valence bond terms. If there is delocalized bonding, note this in your description and explain how molecular orbital theory can be useful here.
- Determine the arrangement of electron pairs about Se in the  $\text{SeO}_2$  molecule. What would you expect for the molecular geometry of the  $\text{SeO}_2$  molecule?
- Would you expect the  $\text{O}-\text{Se}-\text{O}$  angle in the  $\text{SeO}_2$  molecule to be greater than, equal to, or less than  $120^\circ$ . Explain your answer.
- Draw an electron-dot formula for the  $\text{H}_2\text{Se}$  molecule and determine its molecular geometry.
- Compare the  $\text{H}-\text{Se}-\text{H}$  bond angle to the  $\text{O}-\text{Se}-\text{O}$  bond angle. Is it larger or smaller? Explain.
- Determine whether the  $\text{H}_2\text{Se}$  and  $\text{SeO}_2$  molecules have dipole moments. Describe how you arrived at your answer.

## Conceptual Problems

**Key:** These problems are designed to check your understanding of the concepts associated with some of the main topics presented in each chapter. A strong conceptual understanding of chemistry is the foundation for both applying chemical knowledge and solving chemical problems. These problems vary in level of difficulty and often can be used as a basis for group discussion.

**10.23** Match the following molecular substances a–d with one of the molecular models (i) to (iv) that correctly depicts the geometry of the corresponding molecule.

- $\text{SeO}_2$
- $\text{BeCl}_2$
- $\text{PBr}_3$
- $\text{BCl}_3$

**10.24** Which of the following molecular models correctly depicts the geometry of  $\text{ClCN}$ ?

**10.25** Suppose that an ethane molecule,  $\text{CH}_3\text{CH}_3$ , is broken into two  $\text{CH}_3$  molecules in such a way that one  $:\text{CH}_3$  molecule retains the electron pair that was originally the one making up the  $\text{C}-\text{C}$  bond. The other  $\text{CH}_3$  molecule has two fewer electrons. Imagine that momentarily this  $\text{CH}_3$  molecule has the geometry it had in the ethane molecule. Describe the electron repulsions present in this molecule, and indicate how they would be expected to rearrange its geometry.

**10.26** Suppose that a  $\text{BF}_3$  molecule approaches the lone pair on the N atom of an  $:\text{NH}_3$  molecule, and that a bond forms between the B atom and the N atom. Consider the arrangement of electron pairs about the B atom at the moment of this bond formation, and describe the repulsions among the electron pairs and how they might be expected to change the geometry about the B atom.

**10.27** Indicate what hybrid orbital depicted below is expected for the central atom of each of the following:

- $\text{BeF}_2$
- $\text{SiF}_4$

**10.28** An atom in a molecule has two bonds to other atoms and one lone pair. What kind of hybrid orbitals do you expect for this atom? Describe how you arrived at your answer.

**10.29** Two compounds have the same molecular formula,  $C_2H_2Br_2$ . One has a dipole moment; the other does not. Both compounds react with bromine,  $Br_2$ , to produce the same compound. This reaction is a generally accepted test for double bonds, and each bromine atom of  $Br_2$  adds to a different atom of the double bond. What is the identity of the original compounds? Describe the argument you use.

**10.30** A neutral molecule is identified as a tetrafluoride,  $XF_4$ , where X is an unknown atom. If the molecule has a dipole moment of 0.63 D, can you give some possibilities for the identity of X?

**10.31** Acetic acid, the sour constituent of vinegar, has the following structure:

Indicate what geometry i–iv is expected to be found about each of the atoms labeled a, b, and c.

**10.32** What are the bond angles predicted by the VSEPR model about the carbon atom in the formate ion,  $HCO_2^-$ ? Considering that the bonds to this atom are not identical, would you expect the experimental values to agree precisely with the VSEPR values? How might they differ?

## Practice Problems

**Key:** These problems are for practice in applying problem-solving skills. They are divided by topic, and some are keyed to exercises (see the ends of the exercises). The problems are arranged in matching pairs; the odd-numbered problem of each pair is listed first, and its answer is given in the back of the book.

### The VSEPR Model

**10.33** Predict the shape or geometry of the following molecules, using the VSEPR model.

- a**  $SiF_4$     **b**  $SF_2$     **c**  $COF_2$     **d**  $PCl_3$

**10.34** Use the electron-pair repulsion model to predict the geometry of the following molecules:

- a**  $GeCl_2$     **b**  $AsCl_3$     **c**  $SO_3$     **d**  $XeO_4$

**10.35** Predict the geometry of the following ions, using the electron-pair repulsion model.

- a**  $BrO_3^-$     **b**  $AsO_4^{3-}$     **c**  $CO_3^{2-}$     **d**  $H_3S^+$

**10.36** Use the VSEPR model to predict the geometry of the following ions:

- a**  $NO_2^-$     **b**  $SO_3^{2-}$     **c**  $N_3^-$     **d**  $BH_4^-$

**10.37** For each of the following molecules, state the bond angle (or bond angles, as appropriate) that you would expect to see on the central atom based on the simple VSEPR model. Would you expect the actual bond angles to be greater or less than this?

- a**  $CCl_4$     **b**  $SCl_2$     **c**  $COCl_2$     **d**  $AsH_3$

**10.38** For each of the following molecules, state the bond angle (or bond angles, as appropriate) that you would expect to see on the central atom based on the VSEPR model. Would you expect the actual bond angles to be greater or less than this?

- a**  $OF_2$     **b**  $NCl_3$     **c**  $CF_2CF_2$     **d**  $GeF_4$

**10.39** What geometry is expected for the following molecules, according to the VSEPR model?

- a**  $PF_5$     **b**  $BrF_3$     **c**  $BrF_5$     **d**  $SCl_4$

**10.40** From the electron-pair repulsion model, predict the geometry of the following molecules:

- a**  $TeF_6$     **b**  $ClF_5$     **c**  $SeF_4$     **d**  $SbF_5$

**10.41** Predict the geometries of the following ions, using the VSEPR model.

- a**  $GeF_5^-$     **b**  $AsF_6^-$     **c**  $BrF_2^-$     **d**  $BrF_4^-$

**10.42** Name the geometries expected for the following ions, according to the electron-pair repulsion model.

- a**  $BrF_6^+$     **b**  $IF_2^-$     **c**  $ICl_4$     **d**  $IF_4^+$

### Dipole Moment and Molecular Geometry

**10.43** **a** The molecule  $AsF_3$  has a dipole moment of 2.59 D. Which of the following geometries are possible: trigonal planar, trigonal pyramidal, or T-shaped? **b** The molecule  $H_2S$  has a dipole moment of 0.97 D. Is the geometry linear or bent?

**10.44** **a** The molecule  $\text{BrF}_3$  has a dipole moment of 1.19 D. Which of the following geometries are possible: trigonal planar, trigonal pyramidal, or T-shaped? **b** The molecule  $\text{TeCl}_4$  has a dipole moment of 2.54 D. Is the geometry tetrahedral, seesaw, or square planar?

**10.45** Which of the following molecules would be expected to have zero dipole moment on the basis of their geometry?

- a**  $\text{CS}_2$     **b**  $\text{TeF}_2$     **c**  $\text{SeCl}_4$     **d**  $\text{XeF}_4$

**10.46** Which of the following molecules would be expected to have a dipole moment of zero because of symmetry?

- a**  $\text{BeBr}_2$     **b**  $\text{H}_2\text{Se}$     **c**  $\text{AsF}_3$     **d**  $\text{SeF}_6$

### Valence Bond Theory

**10.47** What hybrid orbitals would be expected for the central atom in each of the following molecules or ions?

**10.48** What hybrid orbitals would be expected for the central atom in each of the following molecules or ions?

**10.49** What hybrid orbitals would be expected for the central atom in each of the following molecules or ions?

- a**  $\text{SeI}_2$     **b**  $\text{NO}_3^-$     **c**  $\text{BeCl}_2$     **d**  $\text{ClO}_4^-$

**10.50** What hybrid orbitals would be expected for the central atom in each of the following molecules or ions?

- a**  $\text{PCl}_3$     **b**  $\text{SiCl}_4$     **c**  $\text{BeF}_2$     **d**  $\text{SO}_2$

**10.51** **a** Mercury(II) chloride dissolves in water to give poorly conducting solutions, indicating that the compound is largely nonionized in solution—it dissolves as  $\text{HgCl}_2$  molecules. Describe the bonding of the  $\text{HgCl}_2$  molecule, using valence bond theory. **b** Phosphorus trichloride,  $\text{PCl}_3$ , is a colorless liquid with a highly irritating vapor. Describe the bonding in the  $\text{PCl}_3$  molecule, using valence bond theory. Use hybrid orbitals.

**10.52** **a** Nitrogen trifluoride,  $\text{NF}_3$ , is a relatively unreactive, colorless gas. How would you describe the bonding in the  $\text{NF}_3$  molecule in terms of valence bond theory? Use

hybrid orbitals. **b** Silicon tetrafluoride,  $\text{SiF}_4$ , is a colorless gas formed when hydrofluoric acid attacks silica ( $\text{SiO}_2$ ) or glass. Describe the bonding in the  $\text{SiF}_4$  molecule, using valence bond theory.

**10.53** **a** Carbonyl fluoride,  $\text{COF}_2$ , is an extremely poisonous gas used in organofluorine synthesis. Give the valence bond description of the carbonyl fluoride molecule. (Both fluorine atoms are attached to the carbon atom.)

**b** Nitrogen,  $\text{N}_2$ , makes up about 80% of the earth's atmosphere. Give the valence bond description of this molecule.

**10.54** **a** The molecule  $\text{HN}=\text{NH}$  exists as a transient species in certain reactions. Give the valence bond description of this species. **b** Hydrogen cyanide,  $\text{HCN}$ , is a very poisonous gas or liquid with the odor of bitter almonds. Give the valence bond description of  $\text{HCN}$ . (Carbon is the central atom.)

**10.55** The hyponitrite ion,  $^-\text{O}-\text{N}=\text{N}-\text{O}^-$ , exists in solid compounds as the *trans* isomer. Using valence bond theory, explain why *cis-trans* isomers might be expected for this ion. Draw structural formulas of the *cis-trans* isomers.

**10.56** Fumaric acid,  $\text{C}_4\text{H}_4\text{O}_4$ , occurs in the metabolism of glucose in the cells of plants and animals. It is used commercially in beverages. The structural formula of fumaric acid is

Maleic acid is the *cis* isomer of fumaric acid. Using valence bond theory, explain why these isomers are possible.

### Molecular Orbital Theory

**10.57** Describe the electronic structure of each of the following, using molecular orbital theory. Calculate the bond order of each and decide whether it should be stable. For each, state whether the substance is diamagnetic or paramagnetic.

- a**  $\text{Be}_2$     **b**  $\text{He}_2^+$     **c**  $\text{N}_2^-$

**10.58** Use molecular orbital theory to describe the bonding in the following. For each one, find the bond order and decide whether it is stable. Is the substance diamagnetic or paramagnetic?

- a**  $\text{C}_2^+$     **b**  $\text{Be}_2^+$     **c**  $\text{Ne}_2$

**10.59** Assume that the  $\text{CN}$  molecule has molecular orbitals similar to those of a homonuclear diatomic molecule. Write the configuration and bond order of  $\text{CN}$ . Is  $\text{CN}$  diamagnetic or paramagnetic?

**10.60** Write the molecular orbital configuration of the diatomic molecule  $\text{BN}$ . What is the bond order of  $\text{BN}$ ? Is the substance diamagnetic or paramagnetic? Use the order of energies that was given for homonuclear diatomic molecules.

## General Problems

**Key:** These problems provide more practice but are not divided by topic or keyed to exercises. Each section ends with essay questions, each of which is color coded to refer to the *A Chemist Looks at Daily Life* (orange), *A Chemist Looks at Life Science* (pink), and *A Chemist Looks at Environment* (green) chapter essay on which it is based. Odd-numbered problems and the even-numbered problems that follow are similar; answers to all odd-numbered problems except the essay questions are given in the back of the book.

**10.61** Predict the molecular geometry of the following:

- a**  $\text{SnCl}_2$    **b**  $\text{COBr}_2$    **c**  $\text{ICl}_2^-$    **d**  $\text{PCl}_6^-$

**10.62** Predict the molecular geometry of the following:

- a**  $\text{NH}_4^+$    **b**  $\text{HOF}$    **c**  $\text{ClF}_4^+$    **d**  $\text{PF}_5$

**10.63** Which of the following molecules or ions are linear?

- a**  $\text{NO}_2^-$    **b**  $\text{H}_2\text{O}$    **c**  $\text{XeF}_2$    **d**  $\text{CO}_2$

**10.64** Which of the following molecules or ions are trigonal planar?

- a**  $\text{AsH}_3$    **b**  $\text{TeF}_5^-$    **c**  $\text{BBr}_3$    **d**  $\text{ClF}_4^-$

**10.65** Describe the hybrid orbitals used by each carbon atom in the following molecules:

**10.66** Describe the hybrid orbitals used by each nitrogen atom in the following molecules:

**10.67** Explain how the dipole moment could be used to distinguish between the *cis* and *trans* isomers of 1,2-dibromoethene:

**10.68** Two compounds have the formula  $\text{Pt}(\text{NH}_3)_2\text{Cl}_2$ . (Compound B is *cisplatin*, mentioned in the opening to

Chapter 1.) They have square planar structures. One is expected to have a dipole moment; the other is not. Which one would have a dipole moment?

**10.69** Explain in terms of bonding theory why all four hydrogen atoms of allene,  $\text{H}_2\text{C}=\text{C}=\text{CH}_2$ , cannot lie in the same plane.

**10.70** Explain in terms of bonding theory why all atoms of  $\text{H}_2\text{C}=\text{C}=\text{C}=\text{CH}_2$  must lie in the same plane.

**10.71** What is the molecular orbital configuration of  $\text{HeH}^+$ ? Do you expect the ion to be stable?

**10.72** What is the molecular orbital configuration of  $\text{He}_2^+$ ? Do you expect the ion to be stable?

**10.73** Calcium carbide,  $\text{CaC}_2$ , consists of  $\text{Ca}^{2+}$  and  $\text{C}_2^{2-}$  (acetylide) ions. Write the molecular orbital configuration and bond order of the acetylide ion,  $\text{C}_2^{2-}$ .

**10.74** Sodium peroxide,  $\text{Na}_2\text{O}_2$ , consists of  $\text{Na}^+$  and  $\text{O}_2^{2-}$  (peroxide) ions. Write the molecular orbital configuration and bond order of the peroxide ion,  $\text{O}_2^{2-}$ .

**10.75** The oxygen–oxygen bond in  $\text{O}_2^+$  is 112 pm and in  $\text{O}_2$  is 121 pm. Explain why the bond length in  $\text{O}_2^+$  is shorter than in  $\text{O}_2$ . Would you expect the bond length in  $\text{O}_2^-$  to be longer or shorter than that in  $\text{O}_2$ ? Why?

**10.76** The nitrogen–nitrogen bond distance in  $\text{N}_2$  is 109 pm. On the basis of bond orders, would you expect the bond distance in  $\text{N}_2^+$  to be less than or greater than 109 pm? Answer the same question for  $\text{N}_2^-$ .

**10.77** Using molecular orbital theory, determine the electronic structure of the first excited electronic state of  $\text{O}_2$ . What differences are expected in the properties of the excited state of  $\text{O}_2$  compared with the same properties of the ground state?

**10.78** The ionization energy of  $\text{O}_2$  is smaller than the ionization energy of atomic O; the opposite is true for the ionization energies of  $\text{N}_2$  and atomic N. Explain this behavior in terms of the molecular orbital energy diagrams of  $\text{O}_2$  and  $\text{N}_2$ .

**10.79** Describe the property of “handedness.” What is it about the bonding of atoms in molecules that can give rise to handedness in molecules?

- **10.80** Biological molecules frequently display handedness. Describe the difference between the molecule responsible for the flavor of spearmint and the molecule responsible for the flavor of caraway seeds. In which way are the molecules similar and in which way do they differ?
- **10.81** Color vision results from the absorption of light by the cone cells of the retina. Briefly describe how different types of cone cells give rise to color vision. What is the chemical substance primarily responsible for human vision? How can its color absorption be changed?

- **10.82** Describe the *cis-trans* conversion that occurs in the ultraviolet absorption of *cis*-1,2-dichloroethene.
- **10.83** What is the biological importance of stratospheric ozone? Explain.
- **10.84** In 1995, Sherwood Rowland and Mario Molina received the Nobel Prize in chemistry. Explain in some detail the work they did for which they were awarded this prize.

## Strategy Problems

**Key:** As noted earlier, all of the practice and general problems are matched pairs. This section is a selection of problems that are not in matched-pair format. These challenging problems require that you employ many of the concepts and strategies that were developed in the chapter. In some cases, you will have to integrate several concepts and operational skills in order to solve the problem successfully.

**10.85** Each of the following compounds has a nitrogen–nitrogen bond:  $N_2$ ,  $N_2H_4$ ,  $N_2F_2$ . Match each compound with one of the following bond lengths: 110 pm, 122 pm, 145 pm. Describe the geometry about one of the N atoms in each compound. What hybrid orbitals are needed to describe the bonding in valence bond theory?

**10.86** The bond length in  $C_2$  is 131 pm. Compare this with the bond lengths in  $C_2H_2$  (120 pm),  $C_2H_4$  (134 pm), and  $C_2H_6$  (153 pm). What bond order would you predict for  $C_2$  from its bond length? Does this agree with the molecular orbital configuration you would predict for  $C_2$ ?

**10.87** Calcium carbide,  $CaC_2$ , has an ionic structure with ions  $Ca^{2+}$  and  $C_2^{2-}$ . Give the valence bond description of the bonding in the  $C_2^{2-}$  ion. Now write the MO configuration of this ion. What is the bond order according to this configuration? Compare the valence bond and molecular orbital descriptions.

**10.88** Write Lewis formulas for the BF molecule (two with a single B–F bond, two with a double B=F bond, and one with a triple B≡F bond) in which the octet rule is satisfied for at least one of the atoms. Obtain the formal charges of the atoms. Based on the information you have, is there one formula that you think best describes the molecule? Explain. For this best Lewis formula, give the valence bond description of the bonding.

**10.89** Boron trifluoride,  $BF_3$ , reacts with ammonia,  $NH_3$ , to form an addition compound,  $BF_3NH_3$ . Describe the geometries about the B and the N atoms in this compound. Describe the hybridization on these two atoms. Now describe the bonding between the B and N atoms, using valence bond theory. Compare the geometries and hybridization of these atoms in this addition compound with that in the reactant molecules  $BF_3$  and  $NH_3$ .

**10.90** Acetylsalicylic acid (aspirin) has the structure shown by the following molecular model:

Describe the geometry and bonding about the carbon atom shown at the top of the model, in which the carbon atom (in black) is bonded to two oxygen atoms (red) and to another carbon atom. One of the oxygen atoms is bonded to a hydrogen atom (blue).

**10.91** Allene (1,2-propadiene), a gas, has the following structure:

What is the hybridization at each carbon atom? What is the geometry about each carbon atom? Using valence-bond theory, describe the bonding about the center carbon atom. 1,3-dichloroallene is a derivative of allene with the following structure:

Is this a polar molecule? (If you have difficulty visualizing the structure of this molecule, you might build a molecular model of it.)

**10.92** When allene (described in the previous problem) is heated with sodium metal, it rearranges to give the isomeric molecule methyl acetylene, which has the following structure:

What is the hybridization at each carbon atom? What is the geometry about each carbon atom? Using valence bond theory, describe the bonding about the center carbon atom.

**10.93** The triiodide ion,  $\text{I}_3^-$ , and the azide ion,  $\text{N}_3^-$ , have similar skeleton formulas:

Otherwise, how similar are they? To answer, draw electron-dot formulas for each ion, including resonance formulas, if there are any. What is the geometry about the center atom in each molecule? Describe the hybridization about this atom in each molecule.

**10.94** Hydrogen azide (also known as hydrazoic acid),  $\text{HN}_3$ , is a covalent molecule in which the hydrogen atom (as a proton) is bonded to a nitrogen atom at one end of the azide ion (see previous problem). Draw the dominant resonance formula or formulas for this molecule. Describe the hybridization about the nitrogen atom to which the hydrogen atom is bonded in the dominant formula or formulas. Use valence bond theory to describe the bonding about this nitrogen atom.

**10.95** There are a number of known pentahalides of phosphorus. One of them is the trifluorodibromophosphorus compound,  $\text{PF}_3\text{Br}_2$ , an unstable liquid. Draw the Lewis electron-dot formula of  $\text{PF}_3\text{Br}_2$ . What is the geometry about the phosphorus atom? Describe the placement of fluorine and bromine atoms about the phosphorus atom in this geometry. Explain how you come to this conclusion.

**10.96** A molecule  $\text{XF}_6$  (having no lone pairs) has a dipole moment of zero. (X denotes an unidentified element.) When two atoms of fluorine have been taken away, you get the molecule  $\text{XF}_4$ , which has dipole moment of 0.632 D.

Describe the molecular geometry for each molecule. What are some possibilities for X?

**10.97** Describe the molecular orbital configurations of  $\text{C}_2^+$ ,  $\text{C}_2$ , and  $\text{C}_2^{2-}$ . What are the bond orders of these species? Arrange the three species by increasing bond length. Arrange the species by increasing bond enthalpy. Explain these arrangements of bond length and bond enthalpy.

**10.98** If the HCl molecule were 100% ionic, the molecule would consist of a positive charge  $e$  and a negative charge  $-e$  separated by a distance  $d$  equal to the bond length. The experimental value of the bond length is 127 pm. Calculate the dipole moment for such a completely ionic molecule. The actual dipole moment,  $\mu$ , of HCl is 1.08 D. Linus Pauling, Nobel laureate, used the ratio of the actual dipole moment to that of the 100% ionic molecule as an estimate of the fraction of ionic character in the HCl molecule. What is the fraction of ionic character in this molecule according to this estimate?

**10.99** Three different compounds have the same molecular formula,  $\text{C}_2\text{H}_2\text{F}_2$ ; call them A, B, and C. Compound A has a dipole moment of 2.42 D, compound B has a dipole moment of 1.38 D, and compound C has a dipole moment of 0 D. All three compounds react with hydrogen,  $\text{H}_2$ :

Compound A gives product D (molecular formula  $\text{C}_2\text{H}_4\text{F}_2$ ), compound B gives product E (same molecular formula,  $\text{C}_2\text{H}_4\text{F}_2$ , but different from product D), and compound C gives product D. Identify the structural formulas of compounds A, B, and C.

**10.100** Obtain a Lewis formula of  $\text{H}_2\text{N}_2$ . This molecule exhibits isomerism (it has two isomers). Sketch the electron-dot formulas of these isomers. Describe the bonding in terms of valence bond theory, and explain this isomerism in terms of this bonding description.

**10.101** Dioxygen,  $\text{O}_2$ , has sometimes been represented by the electron-dot formula

Note, however, that this formula implies that all electrons are paired. Give the molecular orbital description of the state of the  $\text{O}_2$  molecule of lowest energy in which all electrons are paired in this way. Compare this configuration with that of the ground state of  $\text{O}_2$ . In what way are they similar, and in what way are they different?

**10.102** Solid sulfur normally consists of crystals of  $\text{S}_8$  molecules, but when heated strongly, the solid vaporizes to give  $\text{S}_2$  molecules (among other molecular species). Describe the bonding in  $\text{S}_2$  in molecular orbital terms, assuming the orbitals are analogous to those of the preceding period. What would you expect to happen to the sulfur-sulfur bond length if two electrons were added to give the  $\text{S}_2^{2-}$  ion? What would you expect to happen to the bond length if, instead, two electrons were taken away to give  $\text{S}_2^{2+}$ ?

**10.103** Formaldehyde has the formula  $\text{H}_2\text{CO}$ . Describe the bonding between the C and O atoms in VB terms. Formaldehyde absorbs UV light at about 270 nm. The absorption is described as a  $\pi$  to  $\pi^*$  transition. Explain in molecular orbital terms what is involved.

**10.104** Consider the bonding in nitrate ion,  $\text{NO}_3^-$ . First draw resonance formulas of this ion. Now describe the bonding of this ion in terms of molecular orbitals. (Refer to the delocalized bonding of the ozone molecule described in the text.) Suppose each atom uses  $sp^2$  hybrid orbitals. How many  $\pi$  molecular orbitals can you form from the  $2p$  orbitals that remain on these atoms? How many of these  $\pi$  orbitals will be occupied?

## Capstone Problems

**Key:** The problems under this heading combine skills, strategies, and concepts learned in previous chapters with those introduced in the current one.

**10.105** A molecular compound is composed of 52.5% Xe, 19.2% O, and 28.3% Cl, by mass. If the molecular weight is 250.2 amu, what is the molecular formula? What is the

Lewis formula? Predict the molecular geometry using the VSEPR model.

**10.106** A molecular compound is composed of 58.8% Xe, 7.2% O, and 34.0% F, by mass. If the molecular weight is 223 amu, what is the molecular formula? What is the Lewis formula? Predict the molecular geometry using the VSEPR model.

**10.107** A compound of chlorine and fluorine,  $\text{ClF}_n$ , reacts at about  $75^\circ\text{C}$  with uranium metal to produce uranium hexafluoride,  $\text{UF}_6$ , and chlorine monofluoride,  $\text{ClF}(g)$ . A quantity of uranium produced 7.04 g  $\text{UF}_6$  and 343 mL  $\text{ClF}$  at  $75^\circ\text{C}$  and 2.50 atm. What is the formula ( $n$ ) of the compound? Predict the molecular geometry using the VSEPR model.

**10.108** Excess fluorine,  $\text{F}_2(g)$ , reacts at  $150^\circ\text{C}$  with bromine,  $\text{Br}_2(g)$ , to give a compound  $\text{BrF}_n$ . If 423 mL  $\text{Br}_2(g)$  at  $150^\circ\text{C}$  and 748 mmHg produced 4.20 g  $\text{BrF}_n$ , what is  $n$ ? Predict the molecular geometry using the VSEPR model.

**10.109** Draw resonance formulas of the nitric acid molecule,  $\text{HNO}_3$ . What is the geometry about the N atom? What is the hybridization on N? Use bond enthalpies and one Lewis formula for  $\text{HNO}_3$  to estimate  $\Delta H_f^\circ$  for  $\text{HNO}_3(g)$ . The actual value of  $\Delta H_f^\circ$  for  $\text{HNO}_3(g)$  is  $-135$  kJ/mol, which is lower than the estimated value because of stabilization of  $\text{HNO}_3$  by resonance. The *resonance energy* is

defined as  $\Delta H_f^\circ$  (estimated)  $-\Delta H_f^\circ$  (actual). What is the resonance energy of  $\text{HNO}_3$ ?

**10.110** One resonance formula of benzene,  $\text{C}_6\text{H}_6$ , is

What is the other resonance formula? What is the geometry about a carbon atom? What hybridization would be used in valence bond theory to describe the bonding? The  $\Delta H_f^\circ$  for  $\text{C}_6\text{H}_6(g)$  is  $-83$  kJ/mol;  $\Delta H_f^\circ$  for  $\text{C}(g)$  is 715 kJ/mol. Obtain the resonance energy of benzene. (See Problem 10.109.)

States of Matter;  
Liquids and Solids

When a liquid such as water boils, the vapor state forms bubbles within the liquid state.

Alfred Pasielak/Science Source

## CONTENTS AND CONCEPTS

**11.1** Comparison of Gases, Liquids, and Solids

**Changes of State**

We look at the changes of state (or phase transitions) a substance can undergo, as well as vapor pressure, melting point, and freezing point.

**11.2** Phase Transitions

**11.3** Phase Diagrams

**Liquid State**

We now look at several physical properties of liquids and then explain those properties in terms of *intermolecular forces* (weak forces between molecules).

**11.4** Properties of Liquids; Surface Tension and Viscosity

**11.5** Intermolecular Forces; Explaining Liquid Properties

**Solid State**

We look at the kinds of forces that hold the units of a solid together. Then, we look at crystalline solids and their structure.

**Figure 11.1** ▲

**Dry ice** Dry ice is solid carbon dioxide,  $\text{CO}_2$ , whose temperature is about  $-78^\circ\text{C}$ . It passes directly from the solid to the gaseous state. The white plumes are composed of ice crystals ( $\text{H}_2\text{O}$ , not  $\text{CO}_2$ ) formed as water condenses from the surrounding air as it cools.

**S**olid carbon dioxide is shown in Figure 11.1. It has an interesting property: at normal pressures it passes directly to the gaseous state without first melting to the liquid. This property, together with the fact that this change occurs at  $-78^\circ\text{C}$ , makes solid carbon dioxide useful for keeping materials very cold. Because solid  $\text{CO}_2$  cools other objects and does not leave a liquid residue, it is called *dry ice*.

Liquid carbon dioxide is obtained by putting carbon dioxide gas under pressure; it can exist only at pressures greater than 5 atm. In most cases, carbon dioxide is transported as a liquid in high-pressure steel tanks or at low temperature (about  $-18^\circ\text{C}$ ) and moderate pressure. When liquid carbon dioxide evaporates (changes to vapor), it absorbs large quantities of heat, cooling as low as  $-57^\circ\text{C}$ . Because of this property, it is used as a refrigerant. Liquid carbon dioxide is often used to freeze foods for grocery stores and fast-food restaurants. If the compressed gas from the evaporating liquid is allowed to expand through a valve, the rapidly cooled vapor forms solid carbon dioxide “snow.” (Most gases cool when they expand in this manner; for example, air cools when it escapes from the valve of an inflated tire.) This carbon dioxide snow is compacted into blocks and is the source of dry ice.

Carbon dioxide, like water and most other pure substances, exists in solid, liquid, and gaseous states and can undergo changes from one state to another. Substances change state under various temperature and pressure conditions. Can we obtain some understanding of these conditions for a change of state? Why, for example, is carbon dioxide normally a gas, whereas water is normally a liquid? What are the conditions under which carbon dioxide gas changes to a liquid or to a solid?

These are some of the questions we will examine in this chapter. They concern certain physical properties that, as you will see, can often be related to the bonding and structure of the liquid and solid states.

## 11.1 Comparison of Gases, Liquids, and Solids

The different states of matter were defined in Section 1.4, and the gas laws and the kinetic theory of gases were defined in Chapter 5. Here we want to recall the salient features of those discussions and then compare gases, liquids, and solids. We especially want to compare how these states are viewed in terms of kinetic-molecular theory.

Gases are compressible fluids. According to kinetic-molecular theory, gases are composed of molecules or single atoms that are in constant random motion throughout mostly empty space (unless the gas is highly compressed). A gas is easily compressed because the molecules can be pushed into a smaller space. A gas is fluid because individual molecules can move easily relative to one another.

Liquids are relatively incompressible fluids. According to kinetic-molecular theory, the molecules of a liquid are in constant random motion (as in a gas) but are more tightly packed, so there is much less free space. Because the molecules can move relative to one another as in a gas, a liquid can flow (it is fluid). But the lack of empty space explains why a liquid, unlike a gas, is nearly incompressible.

Solids are nearly incompressible and are rigid, not fluid. Kinetic-molecular theory explains this by saying that the particles making up a solid (which may be atoms, molecules, or ions) exist in close contact and (unlike those in a gas or liquid) do not move about but oscillate or vibrate about fixed sites. This explains the rigidity of a solid. And, of course, the compact structure explains its incompressibility. Figure 11.2 compares the gaseous, liquid, and solid states in kinetic-molecular terms.

Recall that gases normally follow closely the ideal gas law,  $PV = nRT$ . The simplicity of this equation is a result of the nearly negligible forces of interaction between molecules and the nearly negligible molecular size compared with the total

Figure 11.2 ◀

**Representation of the states of matter** In a solid, the basic units (atoms, ions, or molecules) are closely packed and vibrate about fixed sites. In a liquid, molecules are rather closely packed, similar to those in a molecular solid, but can slip by one another and are in constant random motion. In a gas, molecules are widely spaced and, similar to those in a liquid, are in constant random motion.

volume of gas. Still, to be accurate we should account for both of these quantities, and the van der Waals equation, which we discussed in Section 5.8, is one attempt to do this.

$$(P + n^2a/V^2)(V - nb) = nRT$$

In this equation, the constants  $a$  and  $b$  depend on the nature of the gas. The constant  $a$  depends on the magnitude of the intermolecular forces; the constant  $b$  depends on the relative size of the molecules.

No such simple equations exist for the liquid and solid states. The size of the particles making up the liquid and solid states cannot be neglected relative to the total volume or accounted for in a simple way. Similarly, the forces of interaction between particles in the liquid and the solid states cannot be neglected; indeed, these forces of interaction are crucial when you describe the properties of the liquid and solid states.

Some of the most important properties of liquids and solids are concerned with changes of physical state. Therefore, we begin with this topic. In later sections, we will look specifically at the liquid and solid states and see how their properties depend on the forces of attraction between particles.

## ► Changes of State

In the chapter opener, we discussed the change of solid carbon dioxide (dry ice) directly to a gas. Such a *change of a substance from one state to another* is called a **change of state** or **phase transition**. In the next sections, we will look at the different kinds of phase transitions and the conditions under which they occur. (A *phase* is a homogeneous portion of a system—that is, a given state of either a substance or a solution.)

### 11.2 Phase Transitions

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. WCN 02-200-203

In general, each of the three states of a substance can change into either of the other states by undergoing a phase transition. ►

**Melting** is the change of a solid to the liquid state (melting is also referred to as *fusion*). For example,

**Freezing** is the change of a liquid to the solid state. The freezing of liquid water to ice is a common example.

The casting of a metal object involves the melting of the metal, then its freezing in a mold.

Solids often occur in several different crystalline forms, or phases. Thus, solid to solid phase transitions are possible, though not discussed here. An example is calcium carbonate, which commonly exists as calcite crystals and aragonite crystals. At normal temperatures and pressures, aragonite very slowly undergoes a phase transition to calcite.

**Vaporization** is the change of a solid or a liquid to the vapor. For example,

The change of a solid directly to the vapor is specifically referred to as **sublimation**. Although the vapor pressure of many solids is quite low, some (usually molecular solids) have appreciable vapor pressure. Ice, for instance, has a vapor pressure of 4.7 mmHg at 0°C. For this reason, a pile of snow slowly disappears in winter even though the temperature is too low for it to melt. The snow is being changed directly to water vapor.

Sublimation can be used to purify solids that readily vaporize. Figure 11.3 shows a simple way to purify iodine by sublimation. Impure iodine is heated in a beaker so that it vaporizes, leaving nonvolatile impurities behind. The vapor crystallizes on the bottom surface of a dish containing ice that rests on top of the beaker. Freeze-drying of foods is a commercial application of sublimation. Brewed coffee, for example, is frozen and placed in a vacuum to remove water vapor. The ice continues to sublime until it is all gone, leaving freeze-dried coffee. Most freeze-dried foods are easily reconstituted by adding water.

**Condensation** is the change of a gas to either the liquid or the solid state (the change of vapor to solid is sometimes called *deposition*). Dew is liquid water formed by condensation of water vapor from the atmosphere. Frost is solid water formed by direct condensation of water vapor from the atmosphere without first forming liquid water. Snow is formed by a similar process in the upper atmosphere.

When a substance that is normally a gas, such as carbon dioxide, changes to the liquid state, the phase transition is often referred to as *liquefaction*. The following diagram summarizes these phase transitions.

**Figure 11.3** ▼

**Sublimation of iodine**

**a** The beaker contains iodine crystals,  $\text{I}_2$ ; a dish of ice rests on top of the beaker.

**b** Iodine has an appreciable vapor pressure even below its melting point (114°C); thus, when heated carefully, the solid sublimates without melting. The vapor deposits as crystals on the cool underside of the dish.

### Vapor Pressure

Liquids, and even some solids, are continuously vaporizing. If a liquid is in a closed vessel with space above it, a partial pressure of the vapor state builds up in this space. The **vapor pressure** of a liquid is *the partial pressure of the vapor over the liquid, measured at equilibrium at a given temperature*. To understand what we mean by equilibrium, let us look at a simple method for measuring vapor pressure.

You introduce a few drops of water from a medicine dropper into the mercury column of a barometer (Figure 11.4a). Being less dense than mercury, the water rises in the tube to the top of the mercury, where it evaporates, or vaporizes.

To understand the process of vaporization, it is necessary to realize that the molecules in a liquid have a distribution of kinetic energies (Figure 11.5). Those molecules moving away from the surface and toward the vapor phase will escape only if their kinetic energies are greater than a certain minimum value equal to the potential energy from the attraction of molecules in the body of the liquid.

As molecules at the surface gain sufficient kinetic energy (through collisions with neighboring molecules), they escape the liquid and go into the space at the top

**a** The mercury column drops a distance  $h$  because of the vapor pressure of water.

**b** A detail of the upper portion of the tube, showing water molecules evaporating from and condensing on the water surface.

**Figure 11.4** ◀  
Measurement of the vapor pressure of water

**Figure 11.5** ▶

**Distribution of kinetic energies of molecules in a liquid** Distributions of kinetic energies are shown for two different temperatures. The fraction of molecules having kinetic energies greater than the minimum necessary for escape is given by the colored areas (orange for the lower temperature, red plus orange area at the higher temperature). Note that the fraction of molecules having kinetic energies greater than the minimum value for vaporization increases with temperature.

of the barometer column (see Figure 11.4b). More and more water molecules begin to fill this space. As the number of molecules in the vapor state increases, more and more gaseous molecules collide with the liquid water surface, exerting pressure on it. So, as vaporization of water proceeds, the mercury column moves downward.

Some of the molecules in the vapor collide with the liquid surface and stick; that is, the vapor condenses to liquid. The rate of condensation steadily increases as the number of molecules in the volume of vapor increases, until the rate at which molecules are condensing on the liquid equals the rate at which molecules are vaporizing (Figure 11.6).

**Figure 11.6** ▶

**Rates of vaporization and condensation of a liquid over time** As vaporization continues at a constant rate, the rate of condensation increases. Eventually, the two rates become equal. The partial pressure of vapor reaches a steady value at a given temperature, which is the vapor pressure of the liquid. The process is said to reach equilibrium. The flasks, A, B, and C, present the molecular view of the process at positions A, B, and C on the curve.

Figure 11.7 ◀

**Variation of vapor pressure with temperature** Several common liquids are shown. Note that the vapor pressure increases rapidly with temperature.

When the rates of vaporization and condensation have become equal, the number of molecules in the vapor at the top of the column in Figure 11.4 stops increasing and remains unchanged. The partial pressure of the vapor (as measured by the change in height of the mercury column) reaches a steady value, which is its vapor pressure. The liquid and vapor are in *equilibrium*. Although the partial pressure of the vapor is unchanging, molecules are still leaving the liquid and coming back to the liquid. For this reason, you speak of this as a *dynamic equilibrium*—one in which the molecular processes (in this case, vaporization and condensation) are continuously occurring. You represent this dynamic equilibrium for the vaporization and condensation of water by the equation with a double arrow.

As Figure 11.7 demonstrates, the vapor pressure of a substance depends on the temperature. (Appendix B gives a table of the vapor pressures of water at various temperatures.) As the temperature increases, the kinetic energy of molecular motion becomes greater, and the vapor pressure increases. Liquids and solids with relatively high vapor pressure at normal temperatures are said to be *volatile*. Chloroform and carbon tetrachloride are volatile liquids. Naphthalene,  $\text{C}_{10}\text{H}_8$ , and *para*-dichlorobenzene,  $\text{C}_6\text{H}_4\text{Cl}_2$ , are volatile solids: they have appreciable vapor pressures at room temperature. Both are used to make mothballs.

### Boiling Point and Melting Point

The temperature at which the vapor pressure of a liquid equals the pressure exerted on the liquid (atmospheric pressure, unless the vessel containing the liquid is closed) is called the **boiling point** of the liquid. As the temperature of a liquid is raised, the vapor pressure increases. When the vapor pressure equals the atmospheric pressure, stable bubbles of vapor form within the body of the liquid (Figure 11.8). This process is called boiling. Once boiling starts, the temperature of the liquid remains at the boiling point (as long as sufficient heat is supplied).

Because the pressure exerted on a liquid can vary, the boiling point of a liquid can vary. For instance, at 1.00 atm (the average atmospheric pressure at sea level), the boiling point of water is 100°C. But at 0.83 atm (the average atmospheric pressure in Denver, Colorado, at 1609 m above sea level), the boiling point of water is 95°C. The *normal boiling point* of a liquid is the boiling point at 1 atm. ▶

Figure 11.8 ▲

**Boiling of a liquid** A liquid boils when the vapor pressure inside a bubble of vapor equals the external pressure. The temperature at which this occurs is called the boiling point.

If you want to cook a stew in less time than is possible at atmospheric pressure, you can use a pressure cooker. This is especially valuable at high altitudes, where water boils at a lower temperature. The steam pressure inside the cooker is allowed to build up to a given value before being released by a valve. The stew liquid then boils at a higher temperature and the vegetables and meat are cooked more quickly.

**Table 11.1** Melting Points and Boiling Points (at 1 atm) of Several Substances

Name	Type of Solid*	Melting Point, °C	Boiling Point, °C
Neon, Ne	Molecular	−249	−246
Hydrogen sulfide, H <sub>2</sub> S	Molecular	−86	−61
Chloroform, CHCl <sub>3</sub>	Molecular	−64	62
Water, H <sub>2</sub> O	Molecular	0	100
Acetic acid, HC <sub>2</sub> H <sub>3</sub> O <sub>2</sub>	Molecular	17	118
Mercury, Hg	Metallic	−39	357
Sodium, Na	Metallic	98	883
Tungsten, W	Metallic	3410	5660
Cesium chloride, CsCl	Ionic	645	1290
Sodium chloride, NaCl	Ionic	801	1413
Magnesium oxide, MgO	Ionic	2800	3600
Quartz, SiO <sub>2</sub>	Covalent network	1610	2230
Diamond, C	Covalent network	3550	4827

\*Types of solids are discussed in Section 11.6.

The temperature at which a pure liquid changes to a crystalline solid, or freezes, is called the **freezing point**. The temperature at which a crystalline solid changes to a liquid, or melts, is called the **melting point**; it is identical to the freezing point. The melting or freezing occurs at the temperature where the liquid and solid are in dynamic equilibrium.

Unlike boiling points, melting points are affected significantly only by large pressure changes.

Both the melting point and the boiling point are characteristic physical properties of a substance and can be used to help identify it. Table 11.1 gives melting points and boiling points of several substances.

### Heat of Phase Transition

Any change of state involves the addition or removal of energy as heat to or from the substance. A simple experiment shows that this is the case. Suppose you add heat at a constant rate to a beaker containing ice at  $-20^{\circ}\text{C}$ . In Figure 11.9, we have plotted the temperature of the different phases of water as heat is added. The temperature of the ice begins to rise from  $-20^{\circ}\text{C}$ , as you would expect; the addition of heat normally raises the temperature of a substance. At  $0^{\circ}\text{C}$ , the ice begins to melt, so that you get

**Figure 11.9** ▶

**Heating curve for water** Heat is being added at a constant rate to a system containing water. Note the flat regions of the curve. When heat is added during a phase transition, the temperature does not change.

a beaker of ice in water. Note the flat region in the curve, labeled ice and water. Why is this region flat? It means that heat is being added to the system without a change in temperature; the temperature remains at 0°C. This temperature, of course, is the melting point of ice. The heat being added is energy required to melt ice to water at the same temperature. The intermolecular forces binding water molecules to specific sites in the solid phase must be partially broken to allow water molecules the ability to slide over one another easily, as happens in the liquid state. Note the flat regions for each of the phase transitions. Because heat is being added at a constant rate, the length of each flat region is proportional to the *heat of phase transition*.

The heat needed for the melting of a solid is called the **heat of fusion** (or *enthalpy of fusion*) and is denoted  $\Delta H_{fus}$ . For ice, the heat of fusion is 6.01 kJ per mole.

The heat needed for the vaporization of a liquid is called the **heat of vaporization** (or *enthalpy of vaporization*) and is denoted  $\Delta H_{vap}$ . At 100°C, the heat of vaporization of water is 40.7 kJ per mole. ►

Note that much more heat is required for vaporization than for melting. Melting needs only enough energy for the molecules to escape from their sites in the solid. For vaporization, enough energy must be supplied to break most of the intermolecular attractions.

A refrigerator relies on the cooling effect accompanying vaporization. The mechanism contains an enclosed gas that can be liquefied under pressure, such as ammonia or 1,1,1,2-tetrafluoroethane,  $\text{CH}_2\text{FCF}_3$ . As the liquid is allowed to evaporate, it absorbs heat and thus cools its surroundings (the interior space of the refrigerator). Gas from the evaporation is recycled to a compressor and then to a condenser, where it is liquefied again. Heat leaves the condenser, going into the surrounding air.

The fact that heat is required for vaporization can be demonstrated by evaporating a dish of water inside a vessel attached to a vacuum pump. With the pressure kept low, water evaporates quickly enough to freeze the water remaining in the dish.

### Example 11.1 Calculating the Heat Required for a Phase Change of a Given Mass of Substance

#### Gaining Mastery Toolbox

##### Critical Concept 11.1

Substances undergoing a phase transition do not change temperature. The energy associated with phase transitions is linked to structural changes in the substance and not to changes in the kinetic energy of the molecules (temperature). For example, when ice melts at 0°C and 1 atm of pressure by absorbing energy, the molecular structure of water undergoes a change without any change in temperature.

##### Solution Essentials:

- Heat of fusion
- Heat of vaporization
- Freezing point
- Phase transition

A particular refrigerator cools by evaporating liquefied dichlorodifluoromethane,  $\text{CCl}_2\text{F}_2$ . How many kilograms of this liquid must be evaporated to freeze a tray of water at 0°C to ice at 0°C? The mass of the water is 525 g, the heat of fusion of ice is 6.01 kJ/mol, and the heat of vaporization of dichlorodifluoromethane is 17.4 kJ/mol.

**Problem Strategy** The cooling effect as  $\text{CCl}_2\text{F}_2$  liquid evaporates is used to freeze water at 0°C to ice. You first need to obtain the quantity of heat removed from the water to freeze it (using the heat of fusion of ice as a conversion factor, converting moles of  $\text{H}_2\text{O}$  to the heat required). Then you use this quantity of heat to determine the amount of  $\text{CCl}_2\text{F}_2$  to evaporate (now using the heat of vaporization of  $\text{CCl}_2\text{F}_2$  to convert this quantity of heat to the amount of  $\text{CCl}_2\text{F}_2$  that must be vaporized).

**Solution** The heat that must be removed to freeze 525 g of water at 0°C is

$$525 \text{ g H}_2\text{O} \times \frac{1 \text{ mol H}_2\text{O}}{18.0 \text{ g H}_2\text{O}} \times \frac{-6.01 \text{ kJ}}{1 \text{ mol H}_2\text{O}} = -175 \text{ kJ}$$

The minus sign indicates that heat energy is taken away from the water. Consequently, the vaporization of dichlorodifluoromethane absorbs 175 kJ of heat. The mass of  $\text{CCl}_2\text{F}_2$  that must be vaporized to absorb this quantity of heat is

$$175 \text{ kJ} \times \frac{1 \text{ mol CCl}_2\text{F}_2}{17.4 \text{ kJ}} \times \frac{121 \text{ g CCl}_2\text{F}_2}{1 \text{ mol CCl}_2\text{F}_2} = 1.22 \times 10^3 \text{ g CCl}_2\text{F}_2$$

**1.22 kg of dichlorodifluoromethane must be evaporated.**

(continued)

**Example 11.1** (continued)

**Answer Check** The calculations are similar to the stoichiometry calculations we did in Chapter 3. As in those calculations, make sure that the units properly cancel to convert those of the known quantity to the units of the desired quantity.

**Exercise 11.1** The heat of vaporization of ammonia is 23.4 kJ/mol. How much heat is required to vaporize 1.00 kg of ammonia? How many grams of water at 0°C could be frozen to ice at 0°C by the evaporation of this amount of ammonia?

See Problems 11.43, 11.44, 11.45, and 11.46.

$t = 0$

 **CONCEPT CHECK 11.1**

Shown here is a representation of a closed container in which you have just placed 10 L of  $\text{H}_2\text{O}$ . In our experiment, we are going to call this starting point in time  $t = 0$  and assume that all of the  $\text{H}_2\text{O}$  is in the liquid phase. We have represented a few of the  $\text{H}_2\text{O}$  molecules in the water as dots.

- a** Consider a time  $t = 1$ , at which some time has passed but the system has not reached equilibrium.
- How will the level of the liquid  $\text{H}_2\text{O}$  compare to that at  $t = 0$ ?
  - How will the vapor pressure in the flask compare to that at  $t = 0$ ?
  - How will the number of  $\text{H}_2\text{O}$  molecules in the vapor state compare to that at  $t = 0$ ?
  - How does the rate of evaporation in this system compare to the rate of condensation?
  - Draw a picture of the system at  $t = 1$ .
- b** Consider a time  $t = 2$ , at which enough time has passed for the system to reach equilibrium.
- How will the level of the liquid  $\text{H}_2\text{O}$  compare to that at  $t = 1$ ?
  - How will the vapor pressure in the flask compare to that at  $t = 1$ ?
  - How will the number of  $\text{H}_2\text{O}$  molecules in the vapor state compare to that at  $t = 1$ ?
  - How does the rate of evaporation in this system compare to the rate of condensation?
  - Draw a picture of the system at  $t = 2$ .

### Clausius–Clapeyron Equation: Relating Vapor Pressure and Liquid Temperature

We noted earlier that the vapor pressure of a substance depends on temperature. The variation of vapor pressure with temperature of some liquids was given in Figure 11.7.

It can be shown that the logarithm of the vapor pressure of a liquid or solid varies with the absolute temperature according to the following approximate relation:

$$\ln P = -\frac{A}{T} + B$$

Here  $\ln P$  is the natural logarithm of the vapor pressure, and  $A$  and  $B$  are positive constants. You can confirm this relation for the liquids shown in Figure 11.7 by replotting the data. If you put  $y = \ln P$  and  $x = 1/T$ , the previous relation becomes

$$y = -Ax + B$$

This means that if you plot  $\ln P$  versus  $1/T$ , you should get a straight line with slope  $-A$ . The data of Figure 11.7 are replotted this way in Figure 11.10. ▶

The previous equation has been derived from thermodynamics, by assuming the vapor behaves like an ideal gas. The result, known as the *Clausius–Clapeyron equation*, shows that the constant  $A$  is proportional to the heat of vaporization of the liquid,  $\Delta H_{\text{vap}}$ .

$$\ln P = \frac{-\Delta H_{\text{vap}}}{RT} + B$$

A two-point form of the Clausius–Clapeyron equation is very useful for calculations. Let us write the previous equation for two different temperatures:

$$\ln P_2 = \frac{-\Delta H_{\text{vap}}}{RT_2} + B$$

$$\ln P_1 = \frac{-\Delta H_{\text{vap}}}{RT_1} + B$$

Here  $P_1$  is the vapor pressure at absolute temperature  $T_1$ , and  $P_2$  is the vapor pressure at absolute temperature  $T_2$ . If you subtract the second equation from the first, you get

$$\ln P_2 - \ln P_1 = \frac{-\Delta H_{\text{vap}}}{RT_2} - \frac{-\Delta H_{\text{vap}}}{RT_1} + B - B$$

which you can write as

$$\ln \frac{P_2}{P_1} = \frac{\Delta H_{\text{vap}}}{R} \left( \frac{1}{T_1} - \frac{1}{T_2} \right)$$

The next two examples illustrate the use of this two-point form of the Clausius–Clapeyron equation.

See Appendix A for the graphing of a straight line.

**Figure 11.10** ▲

**Plot of the logarithm of vapor pressure versus  $1/T$**  The liquids shown in Figure 11.7 are replotted in this graph. Note the straight-line relationship.

### Example 11.2 Calculating the Vapor Pressure at a Given Temperature

#### Gaining Mastery Toolbox

##### Critical Concept 11.2

The vapor pressure of a liquid varies with temperature in a predictable manner. The variation of vapor pressure with temperature of a liquid can be expressed as the Clausius–Clapeyron equation.

##### Solution Essentials:

- Clausius–Clapeyron equation

$$\left( \ln \frac{P_2}{P_1} = \frac{\Delta H_{\text{vap}}}{R} \left( \frac{1}{T_1} - \frac{1}{T_2} \right) \right)$$

- Heat of vaporization
- Vapor pressure
- Normal boiling point

Estimate the vapor pressure of water at 85°C. Note that the normal boiling point of water is 100°C and that its heat of vaporization is 40.7 kJ/mol.

**Problem Strategy** The two-point form of the Clausius–Clapeyron equation relates five quantities:  $P_1$ ,  $T_1$ ,  $P_2$ ,  $T_2$ , and  $\Delta H_{\text{vap}}$ . The normal boiling point is the temperature at which the vapor pressure equals 760 mmHg. Thus, you can let  $P_1$  equal 760 mmHg and  $T_1$  equal 373 K (100°C). Then  $P_2$  would be the vapor pressure at  $T_2$ , or 358 K (85°C). The heat of vaporization,  $\Delta H_{\text{vap}}$ , is  $40.7 \times 10^3$  J/mol. Note that we have expressed this quantity in joules per mole to agree with the units of the molar gas constant,  $R$ , which equals 8.31 J/(K·mol).

(continued)

**Example 11.2** (continued)

**Solution** You can now substitute into the two-point equation (the equation shaded in color just before this example).

$$\ln \frac{P_2}{760 \text{ mmHg}} = \frac{40.7 \times 10^3 \text{ J/mol}}{8.31 \text{ J/(K} \cdot \text{mol)}} \left( \frac{1}{373 \text{ K}} - \frac{1}{358 \text{ K}} \right)$$

$$= (4898 \text{ K}) \times (-1.123 \times 10^{-4}/\text{K}) = -0.550$$

You now want to solve this equation for  $P_2$ , which is the vapor pressure of water at  $85^\circ\text{C}$ . To do so, you take the antilogarithm (antiln) of both sides of the equation. This gives

$$\frac{P_2}{760 \text{ mmHg}} = \text{antiln}(-0.550)$$

The antiln ( $-0.550$ ) is  $e^{-0.550} = 0.577$ . (Appendix A describes how to obtain the antilogarithm.) Thus

$$\frac{P_2}{760 \text{ mmHg}} = 0.577$$

Therefore,

$$P_2 = 0.577 \times 760 \text{ mmHg} = \mathbf{439 \text{ mmHg}}$$

This value may be compared with the experimental value of 434 mmHg, given in Appendix B. Differences from the experimental value stem from the fact that the Clausius–Clapeyron equation is an approximate relation.

**Answer Check** The result should be less than 760 mmHg, because the vapor pressure is lower at a lower temperature. If you inadvertently dropped the minus sign before taking the antiln, you would have gotten a result larger than 760 mmHg. Also, if you had entered  $\Delta H_{\text{vap}}$  in kilojoules, rather than joules, the result would be close to zero, which is not reasonable given that the water is at  $85^\circ\text{C}$ .

**Exercise 11.2** Carbon disulfide,  $\text{CS}_2$ , has a normal boiling point of  $46^\circ\text{C}$  and a heat of vaporization of 26.8 kJ/mol. What is the vapor pressure of carbon disulfide at  $35^\circ\text{C}$ ?

See Problems 11.49 and 11.50.

**Example 11.3** Calculating the Heat of Vaporization from Vapor Pressures**Gaining Mastery Toolbox****Critical Concept 11.3**

The heat of vaporization of a liquid,  $\Delta H_{\text{vap}}$ , does not depend upon temperature. The two-point form of the Clausius–Clapeyron equation can be used to calculate the  $\Delta H_{\text{vap}}$  of a liquid.

**Solution Essentials:**

- Clausius–Clapeyron equation

$$\left( \ln \frac{P_2}{P_1} = \frac{\Delta H_{\text{vap}}}{R} \left( \frac{1}{T_1} - \frac{1}{T_2} \right) \right)$$

- Heat of vaporization
- Vapor pressure

Calculate the heat of vaporization of diethyl ether (often called simply “ether”),  $\text{C}_4\text{H}_{10}\text{O}$ , from the following vapor pressures: 400 mmHg at  $18^\circ\text{C}$  and 760 mmHg at  $35^\circ\text{C}$ . (Each pressure value has three significant figures.)

**Problem Strategy** If you let  $P_1$  be 400 mmHg, then  $T_1$  is 291 K ( $18^\circ\text{C}$ ),  $P_2$  is 760 mmHg, and  $T_2$  is 308 K ( $35^\circ\text{C}$ ). You substitute these values into the Clausius–Clapeyron equation.

**Solution**

$$\ln \frac{760 \text{ mmHg}}{400 \text{ mmHg}} = \frac{\Delta H_{\text{vap}}}{8.31 \text{ J/(K} \cdot \text{mol)}} \times \left( \frac{1}{291 \text{ K}} - \frac{1}{308 \text{ K}} \right)$$

$$0.642 = (2.28 \times 10^{-5}) \times \Delta H_{\text{vap}}(\text{J/mol})$$

Therefore,

$$\Delta H_{\text{vap}} = 2.82 \times 10^4 \text{ J/mol} \quad \mathbf{(28.2 \text{ kJ/mol})}$$

(continued)

**Example 11.3** (continued)

**Answer Check** Whenever you are dealing with calculated quantities of heat, always make sure that the sign of your answer makes sense. In this case, because vaporization is a process that requires energy, the answer should always be a positive quantity as it is here. Also, enthalpies of vaporization generally fall in the range of tens of kilojoules per mole, so anything much outside that range should be suspect.

**Exercise 11.3** Selenium tetrafluoride,  $\text{SeF}_4$ , is a colorless liquid. It has a vapor pressure of 757 mmHg at  $105^\circ\text{C}$  and 522 mmHg at  $95^\circ\text{C}$ . What is the heat of vaporization of selenium tetrafluoride?

See Problems 11.51 and 11.52.

## 11.3 Phase Diagrams

As we mentioned in the chapter opening, the solid, liquid, and gaseous states of carbon dioxide exist under different temperature and pressure conditions. A **phase diagram** is a graphical way to summarize the conditions under which the different states of a substance are stable.

### Melting-Point Curve

Figure 11.11 is a phase diagram for water. It consists of three curves that divide the diagram into regions labeled “solid,” “liquid,” and “gas.” In each region, the indicated state is stable. Every point on each of the curves indicates experimentally determined temperatures and pressures at which two states are in equilibrium. Thus, the curve  $AB$ , dividing the solid region from the liquid region, represents the conditions under which the solid and liquid are in equilibrium.

This curve gives the melting points of the solid at various pressures.

Usually, the melting point is only slightly affected by pressure. For this reason, the melting-point curve  $AB$  is nearly vertical. If a liquid is more dense than the solid, as is the case for water, the melting point decreases with pressure. ► The melting-point curve in such cases leans slightly to the left. In the case of ice, the decrease is indeed slight—only  $1^\circ\text{C}$  for a pressure increase of 133 atm. For most substances, the liquid state is less dense than the solid. In that case, the melting-point curve leans slightly to the right.

### Vapor-Pressure Curves for the Liquid and the Solid

The curve  $AC$  that divides the liquid region from the gaseous region gives the vapor pressures of the liquid at various temperatures. It also gives the boiling points of the liquid for various pressures. The boiling point of water at 1 atm is shown on the phase diagram (Figure 11.11).

The curve  $AD$  that divides the solid region from the gaseous region gives the vapor pressures of the solid at various temperatures. This curve intersects the other curves at point  $A$ , the **triple point**, which is the point on a phase diagram representing the temperature and pressure at which three phases of a substance coexist in equilibrium. For water, the triple point occurs at  $0.01^\circ\text{C}$ , 0.00603 atm (4.58 mmHg), and the solid, liquid, and vapor phases coexist. ►

The following is a dramatic demonstration of the effect of pressure on the melting of ice: Suspend a block of ice between two chairs. Then loop a length of wire over the block and place weights on the ends of the wire. The pressure of the wire will melt the ice under it. Liquid water will flow over the top of the wire and freeze again, because it is no longer under the pressure of the wire. As a result, the wire will cut through the ice and fall to the floor, but the block of ice will remain as one piece.

Because the triple point for water occurs at a definite temperature, it is used to define the Kelvin temperature scale. The temperature of water at its triple point is defined to be  $273.16\text{ K}$  ( $0.01^\circ\text{C}$ ).

**Figure 11.11** ◀

**Phase diagram for water (not to scale)** The curves  $AB$ ,  $AC$ , and  $AD$  divide the diagram into regions that give combinations of temperature and pressure for which only one state is stable. Along any curve, the two states from the adjoining regions are in equilibrium.

**a** Carbon dioxide. At normal atmospheric pressure (1 atm), the solid sublimes when warmed.

**b** Sulfur. This substance has a complicated phase diagram with three triple points.

**Figure 11.12** ▲

**Phase diagrams for carbon dioxide and sulfur (not to scale)**

Suppose a solid is warmed at a pressure below the pressure at the triple point. In a phase diagram, this corresponds to moving along a horizontal line below the triple point. You can see from Figure 11.11 that such a line will intersect curve *AD*, the vapor-pressure curve for the solid. Thus, the solid will pass directly into the gas; that is, the solid will sublime. Freeze-drying of a food (or brewed coffee) is accomplished by placing the frozen food in a vacuum (below 0.00603 atm) so that the ice in it sublimates. Because the food can be dried at a lower temperature than if heat-dried, it retains more flavor and can often be reconstituted by simply adding water.

The triple point of carbon dioxide is at  $-57^{\circ}\text{C}$  and 5.1 atm (Figure 11.12a). Therefore, the solid sublimates if warmed at any pressure below 5.1 atm. This is why solid carbon dioxide sublimates at normal atmospheric pressure (1 atm). Above 5.1 atm, however, the solid melts if warmed. Sulfur has a more complicated phase diagram (Figure 11.12b). It displays three triple points, one of them involving two different solid forms of sulfur (called rhombic sulfur and monoclinic sulfur), as well as the vapor.

### Critical Temperature and Pressure

Imagine an experiment in which liquid and gaseous carbon dioxide are sealed in a thick-walled glass vessel at  $20^{\circ}\text{C}$ . At this temperature, the liquid is in equilibrium with its vapor at a pressure of 57 atm. You observe that the liquid and vapor are separated by a well-defined boundary, or meniscus. Now suppose the temperature is raised. The vapor pressure increases, and at  $30^{\circ}\text{C}$  it is 71 atm. Then, as the temperature approaches  $31^{\circ}\text{C}$ , a curious thing happens. The meniscus becomes fuzzy and less well defined. At  $31^{\circ}\text{C}$ , the meniscus disappears altogether. Above this temperature and above the critical pressure, there is only one fluid state, called a *supercritical fluid* (see Figure 11.13).

The temperature above which the liquid state of a substance no longer exists regardless of the pressure is called the **critical temperature**. For carbon dioxide it is

**a** Carbon dioxide liquid in equilibrium with its vapor at  $20^{\circ}\text{C}$ .

**b** The same two states in equilibrium at  $30^{\circ}\text{C}$  (just below the critical point); the densities of the liquid and vapor are becoming equal.

**c** Carbon dioxide at  $31^{\circ}\text{C}$  (the critical temperature); the liquid and vapor now have the same densities—in fact, the distinction between liquid and vapor has disappeared, resulting in what is called a supercritical fluid.

**Figure 11.13** ▲

**Observing the critical phenomenon**

31°C. The vapor pressure at the critical temperature is called the **critical pressure** (73 atm for carbon dioxide). It is the minimum pressure that must be applied to a gas at the critical temperature to liquefy it.

On a phase diagram, the preceding experiment corresponds to following the vapor-pressure curve where the liquid and vapor are in equilibrium. Note that this curve in Figure 11.12a ends at a point at which the temperature and pressure have their critical values. This is the *critical point*. If you look at the phase diagram for water, you will see that the vapor-pressure curve for the liquid similarly ends, at point C, which is the critical point for water. In this case, the critical temperature is 374°C and the critical pressure is 218 atm.

Many important gases cannot be liquefied at room temperature. Nitrogen, for example, has a critical temperature of  $-147^{\circ}\text{C}$ . This means the gas cannot be liquefied until the temperature is below  $-147^{\circ}\text{C}$ .

### Example 11.4 Relating the Conditions for the Liquefaction of a Gas to Its Critical Temperature

#### Gaining Mastery Toolbox

##### Critical Concept 11.4

No substance can be liquefied if its temperature is at or above the critical temperature. There are substances that cannot be liquefied at normal (room) temperatures no matter what the pressure.

##### Solution Essentials:

- Critical temperature
- Phase transition

The critical temperatures of ammonia and nitrogen are  $132^{\circ}\text{C}$  and  $-147^{\circ}\text{C}$ , respectively. Explain why ammonia can be liquefied at room temperature by merely compressing the gas to a high enough pressure, whereas the compression of nitrogen requires lower temperatures for liquefaction to occur.

**Problem Strategy** Note that above the critical temperature, a gas cannot be liquefied (that is, transformed so that the gas coexists in equilibrium with the liquid). This can occur only below the critical temperature.

**Solution** The critical temperature of ammonia is well above room temperature. If ammonia gas at room temperature is compressed, it will liquefy. **Nitrogen, however, has a critical temperature well below room temperature.** It cannot be liquefied by compression unless the temperature is below the critical temperature.

**Answer Check** Make sure that you understand the critical temperature correctly; liquefaction can occur only *below* the critical temperature if sufficient pressure has been applied to the gas.

**Exercise 11.4** Describe how you could liquefy the following gases: a. methyl chloride,  $\text{CH}_3\text{Cl}$  (critical point,  $144^{\circ}\text{C}$ , 66 atm); b. oxygen,  $\text{O}_2$  (critical point,  $-119^{\circ}\text{C}$ , 50 atm).

See Problems 11.57 and 11.58.

#### CONCEPT CHECK 11.2

When camping at high altitude, you need to pay particular attention to changes in cooking times for foods that are boiled in water. If you like eggs that are boiled for 10 minutes near sea level, would you have to cook them for a longer or a shorter time at 3200 m to get the egg you like? Be sure to explain your answer.

## Liquid State

Now we will look at some physical properties of liquids. After that, we will explain the experimental values of these properties in terms of intermolecular forces.

### 11.4 Properties of Liquids; Surface Tension and Viscosity

You have seen that molecules tend to escape the liquid state and form a vapor. The vapor pressure is the equilibrium partial pressure of this vapor over the liquid; it increases with temperature. The boiling point is the temperature at which the vapor

## Removing Caffeine from Coffee

Legend has it that a goat herder named Kaldi, in the ancient country of Abyssinia (now Ethiopia, in northeast Africa), discovered the pleasant effect of coffee beans when he noted that his goats danced wildly about after eating the shiny leaves and red berries of a small tree. Later he tried eating the whole berries himself, and he soon found that he was dancing with his goats. Whether the legend is true or not, it does effectively describe the stimulant effect of this berry from the coffee tree. As we now know, coffee, which today is obtained by roasting the berries' green pits, or beans as they are called, contains the stimulant caffeine, a bitter-tasting white substance with the formula  $C_8H_{10}N_4O_2$ . (Figure 11.14 shows the structural formula of caffeine.)

For those who like the taste of roasted coffee but don't want the caffeine, decaffeinated coffee is available. A German chemist, Ludwig Roselius, first made "decaf" coffee about 1900 by extracting the caffeine from green coffee beans with the solvent chloroform,  $CHCl_3$ . Later, commercial processes replaced chloroform with the safer organic solvent methylene chloride,  $CH_2Cl_2$ . Today, though, most of the commercial decaffeinated coffee produced (Figure 11.15) uses *supercritical* carbon dioxide as the extracting fluid.

In a tank of carbon dioxide under pressure (for example, in a  $CO_2$  fire extinguisher), the substance normally exists as the liquid in equilibrium with its gas phase. But we know from the previous text discussion that above  $31^\circ C$  ( $88^\circ F$ ), the

two phases, gas and liquid, are replaced by a single fluid phase. So, on a hot summer day (above  $31^\circ C$ , or  $88^\circ F$ ), the carbon dioxide in such a tank is above its critical temperature and pressure and exists as the supercritical fluid.

Supercritical carbon dioxide is a near-ideal solvent. Under normal conditions, carbon dioxide is not a very good solvent for organic substances, but supercritical carbon dioxide readily dissolves many of these substances, including caffeine. It is nontoxic and nonflammable. It also has no effect on the stratospheric ozone layer, whereas methylene chloride does. (See the essay on stratospheric ozone at the end of Chapter 10.) Carbon dioxide does contribute to the greenhouse effect (discussed in the essay at the end of Chapter 5), but the gas once used can be recirculated for solvent use and not vented to the atmosphere.

Supercritical fluids have gained much attention recently because of the possibility of replacing toxic and environmentally less desirable solvents. For example, at the moment, the usual solvent used to dry-clean clothes is perchloroethylene,  $CCl_2CCl_2$ . Although nonflammable and less toxic than carbon tetrachloride, which was the solvent previously used, perchloroethylene is regulated as an air pollutant under the Clean Air Act. Some scientists have shown that you can dry-clean with supercritical carbon dioxide if you use a special detergent.

Substances other than carbon dioxide have also shown intriguing solvent properties. For example, whereas water under normal conditions dissolves ionic and polar substances, above its critical point ( $374^\circ C$ , 217 atm) it becomes an excellent solvent for nonpolar substances. Supercritical water and carbon dioxide promise to replace many toxic or environmentally unfriendly organic solvents.

pressure equals the pressure applied to the liquid. Both vapor pressure and boiling point are important properties of a liquid. Values of the vapor pressure for some liquids at 20°C are listed in Table 11.2 (column 3). Two additional properties given in Table 11.2 are surface tension and viscosity. All of these properties, as you will see in the next section, depend on intermolecular forces, which are related to molecular structure.

### Surface Tension

As Figure 11.16 illustrates, a molecule within the body of a liquid tends to be attracted equally in all directions, so that it experiences no net force. On the other hand, a molecule at the surface of a liquid experiences a net attraction by other molecules toward the interior of the liquid. As a result, there is a tendency for the surface area of a liquid to be reduced as much as possible. This explains why falling raindrops are nearly spherical. (The sphere has the smallest surface area for a given volume of any geometrical shape.)

Energy is needed to reverse the tendency toward reduction of surface area in liquids. **Surface tension** is the energy required to increase the surface area of a liquid by a unit amount. Column 4 in Table 11.2 lists values of the surface tension of some liquids at 20°C.

The surface tension of a liquid can be affected by dissolved substances. Soaps and detergents, in particular, drastically decrease the surface tension of water. An interesting but simple experiment shows the effect of soap on surface tension. Because of surface tension, a liquid behaves as though it had a skin. Water bugs (striders) seem to skitter across this skin as if ice-skating (Figure 11.17). You can actually float a pin on water, if you carefully lay it across the surface

Figure 11.16 ▲

**Explaining surface tension** Note that a molecule at the surface experiences a net force toward the interior of the liquid, whereas a molecule in the interior experiences no net force.

Figure 11.17 ◀

### Water strider on a water surface

The water strider seems to skate on the surface “skin” of the water, which is actually a result of surface tension.

© Cengage Learning

**Figure 11.18** ▲**Demonstration of surface tension of water**

A steel pin will float on the surface of water because of surface tension (*top*). The water surface is depressed and slightly stretched by the pin (*bottom*), but even more surface would have to be created for the pin to submerge, which takes more energy. The easiest way to float a pin is to place a square of tissue paper, with the pin on top of it, on the prongs of a fork. When the fork is lowered into the water, the tissue and pin float on the surface. The paper soon becomes water-logged and sinks, leaving the pin floating.

(Figure 11.18). If you then put a drop of soap solution onto the water, the soap spreads across the surface and the pin sinks. Water bugs also sink in soapy water.

**Capillary rise** is a phenomenon related to surface tension. When a small-diameter glass tube, or capillary, is placed upright in water, a column of the liquid rises in the tube (Figure 11.19a). This capillary rise can be explained in the following way: water molecules happen to be attracted to glass. Because of this attraction, a thin film of water starts to move up the inside of the glass capillary. But in order to reduce the surface area of this film, the water level begins to rise also. The final water level is a balance between the surface tension and the potential energy required to lift the water against gravity. Note that the *meniscus*, or liquid surface within the tube, has its edges curved upward; that is, it has a concave shape.

In the case of mercury, the liquid level in the capillary is lower than for the liquid outside (Figure 11.19b). Also, the meniscus has its edges curved downward; that is, it has a convex shape. The difference between Figures 11.19a and 11.19b results from the fact that the attraction between mercury atoms is greater than the attraction of mercury atoms for glass, in contrast to the situation for water and glass.

**Viscosity**

**Viscosity** is *the resistance to flow that is exhibited by all liquids and gases*. The viscosity of a liquid can be obtained by measuring the time it takes for a given quantity to flow through a capillary tube or, alternatively, by the time it takes for a steel ball of given radius to fall through a column of liquid (Figure 11.20). Even without such quantitative measurements, you know from experience that the viscosity of syrup is greater than that of water; syrup is a *viscous* liquid. Viscosity is an important characteristic of motor oils. In the United States, the Society of Automotive Engineers (SAE) has established numbers to indicate the viscosity of motor oils at a given temperature (0°F, or -18°C); higher numbers indicate greater viscosities at that temperature. The viscosity of a simple oil increases as the temperature decreases, so an SAE 40 oil that is appropriate for an auto engine in the summer would be too viscous in very cold weather. An oil designated as SAE 10W/40 is an oil mixture that behaves

**a** Capillary rise, due to the attraction of water and glass. Hydrogen bonds between the water molecules and the glass are illustrated. The final water level in the capillary is a balance between the force of gravity and the surface tension of water.

**b** Depression, or lowering, of mercury level in a glass capillary. Unlike water, mercury is not attracted to glass.

**Figure 11.19** ▲**Liquid levels in capillaries**

like an SAE 10 oil in the winter (W), but like an SAE 40 oil in the summer. Column 5 in Table 11.2 gives the viscosities (in SI units) of some liquids at 20°C.

## 11.5 Intermolecular Forces; Explaining Liquid Properties

In the preceding section, we described a number of properties of liquids. Now we want to explain these properties. Many of the physical properties of liquids (and certain solids too) can be explained in terms of **intermolecular forces**, *the forces of interaction between molecules*. These forces are normally weakly attractive.

One of the most direct indications of the attraction between molecules is the heat of vaporization of liquids. Consider a substance like neon, which consists of molecules that are single atoms. (There is no tendency for these atoms to bond chemically.) Neon is normally a gas, but it liquefies when the temperature is lowered to  $-246^{\circ}\text{C}$  at 1.00 atm pressure. The heat of vaporization of the liquid at this temperature is 1.77 kJ/mol. Some of this energy (0.23 kJ/mol) is needed to push back the atmosphere when the vapor forms. The remaining energy (1.54 kJ/mol) must be supplied to overcome intermolecular attractions. Because a molecule in a liquid is surrounded by several neighbor molecules, this remaining energy is some multiple of a single molecule–molecule interaction. Typically, this multiple is about 5, so we expect the neon–neon interaction energy to be about 0.3 kJ/mol. Other experiments yield a similar value. By comparison, the energy of attraction between two hydrogen atoms in the hydrogen molecule is 432 kJ/mol. Thus, the energy of attraction between neon atoms is about a thousand times smaller than that between atoms in a chemical bond.

Attractive intermolecular forces can be larger than those in neon. For example, chlorine,  $\text{Cl}_2$ , and bromine,  $\text{Br}_2$ , have intermolecular attractive energies of 3.0 kJ/mol and 4.3 kJ/mol, respectively. But even these values are much smaller than bond energies.

Three types of attractive forces are known to exist between neutral molecules: dipole–dipole forces, London (or dispersion) forces, and hydrogen bonding forces. Each of these will be explained in this section. The term **van der Waals forces** is a general term for those intermolecular forces that include dipole–dipole and London forces. ▶ Van der Waals forces are the weak attractive forces in a large number of substances, including Ne,  $\text{Cl}_2$ , and  $\text{Br}_2$ , which we just discussed. Hydrogen bonding occurs in substances containing hydrogen atoms bonded to certain very electronegative atoms. Approximate energies of intermolecular attractions are compared with those of chemical bonds in Table 11.3.

### Dipole–Dipole Forces

Polar molecules can attract one another through dipole–dipole forces. The **dipole–dipole force** is an attractive intermolecular force resulting from the tendency of polar molecules to align themselves such that the positive end of one molecule is near the negative end of another. Recall that a polar molecule has a dipole moment as a result of the electronic structure of the molecule. ▶ For example, hydrogen chloride, HCl, is a polar molecule because of the difference in electronegativities of the H and Cl atoms.

Figure 11.21 shows the alignment of polar molecules in the case of HCl. Note that this alignment creates a net attraction between molecules. This attractive force is partly responsible for the fact that hydrogen chloride, a gas at room temperature, becomes a liquid when cooled to  $-85^{\circ}\text{C}$ . At this temperature, HCl molecules have slowed enough (that is, have a low enough kinetic energy) for the intermolecular forces to hold the molecules in the liquid state.

### London (Dispersion) Forces

In nonpolar molecules, there can be no dipole–dipole force. Yet such substances liquefy, so there must be another type of

Figure 11.20 ▲

**Comparison of the viscosities of two liquids** Similar steel balls were dropped simultaneously into two graduated cylinders, the right one containing water and the left one glycerol. A steel ball takes considerably longer to fall through a column of glycerol than through a similar column of water, because glycerol has a greater viscosity than water.

The Dutch physicist Johannes van der Waals (1837–1923) was the first to suggest the importance of intermolecular forces and used the concept to derive his equation for gases. (See van der Waals equation, Section 5.8.)

Dipole moments were discussed in Section 10.2.

Table 11.3 Types of Intermolecular and Chemical Bonding Interactions

Type of Interaction	Approximate Energy (kJ/mol)
Intermolecular	
Van der Waals	
(dipole–dipole, London)	0.1 to 10
Hydrogen bonding	10 to 40
Chemical bonding	
Ionic	100 to 1000
Covalent	100 to 1000

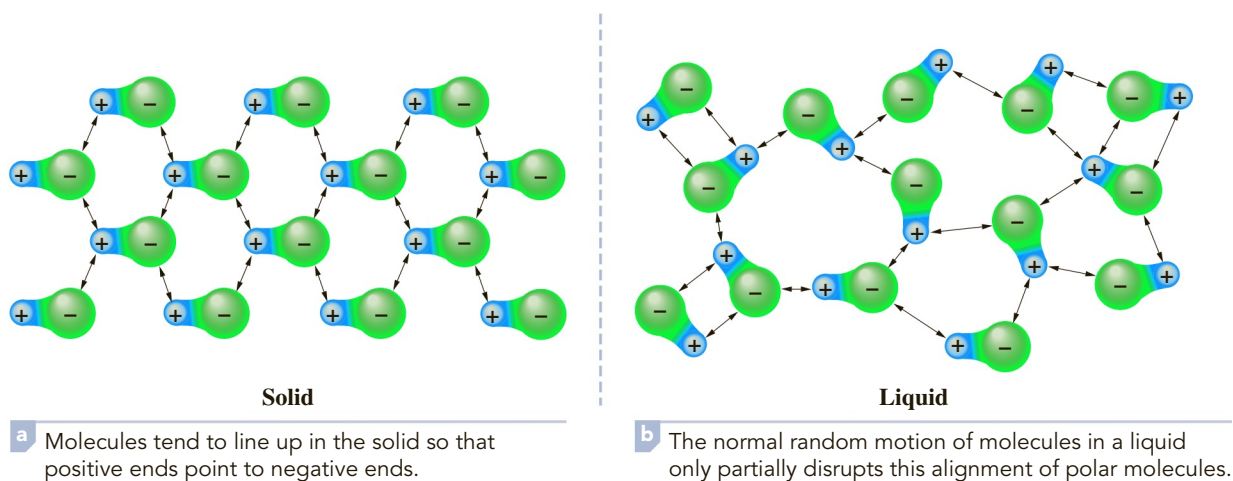

Figure 11.21 ▲

## Alignment of polar molecules of HCl

attractive intermolecular force. Even in hydrogen chloride, calculations show that the dipole–dipole force accounts for less than 20% of the total energy of attraction. What is the nature of the additional attractive force?

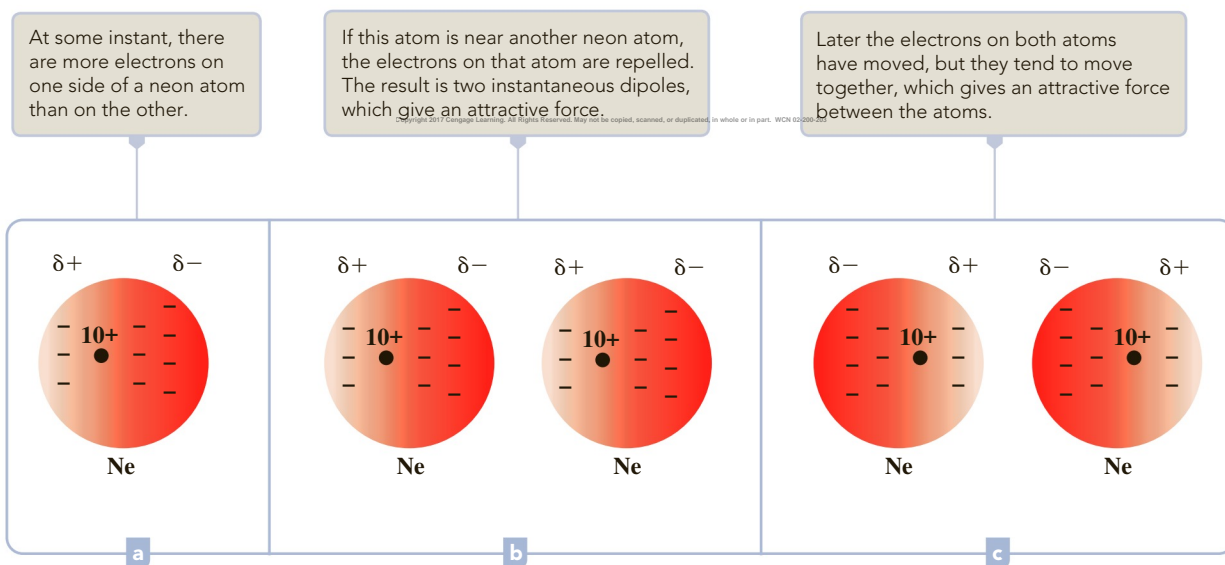

In 1930 Fritz London found he could account for a weak attraction between any two molecules. Let us use neon to illustrate his argument. The electrons of this atom move about the nucleus so that over a period of time they have a spherical distribution. The electrons spend as much time on one side of the nucleus as on the other. Experimentally, you find that the atom has no dipole moment. However, at any instant, more electrons may be on one side of the nucleus than on the other. The atom becomes a small, instantaneous dipole, with one side having a partial negative charge,  $\delta^-$ , and the other side having a partial positive charge,  $\delta^+$  (see Figure 11.22a).

Now imagine that another neon atom is close to this first atom—say, next to the partial negative charge that appeared at that instant. This partial negative charge repels the electrons in the second atom, so at this instant it too becomes a small dipole (see Figure 11.22b). Note that these two dipoles are oriented with the partial negative charge of one atom next to the partial positive charge of the other atom. Therefore, an attractive force exists between the two atoms.

Electrons are in constant motion, but the motion of electrons on one atom affects the motion of electrons on the other atom. As a result, the *instantaneous dipoles* of the atoms tend to change together, maintaining a net attractive force (compare b and c of Figure 11.22). Such instantaneous changes of electron

Figure 11.22 ▼

## Origin of the London force

distributions occur in all molecules. For this reason, an attractive force always exists between any two molecules.

Thus, you see that **London forces** (also called **dispersion forces**) are *the weak attractive forces between molecules resulting from the small, instantaneous dipoles that occur because of the varying positions of the electrons during their motion about nuclei*.

London forces tend to increase with molecular weight. This is because molecules with larger molecular weight usually have more electrons, and London forces increase in strength with the number of electrons. Also, larger molecular weight often means larger atoms, which are more *polarizable* (more easily distorted to give instantaneous dipoles because the electrons are farther from the nuclei). The relationship of London forces to molecular weight is only approximate, however. For molecules of about the same molecular weight, the more compact one is less polarizable, so the London forces are smaller. Consider pentane, 2-methylbutane, and 2,2-dimethylpropane.

All have the same molecular formula,  $\text{C}_5\text{H}_{12}$ , and thus the same molecular weight, but they differ in the arrangement of the atoms. Pentane is a long chain of carbon atoms to which hydrogen atoms are attached. However, 2-methylbutane and neopentane have increasingly more compact arrangements of atoms. As a result, you expect London forces to decrease from pentane to 2-methylbutane and from 2-methylbutane to neopentane. This is confirmed in the heats of vaporization and boiling points listed above.

### Intermolecular Forces and the Properties of Liquids

The vapor pressure of a liquid depends on intermolecular forces, because the ease or difficulty with which a molecule leaves the liquid depends on the strength of its attraction to other molecules. When the intermolecular forces in the liquid are strong, you expect the vapor pressure to be low.

Let us look again at Table 11.2, which lists vapor pressures as well as surface tensions and viscosities of some liquids at 20°C. The intermolecular attractions in these liquids (except for water and glycerol) are due entirely to van der Waals forces. Of the van der Waals forces, the London force is always present and usually dominant. The dipole-dipole force is usually appreciable only in small polar molecules or in large molecules having very large dipole moments. As noted earlier, the dipole-dipole attraction in the small, polar molecule HCl accounts for less than 20% of its interaction energy.

The liquids in Table 11.2 are listed in order of increasing molecular weight. Recall that London forces tend to increase with molecular weight. Therefore, London forces would be expected to increase for these liquids from the top to the bottom of the table. If London forces are the dominant attractive forces in these liquids, the vapor pressures should decrease from top to bottom in the table. And this is what you see, except for water and glycerol. (Their vapor pressures are relatively low, and an additional force, hydrogen bonding, is needed to explain them.)

The normal boiling point of a liquid must depend on intermolecular forces, because it is related to the vapor pressure. Normal boiling points are approximately proportional to the energy of intermolecular attraction. Thus, they are lowest for liquids with the weakest intermolecular forces.

Surface tension also depends on intermolecular forces. Surface tension is the energy needed to increase the surface area of a liquid. To increase the surface area, it is necessary to pull molecules apart against the intermolecular forces of attraction. Thus, surface tension would be expected to increase with the strength of attractive forces. If London forces are the dominant attractive forces in the liquid, surface tension should increase with molecular weight—that is, it should increase from top to bottom in Table 11.2. This is what you see, except for water and glycerol, which have relatively high surface tensions.

The viscosity of a liquid depends in part on intermolecular forces, because increasing the attractive forces between molecules increases the resistance to flow. If London forces are dominant, you should expect the viscosity of the liquids in Table 11.2 to increase from the top of the column to the bottom, which it does (again with the exception of water and glycerol; these liquids have relatively high viscosities). Note, however, that the viscosity also depends on other factors, such as the possibility of molecules tangling together. Liquids with long molecules that tangle together are expected to have high viscosities.

### ✓ CONCEPT CHECK 11.3

Consider two liquids, labeled A and B, that are both pure substances. Liquid A has relatively strong intermolecular forces when compared to liquid B. The molecular structures of A and B are similar. Which one of the statements regarding liquids A and B is false?

- a** Liquid A would have a higher boiling point than liquid B.
- b** Liquid B would be more viscous than liquid A.
- c** Liquid B would have a lower freezing point than liquid A.
- d** Liquid A would have a lower vapor pressure than Liquid B.
- e** Liquid A and B would melt at different temperatures.

**Figure 11.23** ▲  
**Fluoromethane and methanol** Space-filling molecular models.

### Hydrogen Bonding

It is interesting to compare fluoromethane, CH<sub>3</sub>F, and methanol, CH<sub>3</sub>OH (Figure 11.23). They have about the same molecular weight (34 for CH<sub>3</sub>F and 32 for CH<sub>3</sub>OH) and about the same dipole moment (1.81 D for CH<sub>3</sub>F and 1.70 D for CH<sub>3</sub>OH). You might expect these substances to have about the same intermolecular attractive forces and therefore about the same boiling points. In fact, the boiling points are quite different. Fluoromethane boils at  $-78^{\circ}\text{C}$  and is a gas under normal conditions. Methanol boils at  $65^{\circ}\text{C}$  and is normally a liquid. We must conclude that there is an intermolecular attraction in methanol that is not present in fluoromethane.

We have already seen that the properties of water and glycerol cannot be explained in terms of van der Waals forces alone. What water, glycerol, and methanol have in common is one or more —OH groups.

Molecules that have the —OH group are subject to an additional attractive force called hydrogen bonding. **Hydrogen bonding** is a weak to moderate attractive force that exists between a hydrogen atom covalently bonded to a very electronegative atom,  $X$ , and a lone pair of electrons on another small, electronegative atom,  $Y$ . Hydrogen bonding is represented in structural drawings by a series of dots.

Usually, hydrogen bonding is seen in cases where  $X$  and  $Y$  are the atoms F, O, or N.

Figure 11.24a shows a plot of boiling point versus molecular weight for the hydrides (binary compounds with hydrogen) of the Group 6A elements. If London forces were the only intermolecular forces present in this series of compounds, the

Figure 11.24 ◀

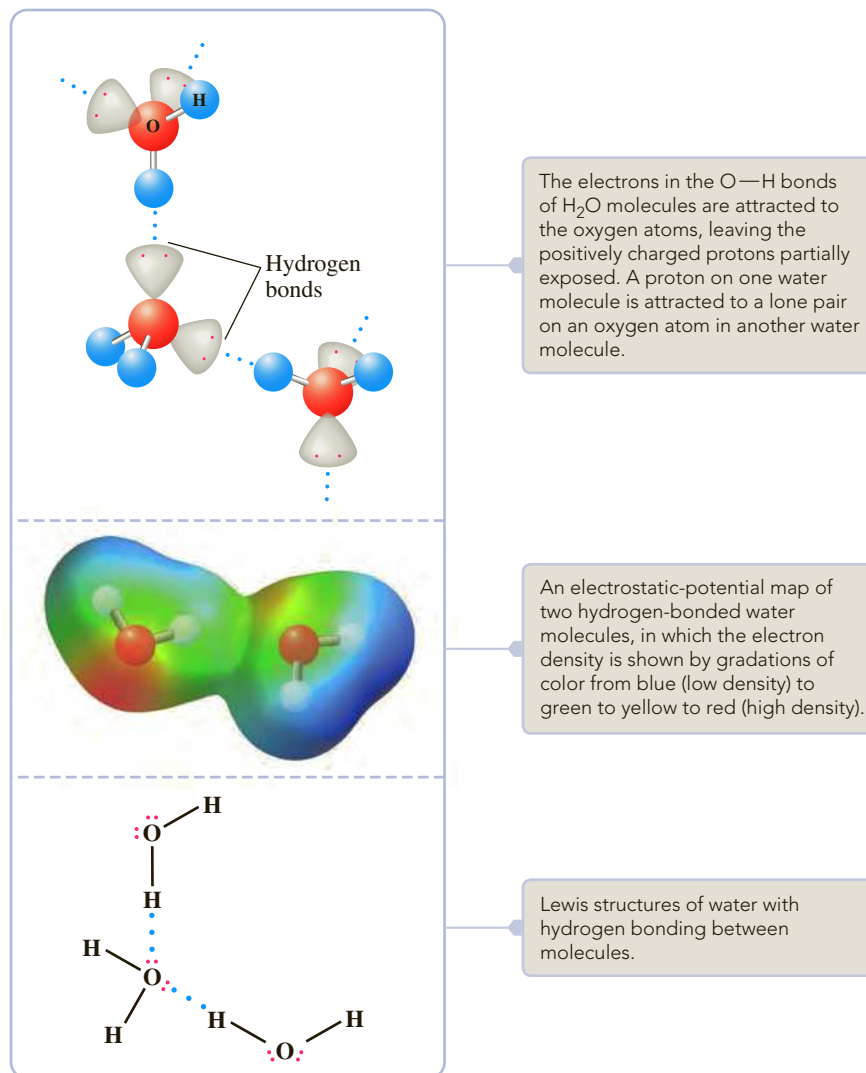

Boiling point versus molecular weight for hydrides

**a** Plot for the Group 6A hydrides. Note that the boiling points of H<sub>2</sub>S, H<sub>2</sub>Se, and H<sub>2</sub>Te increase fairly smoothly, as you would expect if London forces are dominant. H<sub>2</sub>O has a much higher boiling point, indicating an additional intermolecular attraction.

**b** Plot for the hydrides of Groups 7A, 5A, and 4A. Of the molecules on the plot, HF and NH<sub>3</sub> are the only ones that have hydrogen bonding.

Figure 11.25 ►

## Hydrogen bonding in water

boiling points should increase regularly with molecular weight. You do see such a regular increase in boiling point for  $\text{H}_2\text{S}$ ,  $\text{H}_2\text{Se}$ , and  $\text{H}_2\text{Te}$ . On the other hand,  $\text{H}_2\text{O}$  has a much higher boiling point than you would expect if only London forces were present. This is consistent with the view that hydrogen bonding exists in  $\text{H}_2\text{O}$  but is essentially absent in  $\text{H}_2\text{S}$ ,  $\text{H}_2\text{Se}$ , and  $\text{H}_2\text{Te}$ .

Studies of the structure of  $\text{H}_2\text{O}$  in its different physical states show that hydrogen bonding is present. The hydrogen atom of one water molecule is attracted to the electron pair of another water molecule (Figure 11.25). Many  $\text{H}_2\text{O}$  molecules can be linked this way to form clusters of molecules. Similar hydrogen bonding is seen in other molecules containing —O—H groups.

Figure 11.24b shows plots of boiling point versus molecular weight for Groups 7A, 5A, and 4A hydrides. Hydrogen fluoride, HF, and ammonia,  $\text{NH}_3$ , have particularly high boiling points compared with other hydrides of their periodic group. Definite structural evidence has established hydrogen bonding in HF. In solid hydrogen fluoride, the structure shows a zigzag arrangement involving hydrogen bonding.

The hydrogen bonding attraction between two water molecules may be explained in part on the basis of the dipole moment of the —O—H bond.

The partial positive charge on the hydrogen atom of one water molecule is attracted to the partial negative charge of a lone pair on another water molecule. In addition, however, a hydrogen atom covalently bonded to an electronegative atom appears to be special. The electrons in the —O—H bond are drawn to the O atom, leaving the concentrated positive charge of the proton partially exposed. This concentrated positive charge is strongly attracted to a lone pair of electrons on another O atom. Figure 11.26 shows the hydrogen bonding between two biologically important molecules.

**Figure 11.26** ◀

**Hydrogen bonding between two biologically important molecules** These electrostatic-potential maps show the electron densities (relative to the nuclei) of two molecules (guanine and cytosine). The electron densities increase as the color changes from blue to green to yellow to red. Note the three H bonds between the two molecules. Each H bond is between an H atom with low electron density (exposing the positive charge on the atom) and the lone electron pair (high density) of either an O or N atom. (The molecules are guanine and cytosine, which are two of the four bases used as codes in DNA; this is explained in Chapter 24.)

### Example 11.5 Identifying Intermolecular Forces in a Substance

#### Gaining Mastery Toolbox

##### Critical Concept 11.5

There are three types of intermolecular forces possible in molecular substances: London, dipole–dipole, and hydrogen bonding. All molecular substances have London forces. Molecular structure and chemical composition determine if dipole–dipole forces are expected. Hydrogen bonding is an important special case of very strong dipole–dipole forces.

##### Solution Essentials:

- Hydrogen bonding
- London forces
- Dipole–dipole forces
- Intermolecular forces

What kinds of intermolecular forces (London, dipole–dipole, hydrogen bonding) are expected in the following substances?

- methane,  $\text{CH}_4$
- (trichloromethane see first model at left)
- butanol (butyl alcohol),  $\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{OH}$

**Problem Strategy** Note that London forces are always present. Then ask yourself whether the molecule is polar—in which case, dipole–dipole forces exist. (Refer to Section 10.2 on dipole moment and molecular geometry.) Now note whether hydrogen bonding is present. (Is a hydrogen atom bonded to F, O, or N?)

#### Solution

a. Methane is a nonpolar molecule. Hence, the only intermolecular attractions are **London forces**. b. Trichloromethane is an unsymmetrical molecule with polar bonds. Thus, we expect **dipole–dipole forces**, in addition to **London forces**. c. Butanol has a hydrogen atom attached to an oxygen atom. Therefore, you expect **hydrogen bonding**. Because the molecule is polar (from the O—H bond), you also expect **dipole–dipole forces**. **London forces** exist too, because such forces exist between all molecules.

(continued)

**Example 11.5** (continued)

**Answer Check** Remember that London forces are always present, even when other types of intermolecular forces exist.

**Exercise 11.5** List the different intermolecular forces you would expect for each of the following compounds:

- propanol,  $\text{CH}_3\text{CH}_2\text{CH}_2\text{OH}$
- (carbon dioxide see second model at left)
- sulfur dioxide,  $\text{SO}_2$

See Problems 11.63 and 11.64.

**Example 11.6** Determining Relative Vapor Pressures on the Basis of Intermolecular Attractions**Gaining Mastery Toolbox****Critical Concept 11.6**

The strength of the intermolecular forces in a liquid determines the properties of the liquid: vapor pressure, freezing point, and boiling point. The stronger the intermolecular forces in a substance, the higher the vapor pressure, freezing point, and boiling point.

**Solution Essentials:**

- Hydrogen bonding
- London forces
- Dipole–dipole forces
- Intermolecular forces
- Vapor pressure
- Freezing point
- Boiling point

For each of the following pairs, choose the substance you expect to have the lower vapor pressure at a given temperature: a. carbon dioxide ( $\text{CO}_2$ ) or sulfur dioxide ( $\text{SO}_2$ ); b. dimethyl ether ( $\text{CH}_3\text{OCH}_3$ ) or ethanol ( $\text{CH}_3\text{CH}_2\text{OH}$ ).

**Problem Strategy** There are a couple of basic ideas to keep in mind. First, London forces tend to increase with molecular weight. Second, hydrogen bonding tends to dominate other types of forces if it is present.

**Solution**

a. The molecular weights for  $\text{SO}_2$  and  $\text{CO}_2$  are 64 amu and 44 amu, respectively. Therefore, the London forces between  $\text{SO}_2$  molecules should be greater than those between  $\text{CO}_2$  molecules. Moreover, because  $\text{SO}_2$  is polar but  $\text{CO}_2$  is not, there are dipole–dipole forces between  $\text{SO}_2$  molecules but not between  $\text{CO}_2$  molecules. **You conclude that sulfur dioxide has the lower vapor pressure.** Experimental values of the vapor pressure at  $20^\circ\text{C}$  are:  $\text{CO}_2$ , 56.3 atm;  $\text{SO}_2$ , 3.3 atm. b. Dimethyl ether and ethanol have the same molecular formulas but different structural formulas. The structural formulas are

The molecular weight are equal, and therefore the London forces are approximately the same. However, there will be strong hydrogen bonding in ethanol but not in dimethyl ether. **You expect ethanol to have the lower vapor pressure.** Experimental values of vapor pressure at  $20^\circ\text{C}$  are:  $\text{CH}_3\text{OCH}_3$ , 4.88 atm;  $\text{CH}_3\text{CH}_2\text{OH}$ , 0.056 atm.

**Answer Check** Make sure you have the correct molecular weights for the substances and that you have the correct molecular structures so that you will see hydrogen bonding if it is present.

**Exercise 11.6** Arrange the following hydrocarbons in order of increasing vapor pressure: ethane,  $\text{C}_2\text{H}_6$ ; propane,  $\text{C}_3\text{H}_8$ ; and butane,  $\text{C}_4\text{H}_{10}$ . Explain your answer.

See Problems 11.67 and 11.68.

**Exercise 11.7** At the same temperature, methyl chloride,  $\text{CH}_3\text{Cl}$ , has a vapor pressure of 1490 mmHg, and ethanol has a vapor pressure of 42 mmHg. Explain why you might expect methyl chloride to have a higher vapor pressure than ethanol, even though methyl chloride has a somewhat larger molecular weight.

See Problems 11.69 and 11.70.

A CHEMIST Looks at . . .

## Gecko Toes, Sticky But Not Tacky

A gecko (Figure 11.27) can effortlessly climb a wall or walk across a glass ceiling. And like a superacrobat, it can catch itself by a toe while falling. How does it do this? Does the gecko have a gluey substance, or something like sticky tape, on its toes? But if so, how is it possible for the gecko to plant its feet and remove them 15 times a second, which it does when it scurries up a tree? Having a toe stick to a leaf is one thing; being able to remove it easily is another. Recently, the biologist Kellar Autumn at Lewis and Clark College, with other scientists, discovered that the gecko uses van der Waals forces to attach itself to surfaces and employs a special technique to disengage from that surface.

Van der Waals forces exist between any two surfaces, but they are extremely weak unless relatively large areas of the two surfaces come quite close together. The toe of a gecko is covered with fine hairs, each hair having over a thousand split ends. As the gecko walks across a surface, it presses these stalks of hairs against the surface. The intimate contact of a billion or so split ends of hairs with the surface results in a large, attractive force that holds the gecko fast. Just as easily, a gecko's foot comes cleanly away. As the gecko walks, its foot naturally bends so the hairs at the back edge of its toes disengage, row after row, until the toe is free. It is the mechanics of the gecko's walk that allows it to connect to and disengage easily from a surface.

It is interesting to compare gecko toes to adhesive tapes. These tapes are covered with a soft, tacky material that flows when pressure is applied. The tacky adhesive and a surface can then come in close contact, where intermolecular forces provide effective attraction. The problem with a tacky adhesive is that it sticks to not only the surface but dirt as well. You can pull a Post-it Note off one surface

© le pur photography/Shutterstock.com

**Figure 11.27** ▲

**A Tokay gecko** This is a common gecko, a small lizard of the type studied by Kellar Autumn.

and stick it to another surface several times. Eventually, the adhesive gets dirty, and the note loses its adhesive quality and refuses to stick. Gecko toes, though, are sticky but not tacky. The fine hairs do not continue to stick to dirt and can stick and unstick from surfaces indefinitely.

Materials scientists are busy trying to imitate the gecko by developing a "gecko tape," a plastic tape with the property that it can stick and unstick from surfaces many times. The plastic tape is covered in many hairs with split ends, like those on the gecko's toes. Other scientists are trying to design robots that mimic the way a gecko walks. Using gecko tape on the robot's feet might allow it to climb walls. Would we have tried to design such devices if no one had discovered how the gecko does it?

### CONCEPT CHECK 11.4

A common misconception is that the following chemical reaction occurs when water is boiled:

instead of

- What evidence do you have that the second reaction is correct?
- How would the enthalpy of the wrong reaction compare with that of the correct reaction?
- How could you calculate the enthalpy change for the wrong reaction (Chapter 6)?

## ► Solid State

A solid is a nearly incompressible state of matter with a well-defined shape, because the units (atoms, molecules, or ions) making up the solid are in close contact and in fixed positions or sites. In the next section, we will look at the kinds of forces holding the units together in different types of solids. In later sections, we will look at crystalline solids and their structure.

### 11.6 Classification of Solids by Type of Attraction of Units

A solid consists of structural units—atoms, molecules, or ions—that are attracted to one another strongly enough to give a rigid substance. One way to classify solids is by the type of force holding the structural units together. In some cases, these forces are intermolecular and hold molecules together. In other cases, these forces are chemical bonds (metallic, ionic, or covalent) and hold atoms together. From this point of view, then, there are four different types of solids: molecular, metallic, ionic, and covalent. It should be noted, however, that a given ionic bond may have considerable covalent character, and vice versa, so the distinction between ionic and covalent solids is not a precise one.

#### Types of Solids

A **molecular solid** is a solid that consists of atoms or molecules held together by intermolecular forces. Many solids are of this type. Examples include solid neon, solid water (ice), and solid carbon dioxide (dry ice).

A **metallic solid** is a solid that consists of positive cores of atoms held together by a surrounding “sea” of electrons (metallic bonding). In this kind of bonding, positively charged atomic cores are surrounded by delocalized electrons. Examples include iron, copper, and silver.

An **ionic solid** is a solid that consists of cations and anions held together by the electrical attraction of opposite charges (ionic bonds). Examples are cesium chloride, sodium chloride, and zinc sulfide (but ZnS has considerable covalent character).

A **covalent network solid** is a solid that consists of atoms held together in large networks or chains by covalent bonds. Diamond is an example of a three-dimensional network solid. Every carbon atom in diamond is covalently bonded to four others, so an entire crystal might be considered an immense molecule. Graphite is another example of a network solid. It consists of carbon atoms held together by covalent bonds to form two-dimensional networks or sheets. The sheets are stacked one on top of the other, and they are held together by weak van der Waals forces between sheets. Figure 11.28 shows the structures of diamond and graphite. Table 11.4 summarizes these four types of solids.

The so-called “lead” of a pencil is actually graphite. When you draw a pencil lead across a sheet of paper, layers of graphite are drawn off the pencil lead and stick to the paper. Andre Geim, who specializes in thin materials, wondered if it would not be possible to separate off a single sheet of graphite, to form the world’s thinnest material. Physical scientists had already speculated about the properties of such a material, which they called graphene, but most had thought that actually

Table 11.4 Types of Solids

Type of Solid	Structural Units	Attractive Forces Between Structural Units	Examples
Molecular	Atoms or molecules	Intermolecular forces	Ne, H <sub>2</sub> O, CO <sub>2</sub>
Metallic	Atoms (positive cores surrounded by electron “sea”)	Metallic bonding (extreme delocalized bonding)	Fe, Cu, Ag
Ionic	Ions	Ionic bonding	CsCl, NaCl, ZnS
Covalent network	Atoms	Covalent bonding	Diamond, graphite, graphene

**Figure 11.28** ▲

**Structures of diamond and graphite** Diamond is a three-dimensional network solid; every carbon atom is covalently bonded to four others. Graphite consists of sheets of carbon atoms covalently bonded to form a hexagonal pattern of atoms; the sheets are held together by van der Waals forces.

obtaining a single sheet would be impossible. Geim and his collaborator Konstantin Novoselov, both at the University of Manchester, in England, managed to do just that and published their result in 2004. The method they used was unbelievably simple: they put a graphite crystal between layers of Scotch tape and pulled them apart! In that way, they managed to pull layers of graphite apart. Doing this several times, they eventually succeeded in producing single layers of graphite—or graphene. Geim and Novoselov also managed to obtain a number of properties of graphene. Graphene has been shown to be a mechanically strong, transparent, and a flexible electrical conductor. Soon after Geim and Novoselov's initial publications, many other scientists jumped in to investigate the possible applications of this material, particularly in electronics. Different methods of producing graphene have been discovered since its initial discovery, so that wide rolls of graphene can now be made. In 2010, Geim and Novoselov received the Nobel Prize in Physics for their work on this thinnest of materials. Since the preparation of graphene, other two-dimensional, single-sheet materials have been discovered.

### Example 11.7 Identifying Types of Solids

#### Gaining Mastery Toolbox

##### Critical Concept 11.7

The type of solid (molecular, metallic, ionic, or covalent network) is determined by the bonding between the structural units. Molecular solids have molecules as the structural units, metals have metal atoms as the structural units, ionic solids have ions (cations and anions) as the structural units, and covalent network solids have covalently bonded atoms as the structural units.

Which of the four basic types of solids would you expect the following substances to be? a. solid ammonia,  $\text{NH}_3$ ; b. cesium, Cs; c. cesium iodide, CsI; d. silicon, Si.

**Problem Strategy** Some general notions of bonding can be helpful, from which the type of solid formed follows. The metallic elements, of course, have metallic bonding. The nonmetallic elements in Groups 5A to 7A, which are rather reactive, are usually molecular, whereas those in Group 8A (the noble gases) are atomic. The nonmetals in Groups 3A (B) and 4A (C and Si) often occur with network bonding. A compound of two nonmetals is likely to be molecular, although in some cases network bonding occurs (involving Groups 3A and 4A elements especially, such as BN,  $\text{SiO}_2$ , and SiC, with strong single bonds). A compound of a metal and a nonmetal is likely to have ionic bonds.

(continued)

**Example 11.7** (continued)**Solution Essentials:**

- Covalent network solid
- Ionic solid
- Metallic solid
- Molecular solid
- Ionic bond
- Molecule
- Ionic compound

**Solution**

a. Ammonia has a molecular structure; therefore, it freezes as a **molecular solid**.  
 b. Cesium is a metal; it is a **metallic solid**. c. Cesium iodide is an ionic substance; it exists as an **ionic solid**. d. Silicon atoms might be expected to form covalent bonds to other silicon atoms, as carbon does in diamond. A **covalent network solid** would result.

**Answer Check** Make sure you correctly understand the bonding involved in each case.

**Exercise 11.8** Classify each of the following solids according to the forces of attraction that exist between the structural units:

- a. zinc, Zn; b. sodium iodide, NaI; c. silicon carbide, SiC;  
 d. methane, CH<sub>4</sub>.

See Problems 11.73,  
 11.74, 11.75, and  
 11.76.

**Physical Properties**

Many physical properties of a solid can be directly related to its structure. Let us look at several of these properties.

**Melting Point and Structure** Table 11.1 lists the melting points for various solids and also gives the type of solid. For a solid to melt, the forces holding the structural units in their sites must be overcome, at least partially. In a molecular solid, these forces are weak intermolecular attractions. Thus, molecular solids tend to have low melting points (usually below 300°C). At room temperature, many molecular substances are either liquids (such as water and ethanol) or gases (such as carbon dioxide and ammonia). Note also that the melting points of molecular solids reflect the strengths of intermolecular attractions, just as boiling points do. This can be seen in the melting points of the molecular solids listed in Table 11.1.

For ionic solids and covalent network solids to melt, chemical bonds must be broken. For that reason, the melting points of these types of solids are relatively high. The melting point of the ionic solid sodium chloride is 801°C; that of magnesium oxide is 2800°C. Melting points of covalent network solids are generally quite high. Quartz, for example, melts at 1610°C; diamond, at 3550°C. See Table 11.1. ◀

The difference between the melting points of sodium chloride (801°C) and magnesium oxide (2800°C) can be explained in terms of the charges on the ions. You expect the melting point to rise with lattice energy. ◀ Lattice energies, however, depend on the product of the ionic charges (and inversely on the distance between charges). For sodium chloride (Na<sup>+</sup>Cl<sup>-</sup>) this ion-charge product is (+1) × (-1) = -1, whereas for magnesium oxide (Mg<sup>2+</sup>O<sup>2-</sup>) it is (+2) × (-2) = -4. Thus, the lattice energy is greater for magnesium oxide, and this is reflected in its much higher melting point.

Metals often have high melting points, but there is considerable variability. Mercury, a liquid at room temperature, melts at -39°C. Tungsten melts at 3410°C, the highest melting point of any metallic element. In general, melting points are low for the Groups 1A and 2A elements but increase as you move right in the periodic table to the transition metals. The elements in the center of the transition series (such as tungsten) have high melting points. Then, as you move farther to the right, the melting points decrease and are again low for the Group 2B elements.

Both molecular and covalent network solids have covalent bonds, but none of the covalent bonds are broken during the melting of a molecular solid.

Lattice energy is the energy needed to separate a crystal into isolated ions in the gaseous state. It represents the strength of attraction of ions in the solid.

**Example 11.8 Determining Relative Melting Points Based on Types of Solids****Gaining Mastery Toolbox****Critical Concept 11.8**

The strength of the forces between structural units in a solid determines the melting point of the substance. Ionic solids and covalent network solids generally have the strongest forces between structural units. Molecular substances have relatively weak forces between structural units when compared to ionic and covalent network solids.

**Solution Essentials:**

- Covalent network solid
- Ionic solid
- Metallic solid
- Molecular solid
- Intermolecular forces
- Ionic bond

Arrange the following elements in order of increasing melting point: silicon, hydrogen, lithium. Explain your reasoning.

**Problem Strategy** You first need to decide the type of solid expected for each substance. Of these types, molecular substances tend to have relatively low melting points. In comparing the melting points of two molecular solids, it is helpful to understand the intermolecular forces involved and their relative strengths. (Review Examples 11.5 and 11.6.) Stronger intermolecular forces result in higher melting points. Ionic solids and covalent network solids usually have relatively high melting points. Metals have variable melting points, but roughly these increase in moving right through the periodic table.

**Solution** Hydrogen is a molecular substance ( $H_2$ ) with a very low molecular weight (2 amu). You expect it to have a very low melting point. Lithium is a Group 1A element and is expected to be a relatively low-melting metal. Except for mercury, however, all metals are solids below  $25^\circ C$ . So the melting point of lithium is well above that of hydrogen. Silicon might be expected to have a covalent network structure like carbon and to have a high melting point. Therefore, the list of these elements in order of increasing melting point is **hydrogen, lithium, silicon**.

**Answer Check** Make sure you understand the bonding and type of solid involved in each substance. Note that solving this problem draws on many skills, including your understanding of periodic behavior, bonding, polarity, and intermolecular forces and your ability to distinguish among types of solids.

**Exercise 11.9** Decide what type of solid is formed for each of the following substances:  $C_2H_5OH$ ,  $CH_4$ ,  $CH_3Cl$ ,  $MgSO_4$ . On the basis of the type of solid and the expected magnitude of intermolecular forces (for molecular crystals), arrange these substances in order of increasing melting point. Explain your reasoning.

See Problems 11.77 and 11.78.

**Hardness and Structure** Hardness depends on how easily the structural units of a solid can be moved relative to one another and therefore on the strength of attractive forces between the units. Thus, molecular crystals, with weak intermolecular forces, are rather soft compared with ionic crystals, in which the attractive forces are much stronger. A three-dimensional covalent network solid is usually quite hard because of the rigidity given to the structure by strong covalent bonds throughout. Diamond and silicon carbide ( $SiC$ ), three-dimensional covalent networks, are among the hardest substances known.

We should add that molecular and ionic crystals are generally brittle because they fracture easily along crystal planes. Metallic crystals, by contrast, are *malleable*; that is, they can be shaped by hammering (Figure 11.29).

**Electrical Conductivity and Structure** One of the characteristic properties of metals is good electrical conductivity. The delocalized valence electrons are easily moved by an electrical field and are responsible for carrying the electric current. By contrast, most covalent and ionic solids are nonconductors, because the electrons are localized to particular atoms or bonds. Ionic substances do become conducting in the liquid state, however, because the ions can move. In an ionic liquid, it is the ions that carry the electric current.

Table 11.5 summarizes the properties we discussed for the different types of solids.

© Cengage Learning/Melissa Kelly Photography

**Figure 11.29** ▲

**Behavior of crystals when struck** The lead metal rods, composed of lead crystals, are malleable; rock salt,  $NaCl$ , cracks along the crystal planes.

**Table 11.5** Properties of the Different Types of Solids

Type of Solid	Melting Point	Hardness and Brittleness	Electrical Conductivity
Molecular	Low	Soft and brittle	Nonconducting
Metallic	Variable	Variable hardness; malleable	Conducting
Ionic	High to very high	Hard and brittle	Nonconducting solid (conducting liquid)
Covalent network	Very high	Very hard	Usually nonconducting

## 11.7 Crystalline Solids; Crystal Lattices and Unit Cells

Solids can be crystalline or amorphous. A **crystalline solid** is composed of one or more crystals; each crystal has a well-defined, ordered structure in three dimensions. Sodium chloride (table salt) and sucrose (table sugar) are examples of crystalline substances. Metals are usually compact masses of crystals. An **amorphous solid** has a disordered structure; it lacks the well-defined arrangement of basic units (atoms, molecules, or ions) found in a crystal. A glass is an amorphous solid obtained by cooling a liquid rapidly enough that its basic units are “frozen” in random positions before they can assume an ordered crystalline arrangement. Common window glass is an example, as is obsidian, a natural glass formed when molten rock from a volcanic eruption cools quickly. ◀

When quartz crystals ( $\text{SiO}_2$ ) are melted and then cooled rapidly, they form a glass called silica glass. Though ideal for some purposes, silica glass is difficult to work with because of its high temperature of softening. This temperature can be lowered by adding various oxides, such as  $\text{Na}_2\text{O}$  and  $\text{CaO}$ . In practice, ordinary glass is formed by melting sand (quartz crystals) with sodium carbonate and calcium carbonate. The carbonates decompose to the oxides plus carbon dioxide.

### Crystal Lattices

A crystal is a three-dimensional ordered arrangement of basic units. (The basic unit may be an atom, molecule, or ion, depending on the type of crystal.) The ordered structure of a crystal is conveniently described in terms of a *crystal lattice*. The idea of a crystal lattice is most easily grasped by looking at two-dimensional repeating patterns such as those seen on many fabrics or wallpapers. For simplicity, consider the pattern of *A*'s shown in Figure 11.30a. This pattern consists of a repetition of basic units *A*. A lattice of points is obtained by choosing the same point in each basic unit. (The choice of this point is immaterial as long as the same point is chosen in each basic unit.) In the pattern of Figure 11.30, we have chosen the points to be midway on the crossbar of each *A*. The collection of these points constitutes the lattice of the pattern (Figure 11.30b). This lattice shows the essential arrangement of the basic units (*A*'s) in the pattern. We could have chosen a different location for the point in each *A*, but we would have obtained the same lattice.

Similarly, we define a **crystal lattice** as the geometric arrangement of lattice points of a crystal, in which we choose one lattice point at the same location within each of the basic units of the crystal. Figure 11.31 shows the crystal structure of copper metal. If we place a point at the same location in each copper atom (say at the center of the atom), we obtain the crystal lattice for copper. The crystal lattice and crystal structure are not the same. We can imagine building the crystal

**Figure 11.30** ▶  
A two-dimensional pattern

structure for copper from its crystal lattice by placing a copper atom at each lattice point. Many different crystals have the same crystal lattice. For instance, the crystal lattice for solid methane,  $\text{CH}_4$ , is the same (except for the distances between points) as that for copper. We obtain the methane crystal structure by placing  $\text{CH}_4$  molecules at the lattice points. The crystal lattice shows only the arrangement of basic units of the crystal.

You can imagine dividing a crystal into many equivalent cells, or *unit cells*, so that these cells become the “bricks” from which you mentally construct the crystal. Let us look at the two-dimensional pattern in Figure 11.30c, in which we have connected lattice points by straight lines. The parallelograms formed by the straight lines divide the pattern into small cells. These are the smallest possible cells from which you could imagine constructing the pattern by stacking the individual cells—they are the unit cells of the pattern (Figure 11.30d).

In the same way, you can divide any crystal lattice into boxlike cells, or unit cells. The **unit cell** of a crystal is *the smallest boxlike unit (each box having faces that are parallelograms) from which you can imagine constructing a crystal by stacking the units in three dimensions.*

There are seven basic shapes possible for unit cells, which give rise to the seven *crystal systems* used to classify crystals. A crystal belonging to a given crystal system has a unit cell with one of the seven shapes shown in Figure 11.32. Each unit-cell shape can be characterized by the angles between the edges of the unit cell and the relative lengths of those edges. A crystal belonging to the cubic system, for example, has  $90^\circ$  angles between the edges of the unit cell, and all edges are of equal length. Table 11.6 summarizes the relationships between the angles and edge lengths for the unit cell of each crystal system.

Most of the crystal systems have more than one possible crystal lattice. A *simple* (or *primitive*) lattice has a unit cell in which there are lattice points only at the corners of the unit cell. Other lattices in the same crystal system have additional lattice points either within the *body* of the unit cell or on *faces* of the unit cell. As an example, we will describe the cubic crystal system in some detail.

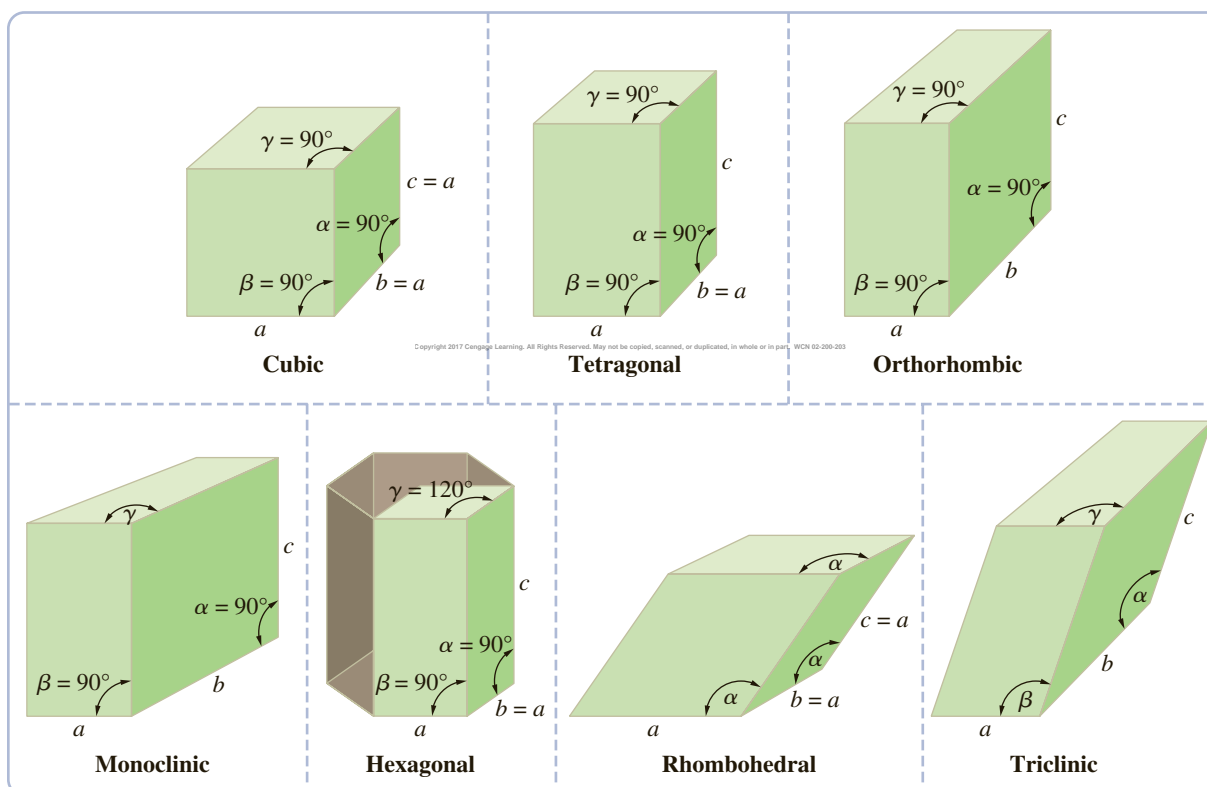

Figure 11.31 ▲

**Crystal structure and crystal lattice of copper** The copper atoms have been shrunk so that the crystal structure is more visible. The crystal lattice is the geometric arrangement of lattice points, which you can take to be the centers of the atoms. Lines have been drawn to emphasize the geometry of the lattice.

Figure 11.32 ▼

**Unit-cell shapes of the different crystal systems** The unit cells of the seven different crystal systems are displayed, showing the relationships between edge lengths and angles (summarized in Table 11.6).

Crystal System	Edge Length	Angles	Examples
Cubic	$a = b = c$	$\alpha = \beta = \gamma = 90^\circ$	NaCl, Cu
Tetragonal	$a = b \neq c$	$\alpha = \beta = \gamma = 90^\circ$	TiO <sub>2</sub> (rutile), Sn (white tin)
Orthorhombic	$a \neq b \neq c$	$\alpha = \beta = \gamma = 90^\circ$	CaCO <sub>3</sub> (aragonite), BaSO <sub>4</sub>
Monoclinic	$a \neq b \neq c$	$\alpha = \beta = 90^\circ, \gamma \neq 90^\circ$	PbCrO <sub>4</sub>
Hexagonal	$a = b \neq c$	$\alpha = \beta = 90^\circ, \gamma = 120^\circ$	C (graphite), ZnO
Rhombohedral	$a = b = c$	$\alpha = \beta = \gamma \neq 90^\circ$	CaCO <sub>3</sub> (calcite), HgS (cinnabar)
Triclinic	$a \neq b \neq c$	$\alpha \neq \beta \neq \gamma \neq 90^\circ$	K <sub>2</sub> Cr <sub>2</sub> O <sub>7</sub> , CuSO <sub>4</sub> · 5H <sub>2</sub> O

Figure 11.33 ►

**Cubic unit cells** The simple cubic unit cell has lattice points only at the corners; the body-centered cubic unit cell also has a lattice point at the center of the cell; and the face-centered cubic unit cell has lattice points at the centers of each face in addition to those at the corners.

### Cubic Unit Cells

The cubic crystal system has three possible cubic unit cells: simple (or primitive) cubic, body-centered cubic, and face-centered cubic. These cells are illustrated in Figure 11.33. A **simple cubic unit cell** is a cubic unit cell in which lattice points are situated only at the corners. A **body-centered cubic unit cell** is a cubic unit cell in which there is a lattice point at the center of the cubic cell in addition to those at the corners. A **face-centered cubic unit cell** is a cubic unit cell in which there are lattice points at the centers of each face of the unit cell in addition to those at the corners.

The simplest crystal structures are those in which there is only a single atom at each lattice point. Most metals are examples. Copper metal has a face-centered cubic unit cell with one copper atom at each lattice point (see Figure 11.31). The unit cells for this and other cubic cells of simple atomic crystals are shown in Figure 11.34. Note that only the portions of the atoms actually within the unit cell are shown. For certain applications, you will need to know the number of atoms in a unit cell of such an atomic crystal. The next example shows how you count atoms in a unit cell.

Figure 11.34 ►

**Space-filling representation of cubic unit cells** Only that portion of each atom belonging to a unit cell is shown. Note that a corner atom is shared with eight unit cells and a face atom is shared with two.

**Example 11.9** Determining the Number of Atoms in a Unit Cell**Gaining Mastery Toolbox****Critical Concept 11.9**

The unit cell is the template for the crystal of the substance. Because unit cells are stacked in three dimensions in order to construct a crystal, only a fraction of each atom on the corner, edge, or face of a unit cell is counted as part of the unit cell.

**Solution Essentials:**

- Face-centered cubic unit cell
- Body-centered cubic unit cell
- Simple-cubic unit cell
- Body, corner, and face of the unit cell
- Unit cell
- Crystal lattice

How many atoms are there in the face-centered cubic unit cell of an atomic crystal having one atom at each lattice point?

**Problem Strategy** Remember that atoms at the corners and faces of a unit cell are shared with adjoining unit cells (see Figure 11.34). Each corner atom is shared with eight unit cells (so there is only one-eighth of any corner atom in the unit cell), while each face is shared between two unit cells (giving one-half of a face atom per unit cell). Now add up the atoms for corners and faces, and then add the number of atoms totally within the unit cell (if any) to obtain the total number of atoms per unit cell.

**Solution** There are six faces on a cube (each face giving one-half atom), yielding a total of three atoms from faces. Also, there are eight corners (each corner giving one-eighth atom), yielding one atom from corners. There are no atoms totally within the unit cell. Thus, there are a total of four atoms in a face-centered cubic unit cell. To summarize:

$$6 \text{ faces} \times \frac{1}{2} \frac{\text{atom}}{\text{face}} = 3 \text{ atoms}$$

$$8 \text{ corners} \times \frac{1}{8} \frac{\text{atom}}{\text{corner}} = 1 \text{ atom}$$

Total      **4 atoms**

**Answer Check** Again, look at Figure 11.34, and see that your calculation agrees with it.

**Exercise 11.10** Figure 11.35 shows solid dots (“atoms”) forming a two-dimensional lattice. A unit cell is marked off by the black line. How many “atoms” are there in this unit cell in such a two-dimensional lattice?

See Problems 11.83 and 11.84.

**Figure 11.35** ▲  
A two-dimensional lattice

## Crystal Defects

So far we have assumed that crystals have perfect order. In fact, real crystals have various defects or imperfections. These are principally of two kinds: chemical impurities and defects in the formation of the lattice.

Ruby is an example of a crystal with a chemical impurity. The crystal is mainly colorless aluminum oxide,  $\text{Al}_2\text{O}_3$ , but occasional aluminum ions,  $\text{Al}^{3+}$ , are replaced by chromium(III) ions,  $\text{Cr}^{3+}$ , which give a red color.

## Daily Life

A CHEMIST Looks at . . .

## Liquid-Crystal Displays

Liquid-crystal displays (LCDs) are now commonly used in cell phones, portable computers, and flat-panel televisions. The liquid crystals that are the basis of these displays consist of rodlike, polar molecules in a phase that is intermediate in order between that of a liquid and that of a crystalline solid. The molecules tend to align or orient themselves in the same direction along their long axes, like matches in a matchbox, but they occupy random positions within the substance. This particular type of liquid crystal, having orientational order but no positional order, is referred to as *nematic* (Figure 11.36). The molecular order in a nematic liquid crystal, which results from weak intermolecular forces, is easily disrupted. And because these molecules are polar, they can be reoriented by the application of an electric field. A liquid-crystal display uses this ease of molecular reorientation by an electric field to change small areas, or *pixels*, of the display from light to dark.

An LCD display consists of many pixel cells arranged in rows and columns, from which an image is formed. Each pixel consists of liquid-crystal molecules contained between glass plates whose interior surfaces are covered with a

Figure 11.36 ▲

**Nematic liquid crystal** The rodlike molecules are aligned in the same direction, although the positions of the molecules are random.

transparent electrode material (Figure 11.37, *top*). Outside each glass plate is a *polarizer*. The polarizer is similar to a Polaroid lens in sunglasses. Only those light waves that are vibrating in a particular direction are allowed to pass—say, up and down at the left side. (We say that the light is *polarized*.) On the right, the polarizer is oriented so that only light vibrating at a  $90^\circ$  angle to that on the left can pass. Imagine light polarized in the up-and-down direction entering the glass plate at the left. Without liquid crystals between the glass plates, the polarized light passes to the right side, where it is blocked by the polarizer on that side. You can demonstrate this blocking effect (if you are willing to sacrifice a pair of sunglasses) by placing one Polaroid lens in front of the other, rotating one lens while holding the other fixed. The image you see varies from light to dark as you rotate.

Liquid-crystal molecules in an LCD cell can redirect polarized light so that it enters at the left vibrating up and down, but exits at the right vibrating at a  $90^\circ$  angle to that at the left. This is accomplished by treating the inner electrode surfaces so that the rodlike liquid-crystal molecules align themselves against the surface in a definite direction. At the left, these molecules are aligned up and down; at the right, they are aligned at a  $90^\circ$  angle to those on the left. From left to right, the molecules tend to line up one against the other, but they twist their orientations from up and down at the left to  $90^\circ$  at the right. Now, polarized light entering at the left is redirected by each molecule until it is vibrating so that it can exit the polarizer on the right. The light is no longer blocked.

Suppose we apply an electric charge to the electrodes. The rodlike, polar molecules of the liquid crystals now align themselves perpendicularly to the glass plates (Figure 11.37, *bottom*). The molecules can no longer reorient the polarized light; the light is blocked and the pixel is dark. By turning the electrodes on or off, it is possible to make the pixels

*(continued)*

Various lattice defects occur during crystallization. Crystal planes may be misaligned, or sites in the crystal lattice may remain vacant. For example, there might be an equal number of sodium ion vacancies and chloride ion vacancies in a sodium chloride crystal. It is also possible to have an unequal number of cation and anion vacancies in an ionic crystal. For example, iron(II) oxide, FeO, usually crystallizes with some iron(II) sites left unoccupied. Enough of the remaining iron atoms have  $3+$  charges to give an electrically balanced crystal. As a result, there are more oxygen atoms than iron atoms in the crystal. Moreover, the exact composition of the crystal can vary, so the formula FeO is only approximate. Such a compound whose composition varies slightly from its idealized formula is said to be *nonstoichiometric*. Other examples of nonstoichiometric compounds are  $\text{Cu}_2\text{O}$

## A CHEMIST Looks at . . . Liquid-Crystal Displays (continued)

**Figure 11.37** ▲

**Liquid-crystal display** *Top:* Liquid crystals are sandwiched between glass plates. The rodlike molecules are aligned up and down at the left plate but gradually twist until, at the right plate, they are oriented at a  $90^\circ$  angle to the original direction. The polarizer at the left allows light to pass that is vibrating up and down. The liquid-crystal molecules turn the plane of polarization of the light so that it can exit at the right. The pixel is on (bright). *Bottom:* When an electric charge is placed on the electrodes, the molecules orient perpendicularly to the plates and can no longer twist the polarized light so that it can exit. The pixel is now off (dark).

and  $\text{Cu}_2\text{S}$ . Each usually has less copper than expected from the formula. Some ceramic materials having superconducting properties at relatively high temperatures (page 876) are nonstoichiometric compounds. An example is yttrium barium copper oxide,  $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ , where  $x$  is approximately 0.1. It is a compound with oxygen atom vacancies.

## 11.8 Structures of Some Crystalline Solids

We have described the structure of crystals in a general way. Now we want to look in detail at the structure of several crystalline solids that represent the different types: molecular, metallic, ionic, and covalent network.

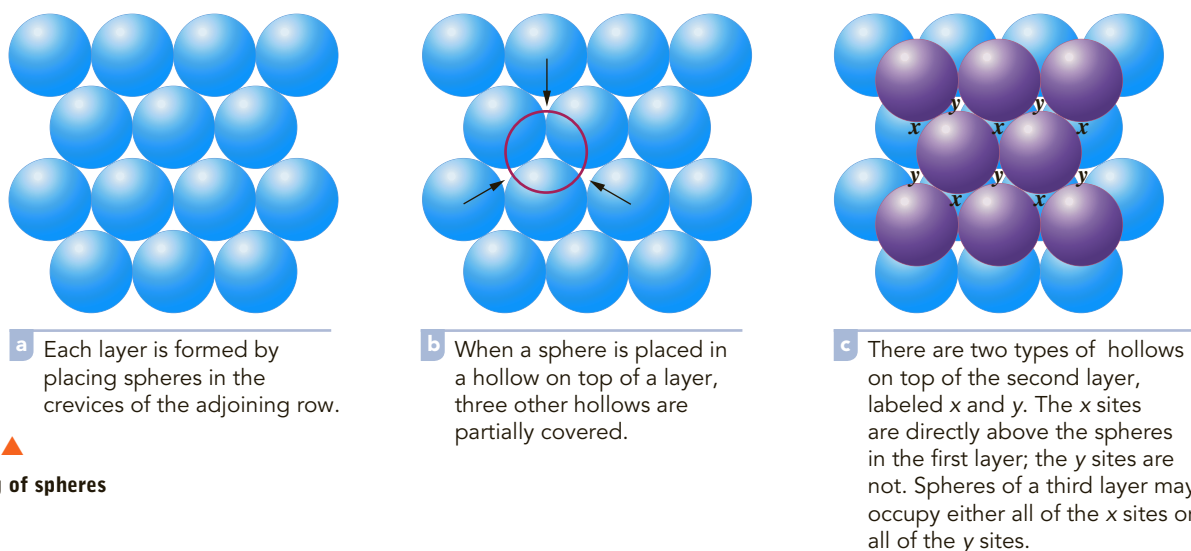

Figure 11.38 ▲

## Closest packing of spheres

## Molecular Solids; Closest Packing

The simplest molecular solids are the frozen noble gases—for example, solid neon. In this case, the molecules are single atoms and the intermolecular interactions are London forces. These forces are nondirectional (in contrast to covalent bonding, which is directional), and the maximal attraction is obtained when each atom is surrounded by the largest possible number of other atoms. The problem, then, is simply to find how identical spheres can be packed as tightly as possible into a given space.

To form a layer of close-packed spheres, you place each row of spheres in the crevices of the adjoining rows. This is illustrated in Figure 11.38a. (You may find it helpful to stack identical coins in the manner described here for spheres.) Place the next layer of spheres in the hollows in the first layer. Only half of these hollows can be filled with spheres. Once you have placed a sphere in a given hollow, it partially covers three neighboring hollows (Figure 11.38b) and completely determines the pattern of the layer (Figure 11.38c).

When you come to fill the third layer, you find that you have a choice of sites for spheres, labeled  $x$  and  $y$  in Figure 11.38c. Note that each of the  $x$  sites has a sphere in the first layer directly beneath it, but the  $y$  sites do not. When the spheres in the third layer are placed in the  $x$  sites, so that the third layer repeats the first layer, you label this stacking  $ABA$ . When successive layers are placed so that the spheres of each layer are directly over a layer that is one layer away, you get a stacking that you label  $ABABABA \dots$  (This notation indicates that the  $A$  layers are directly over other  $A$  layers, whereas the  $B$  layers are directly over other  $B$  layers.) The result is a **hexagonal close-packed structure (hcp)**, a crystal structure composed of close-packed atoms (or other units) with the stacking  $ABABABA \dots$ ; the structure has a hexagonal unit cell.

When the spheres in the third layer are placed in  $y$  sites, so that the third layer is over neither the first nor the second layer, you get a stacking that you label  $ABC$ . The fourth layer must be over either the  $A$  or the  $B$  layer. If subsequent layers are stacked so that they are over the layer two layers below, you get the stacking  $ABCABCABCA \dots$ , which results in a **cubic close-packed structure (ccp)**, a crystal structure composed of close-packed atoms (or other units) with the stacking  $ABCABCABCA \dots$  ◀

The cubic close-packed lattice is identical to the lattice having a face-centered cubic unit cell. To see this, you take portions of four layers from the cubic close-packed array (Figure 11.39, left). When these are placed together, they form a cube, as shown in Figure 11.39, right.

In any close-packed arrangement, each interior atom is surrounded by 12 nearest-neighbor atoms. The number of nearest-neighbor atoms of an atom is called

If you pack into a crate as many perfectly round oranges of the same size as possible, they will be close packed. However, they need not be either hexagonal or cubic close packed, because the A-, B-, and C-type layers can be placed at random (except that similar layers cannot be adjacent). A possible arrangement might be ABCABABABC . . . It is the forces between structural units in a close-packed crystal that determine whether one of the ordered structures, either cubic or hexagonal, will occur.

its **coordination number**. Thinking of atoms as hard spheres, one can calculate that the spheres occupy 74% of the space of the crystal. There is no way of packing identical spheres so that an atom has a coordination number greater than 12 or the spheres occupy more than 74% of the space of the crystal. All the noble-gas solids have cubic close-packed crystals except helium, which has a hexagonal close-packed crystal.

A substance composed of polyatomic molecules with approximately spherical shapes might be expected to crystallize in an approximately close-packed structure. Methane,  $\text{CH}_4$ , is an example. Solid methane has a face-centered cubic lattice with one  $\text{CH}_4$  molecule at each lattice point.

### Metallic Solids

If you were to assume that metallic bonding is completely nondirectional, you would expect metals to crystallize in one of the close-packed structures, as the noble-gas elements do. Indeed, many of the metallic elements do have either cubic or hexagonal close-packed crystals. Copper and silver, for example, are cubic close packed (that is, face-centered cubic with one atom at each lattice point of a face-centered cubic lattice). However, a body-centered cubic arrangement of spheres (having one sphere at each lattice point of a body-centered cubic lattice) occupies almost as great a percentage of space as the close-packed ones. In a body-centered arrangement, 68% of the space is occupied by spheres, compared with the maximal value of 74% in the close-packed arrangement. Each atom in a body-centered lattice has a coordination number of 8, rather than the 12 of each atom in a close-packed lattice.

Figure 11.40 lists the structures of the metallic elements. With few exceptions, they have either a close-packed or a body-centered structure.

### Ionic Solids

The description of ionic crystals is complicated by the fact that you must give the positions in the crystal structure of both the cations and the anions. We will look at the structures of three different cubic crystals with the general formula  $\text{MX}$  (where  $\text{M}$  is the metal and  $\text{X}$  is the nonmetal): cesium chloride ( $\text{CsCl}$ ), sodium chloride ( $\text{NaCl}$ ), and cubic zinc sulfide or zinc blende ( $\text{ZnS}$ ). Many ionic substances of the general formula  $\text{MX}$  have crystal structures that are one of these types. Once you have learned these structures, you can relate the structures of many other compounds to them.

Cesium chloride consists of positive ions and negative ions of about equal size arranged in a cubic array. Figure 11.41 shows the unit cell of cesium chloride. It shows both a space-filling model (ions are shown as spheres of approximately the correct relative sizes) and a model in which the ions are shrunk in size in

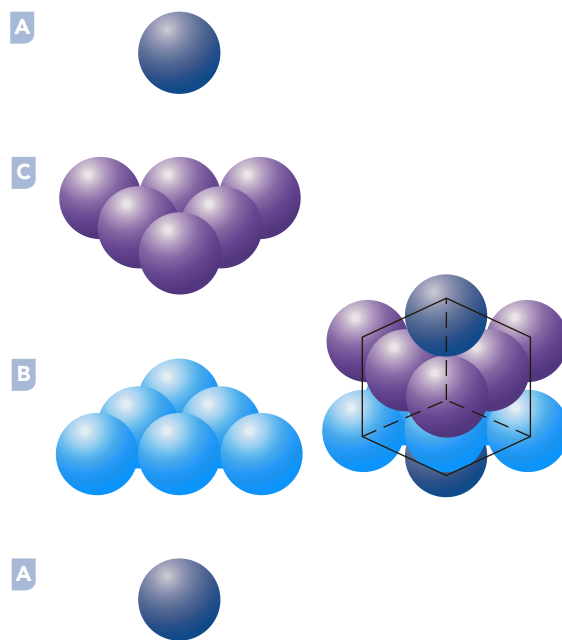

Figure 11.39 ▲

Figure 11.40 ◀

#### Crystal structures of metals

Most metals have one of the close-packed structures (hcp = hexagonal close-packed; ccp = cubic close-packed) or a body-centered cubic structure (bcc; manganese has a complicated bcc lattice, with several atoms at each lattice point). Other structures are body-centered tetragonal (bct), orthorhombic (or), and rhombohedral (rh).

Figure 11.41 ►

**Cesium chloride unit cell**

Cesium chloride consists of interpenetrating simple cubic lattices of  $\text{Cs}^+$  and  $\text{Cl}^-$  ions. The figure shows a unit cell with  $\text{Cl}^-$  ions at the corners of the unit cell and a  $\text{Cs}^+$  ion at the center. (A space-filling model is on the left; a model with ions shrunk in size to emphasize the structure is on the right.) An alternative unit cell would have  $\text{Cs}^+$  ions at the corners with a  $\text{Cl}^-$  ion at the center.

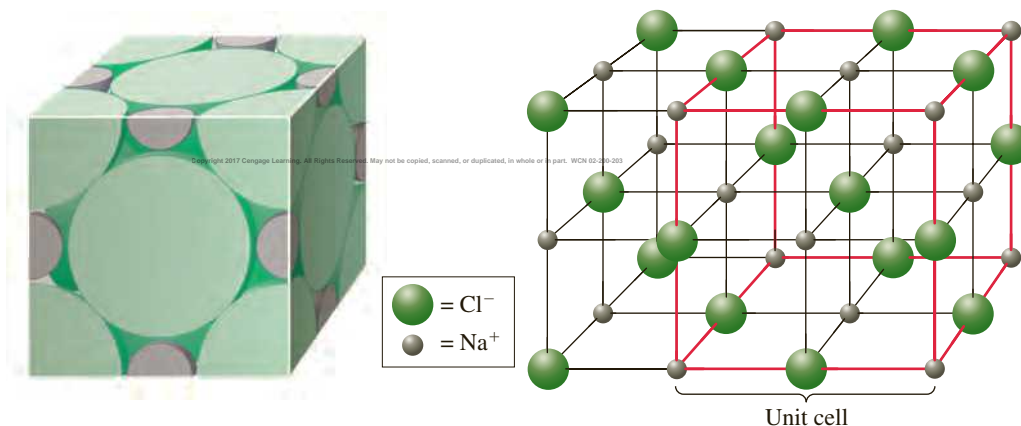

order to display more clearly their relative positions. Note that there are chloride ions at each corner of the cube and a cesium ion at the center. Alternatively, the unit cell may be taken to have cesium ions at the corners of a cube and a chloride ion at the center. In either case, the unit cell contains one  $\text{Cs}^+$  ion and one  $\text{Cl}^-$  ion. (Figure 11.41 has  $\frac{1}{8}\text{Cl}^-$  ion at each of eight corners plus one  $\text{Cs}^+$  ion at the center of the unit cell.) Ammonium chloride,  $\text{NH}_4\text{Cl}$ , and thallium chloride,  $\text{TlCl}$ , are examples of other ionic compounds having this “cesium chloride” structure.

Figure 11.42 shows the unit cell of sodium chloride. It has  $\text{Cl}^-$  ions at the corners as well as at the center of each cube face. Because the chloride ions are so much larger than the sodium ions, the  $\text{Cl}^-$  ions are nearly touching and form an approximate cubic close-packed structure of  $\text{Cl}^-$  ions. The  $\text{Na}^+$  ions are arranged in cavities of this close-packed structure. Some other compounds that crystallize in this structure are potassium chloride,  $\text{KCl}$ ; calcium oxide,  $\text{CaO}$ ; and silver chloride,  $\text{AgCl}$ .

Zinc sulfide,  $\text{ZnS}$ , crystallizes in either of two structures. The zinc sulfide mineral having cubic structure is called zinc blende or sphalerite. Zinc sulfide also exists as hexagonal crystals. (The mineral is called wurtzite.) A solid substance that can occur in more than one crystal structure is said to be *polymorphic*. We will discuss only the zinc blende structure (cubic  $\text{ZnS}$ ).

Figure 11.42 ►

**Sodium chloride unit cell** Sodium chloride has a face-centered cubic lattice.

**a** The unit cell shown here (as a space-filling model) has  $\text{Cl}^-$  ions at the corners and at the centers of the faces of the cube. The  $\text{Cl}^-$  ions are much larger than  $\text{Na}^+$  ions, so the  $\text{Cl}^-$  ions are nearly touching and have approximately a cubic close-packed structure; the  $\text{Na}^+$  ions are in cavities in this structure.

**b** The alternative unit cell shown here has  $\text{Na}^+$  ions at the corners and the centers of the faces of the unit cell.

Figure 11.43 shows the unit cell of zinc blende. Sulfide ions are at the corners and at the center of each face of the unit cell. The positions of the zinc ions can be described if you imagine the unit cell divided into eight cubic parts, or subcubes. Zinc ions are at the centers of alternate subcubes. The number of  $S^{2-}$  ions per unit cell is four ( $8 \text{ corner ions} \times \frac{1}{8} + 6 \text{ face ions} \times \frac{1}{2}$ ), and the number of  $Zn^{2+}$  ions is four (all are completely within the unit cell). Thus, there are equal numbers of  $Zn^{2+}$  and  $S^{2-}$  ions, as expected by the formula  $ZnS$ .

The unit cell of zinc blende can also be taken to have zinc ions at the corners and face centers, with sulfide ions in alternate subcubes. Zinc oxide,  $ZnO$ , and beryllium oxide,  $BeO$ , also have the “zinc blende” structure.

### Covalent Network Solids

The structures of covalent network solids are determined primarily by the directions of covalent bonds. Diamond is a simple example. It is one allotropic form of the element carbon, in which each carbon atom is covalently bonded to four other carbon atoms in tetrahedral directions to give a three-dimensional covalent network (see Figure 11.28). You can describe the bonding by assuming that every carbon atom is  $sp^3$  hybridized. Each C—C bond forms by the overlap of one  $sp^3$  hybrid orbital on one carbon atom with an  $sp^3$  hybrid orbital on the other atom. The unit cell of diamond is similar to that of zinc blende (Figure 11.43); the  $Zn^{2+}$  and  $S^{2-}$  ions are replaced by carbon atoms, as in Figure 11.44. The crystal lattice, which is face-centered cubic, can be obtained by placing lattice points at the centers of alternate carbon atoms (either those shown in dark gray or those shown in light gray). Silicon, germanium, and gray tin (a nonmetallic allotrope) have “diamond” structures.

Graphite is another allotrope of carbon. It consists of large, flat sheets of carbon atoms covalently bonded to form hexagonal arrays, and these sheets are stacked one on top of the other (see Figure 11.27). You can describe each sheet in terms of resonance formulas such as the following:

This is just one of many possible resonance formulas, because others can be drawn by moving the double bonds around. This means that the  $\pi$  electrons are delocalized over a plane of carbon atoms. You can also describe this delocalization in molecular orbital terms. You imagine that each carbon atom is  $sp^2$  hybridized, so each atom has three  $sp^2$  hybrid orbitals in the molecular plane and an additional  $2p$  orbital perpendicular to this plane. A  $\sigma$  bond forms between two carbon atoms when an  $sp^2$  hybrid orbital on one atom overlaps an  $sp^2$  hybrid orbital on another. The result is a planar  $\sigma$ -bond framework. The  $2p$  orbitals of all the atoms overlap to form  $\pi$  orbitals encompassing the entire plane of atoms.

Each carbon–carbon distance within a graphite sheet is 142 pm, which is almost midway between the length of a C—C bond (154 pm) and a C=C bond (134 pm) and which indicates an intermediate bond order (see Figure 11.28). The two-dimensional sheets, or layers, are stacked one on top of the other, and the attraction between sheets results from London forces. The distance between layers is 335 pm, which is greater than the carbon–carbon bond length, because London forces are weaker than covalent bonding forces.

You can explain several properties of graphite on the basis of its structure. The layer structure, which you see in electron micrographs (Figure 11.45), tends to separate

Figure 11.43 ▲

#### Zinc blende (cubic $ZnS$ ) unit cell

Zinc sulfide,  $ZnS$ , crystallizes in two different forms, or polymorphs: a hexagonal form (wurtzite) and a face-centered cubic form (zinc blende, or sphalerite), which is shown here. Sulfide ions,  $S^{2-}$ , are at the corners and at the centers of the faces of the unit cell;  $Zn^{2+}$  ions are in alternate subcubes of the unit cell. The unit cell can also be described as having  $Zn^{2+}$  ions at each corner and at the center of each face, with  $S^{2-}$  ions in alternate subcubes.

Figure 11.44 ▲

**Diamond unit cell** The unit cell of diamond can be obtained from the unit cell of zinc blende by replacing  $Zn^{2+}$  ions with carbon atoms (shown here as dark spheres) and  $S^{2-}$  ions by carbon atoms (shown here as light spheres). Note that each carbon atom is bonded to four others.

**Figure 11.46** ▲  
**Demonstration of the electrical conductivity of graphite** The nonzero reading on the meter shows that the pencil lead (graphite) conducts electricity.

The sliding of graphite layers has recently been shown to depend on the adsorption of water molecules to the layer structure.

easily, so that sheets of graphite slide over one another. The “lead” in a pencil is graphite. As you write with a pencil, layers of graphite rub off to form the pencil mark. ◀ Similarly, the use of graphite to lubricate locks and other closely fitting metal surfaces depends on the ability of graphite particles to move over one another as the layers slide. Another property of graphite is its electrical conductivity. Electrical conductivity is unusual in covalent network solids, because normally the electrons in such bonds are localized. Graphite is a moderately good conductor, however, because delocalization leads to mobile electrons within each carbon atom layer. Figure 11.46 shows a demonstration of the electrical conductivity of graphite.

✓ **CONCEPT CHECK 11.5**

Shown here is a representation of a unit cell for a crystal. The orange balls are atom A, and the gray balls are atom B.

- What is the chemical formula of the compound that has this unit cell ( $A_xB_y$ )?
- Consider the configuration of the A atoms. Is this a cubic unit cell? If so, which type?

## 11.9 Calculations Involving Unit-Cell Dimensions

You can determine the structure and dimensions of a unit cell by diffraction methods, which we will describe briefly in the next section. Once you know the unit-cell dimensions and the structure of a crystal, however, some interesting calculations are possible. For instance, suppose you find that a metallic solid has a face-centered cubic unit cell with all atoms at lattice points, and you determine the edge length of the unit cell. From this unit-cell dimension, you can calculate the volume of the unit cell. Then, knowing the density of the metal, you can calculate the mass of the atoms in the unit cell. Because you know that the unit cell is face-centered cubic with all atoms at lattice points and that such a unit cell has four atoms, you can obtain the mass of an individual atom. This determination of the mass of a single atom gave one of the first accurate determinations of Avogadro’s number. The calculations are shown in the next example.

**Example 11.10** Calculating Atomic Mass from Unit-Cell Dimension and Density**Gaining Mastery Toolbox****Critical Concept 11.10**

The face-centered cubic (FCC) unit cell contains four atoms. Each corner of the unit cell contains  $\frac{1}{8}$  of an atom and each face of the unit cell contains  $\frac{1}{2}$  of an atom.

**Solution Essentials:**

- Face-centered unit cell
- Unit cell

X-ray diffraction from crystals provides one of the most accurate ways of determining Avogadro's number. Silver crystallizes in a face-centered cubic lattice with all atoms at the lattice points. The length of an edge of the unit cell was determined by X-ray diffraction to be 408.6 pm (4.086 Å). The density of silver is 10.50 g/cm<sup>3</sup>. Calculate the mass of a silver atom. Then, using the known value of the atomic mass, calculate Avogadro's number.

**Problem Strategy** Knowing the edge length of a unit cell, you can calculate the unit-cell volume. Then, from the density, you can find the mass of the unit cell and hence the mass of a silver atom.

**Solution** You obtain the volume,  $V$ , of the unit cell by cubing the length of an edge.

$$V = (4.086 \times 10^{-10} \text{ m})^3 = 6.822 \times 10^{-29} \text{ m}^3$$

The density,  $d$ , of silver in grams per cubic meter is

$$d = 10.50 \frac{\text{g}}{\text{cm}^3} \times \left( \frac{1 \text{ cm}}{10^{-2} \text{ m}} \right)^3 = 1.050 \times 10^7 \text{ g/m}^3$$

Density is mass per volume; hence, the mass of a unit cell equals the density times the volume of the unit cell.

$$\begin{aligned} m &= dV \\ &= 1.050 \times 10^7 \text{ g/m}^3 \times 6.822 \times 10^{-29} \text{ m}^3 \\ &= 7.163 \times 10^{-22} \text{ g} \end{aligned}$$

Because there are four atoms in a face-centered unit cell having one atom at each lattice point (see Example 11.9), the mass of a silver atom is

$$\text{Mass of 1 Ag atom} = \frac{1}{4} \times 7.163 \times 10^{-22} \text{ g} = 1.791 \times 10^{-22} \text{ g}$$

The known atomic mass of silver is 107.87 amu. Thus, the molar mass (Avogadro's number of atoms) is 107.87 g/mol, and Avogadro's number,  $N_A$ , is

$$N_A = \frac{107.87 \text{ g/mol}}{1.791 \times 10^{-22} \text{ g}} = 6.023 \times 10^{23} / \text{mol}$$

**Answer Check** In any problem of this type where you have to calculate the mass of an atom, you can always check the validity of your answer by calculating the mass of a mole of atoms (the molar mass). For example, because the calculated mass of the silver atom in this problem is  $1.791 \times 10^{-22}$  g, the molar mass is  $(6.02 \times 10^{23}) \times (1.791 \times 10^{-22}) = 108 \text{ g/mol}$ , which is the expected molar mass of silver to three significant figures.

(continued)

**Example 11.10** (continued)

**Exercise 11.11** Lithium metal has a body-centered cubic structure with all atoms at the lattice points and a unit-cell length of 350.9 pm (see art at left). Calculate Avogadro's number. The density of lithium is  $0.534 \text{ g/cm}^3$ .

See Problems 11.85 and 11.86.

If you know or assume the structure of an atomic crystal, you can calculate the length of the unit-cell edge from the density of the substance. This is illustrated in the next example. Agreement of this value with that obtained from x-ray diffraction confirms that your view of the structure of the crystal is correct.

**Example 11.11** Calculating Unit-Cell Dimensions from Unit-Cell Type and Density**Gaining Mastery Toolbox****Critical Concept 11.11**

The edges of any cubic unit cell are of equal length. If you know the volume of a cubic unit cell, the length of an edge is the cube root of the unit-cell volume ( $l = \sqrt[3]{V}$ ).

**Solution Essentials:**

- Face-centered unit cell
- Unit cell

Platinum crystallizes in a face-centered cubic lattice with all atoms at the lattice points. It has a density of  $21.45 \text{ g/cm}^3$  and an atomic mass of 195.08 amu. From these data, calculate the length of a unit-cell edge. Compare this with the value of 392.4 pm obtained from x-ray diffraction.

**Problem Strategy** The mass of an atom, and hence the mass of a unit cell, can be calculated from the atomic mass. Knowing the density and the mass of the unit cell, we can calculate the volume and the edge length of a unit cell.

**Solution** You can use Avogadro's number ( $6.022 \times 10^{23}/\text{mol}$ ) to convert the molar mass of platinum ( $195.08 \text{ g/mol}$ ) to the mass per atom.

$$\frac{195.08 \text{ g Pt}}{1 \text{ mol Pt}} \times \frac{1 \text{ mol Pt}}{6.022 \times 10^{23} \text{ Pt atoms}} = \frac{3.239 \times 10^{-22} \text{ g Pt}}{1 \text{ Pt atom}}$$

(continued)

**Example 11.11** (continued)

Because there are four atoms per unit cell, the mass per unit cell can be calculated as follows:

$$\frac{3.239 \times 10^{-22} \text{ g Pt}}{1 \text{ Pt atom}} \times \frac{4 \text{ Pt atoms}}{1 \text{ unit cell}} = \frac{1.296 \times 10^{-21} \text{ g}}{1 \text{ unit cell}}$$

The volume of the unit cell is

$$V = \frac{m}{d} = \frac{1.296 \times 10^{-21} \text{ g}}{21.45 \text{ g/cm}^3} = 6.042 \times 10^{-23} \text{ cm}^3$$

If the edge length of the unit cell is denoted as  $l$ , the volume is  $V = l^3$ . Hence, the edge length is

$$\begin{aligned} l &= \sqrt[3]{V} \\ &= \sqrt[3]{6.042 \times 10^{-23} \text{ cm}^3} \\ &= 3.924 \times 10^{-8} \text{ cm (or } 3.924 \times 10^{-10} \text{ m)} \end{aligned}$$

**Thus, the edge length is 392.4 pm, which is in excellent agreement with the x-ray diffraction value.**

**Answer Check** Note that the edge length for the unit cell will be greater by a small factor than the values you see for atomic diameters, so you should obtain something on the order of a few hundred picometers. You should suspect an error if you obtain anything much smaller or larger than this.

**Exercise 11.12** Potassium metal has a body-centered cubic structure with all atoms at the lattice points (see art at left). The density of the metal is  $0.856 \text{ g/cm}^3$ . Calculate the edge length of a unit cell.

See Problems 11.87 and 11.88.

## 11.10 Determining Crystal Structure by X-Ray Diffraction

The determination of crystal structure by x-ray diffraction is one of the most important ways of determining the structures of molecules. Because of its ordered structure, a crystal consists of repeating planes of the same kind of atom. These planes can act as reflecting surfaces for x rays. When x rays are reflected from these planes, they show a *diffraction pattern*, which can be recorded on a photographic plate as a series of spots (see Figure 11.47). By analyzing the diffraction pattern, you can determine the positions of the atoms in the unit cell of the crystal. Once you have determined the positions of each atom in the unit cell of a molecular solid, you have also found the positions of the atoms in the molecule. ►

To understand how such a diffraction pattern occurs, let us look at the diffraction of two waves. Suppose two waves of the same wavelength come together in phase. By *in phase* we mean that the waves come together so that their peaks (maxima) and

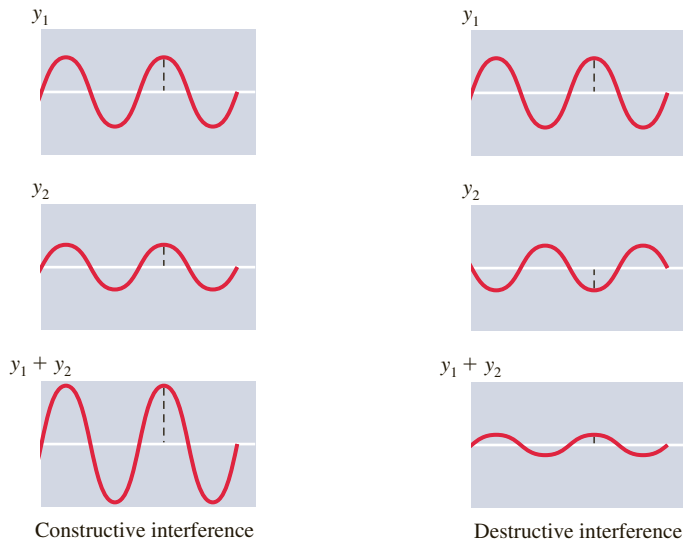

X-ray diffraction has been used to obtain the structure of proteins, which are large molecules essential to life. John Kendrew and Max Perutz received the Nobel Prize in chemistry in 1962 for their x-ray work in determining the structure of myoglobin (MM = 17,600 amu) and hemoglobin (MM = 66,000 amu). Hemoglobin is the oxygen-carrying protein of the red blood cells, and myoglobin is the oxygen-carrying protein in muscle tissue.

From G. D. Preston, "Diffraction of X-Rays by Crystals at Elevated Temperatures," 1939, in Proceedings of the Royal Society, A, Volume 172, plate 4, figure 5A

**Figure 11.47** ▲

**A crystal diffraction pattern** This diffraction pattern was obtained by diffracting X rays from a sodium chloride crystal and collecting the image on photographic film. The resulting negative shows dark spots on a lighter background.

**a** Two waves constructively interfere when they are in phase (when their peaks and troughs match). The two waves add to give a resultant wave with higher peaks and deeper troughs than either wave.

**b** Two waves destructively interfere when they are out of phase (when the peaks of one wave match the troughs of the other wave). The two waves add to give a resultant wave with lower peaks and more shallow troughs than either wave.

**Figure 11.48** ▲

#### Wave interference

troughs (minima) match (see Figure 11.48a). Two waves that come together in phase form a wave with higher peaks and lower troughs than either wave. We say that the waves reinforce each other, or undergo *constructive interference*. The height of an x-ray wave (its *amplitude*) is related to the intensity of the x ray, so constructive interference gives a resultant wave having increased intensity.

Alternatively, suppose two waves of the same wavelength come together out of phase. By *out of phase* we mean that where one wave has its peaks, the other has its troughs (see Figure 11.48b). When two waves come together out of phase, each

**a** At most angles  $\theta$ , reflected waves are out of phase and destructively interfere.

**b** At certain angles  $\theta$ , however, reflected waves are in phase and constructively interfere.

**Figure 11.49** ▲

#### Diffraction of X rays from crystal planes

peak of one wave combines with a trough of the other so that the resultant wave amplitude is smaller than that of either wave (zero, if the two waves have the same amplitudes). We say that the waves undergo *destructive interference*. The resultant wave has decreased intensity.

Now consider the scattering, or reflection, of X rays from a crystal. Figure 11.49 shows two rays: one ray reflected from one plane, the other from another plane. The two rays start out in phase, but because one ray travels farther, they may end up out of phase after reflection. Only at certain angles of reflection do the rays remain in phase. At some angles, the rays constructively interfere (giving dark areas on a negative, corresponding to large X-ray intensity). At other angles the rays destructively interfere (giving light areas on a photographic plate, corresponding to low X-ray intensity). Note the dark and light areas on the photographic negative of the diffraction pattern shown in Figure 11.47.

## Instrumental Methods

# Automated X-Ray Diffractometry

Max von Laue, a German physicist, was the first to suggest the use of X rays for the determination of crystal structure. Soon afterward, in 1913, the British physicists William Bragg and his son Lawrence developed the method on which modern crystal-structure determination is based. They realized that the atoms in a crystal form reflecting planes for X rays, and from this idea they derived the fundamental equation of crystal-structure determination.

$$n\lambda = 2d \sin \theta, n = 1, 2, 3, \dots$$

The *Bragg equation* relates the wavelength of X rays,  $\lambda$ , to the distance between atomic planes,  $d$ , and the angle of reflection,  $\theta$ . Note that reflections occur at several angles, corresponding to different integer values of  $n$ .

A molecular crystal has many different atomic planes, so that it reflects an X-ray beam in many different directions. By analyzing the intensities and angular directions of the reflected beams, you can determine the exact positions

of all the atoms in the unit cell of the crystal and therefore obtain the structure of the molecule. The problem of obtaining the X-ray data (intensities and angular directions of the reflections) and then analyzing them, however, is not trivial. Originally, the reflected X rays were recorded on photographic plates. After taking many pictures, the scientist would pore over the negatives, measuring the densities of the spots and their positions on the plates. Then he or she would work through lengthy and laborious calculations to analyze the data. Even with early computers, the determination of a molecular structure required a year or more.

With the development of electronic X-ray detectors and minicomputers, x-ray diffraction has become automated, so that the time and effort of determining the structure of a molecule have been substantially reduced. Now frequently the most difficult task is preparing a suitable crystal. The crystal should be several tenths of a millimeter in each dimension and without significant defects. Such crystals of protein molecules, for example, can be especially difficult to prepare.

Once a suitable crystal has been obtained, the structure of a molecule of moderate size can often be determined in a day or so. The crystal is mounted on a glass fiber (or in a glass capillary containing an inert gas, if the substance reacts with air) and placed on a pin or spindle within the circular assembly of the X-ray diffractometer (Figure 11.50). The crystal and X-ray detector (placed on the opposite side of the crystal from the X-ray tube) rotate under computer control, while the computer records the intensities and angles of thousands of X-ray reflection spots. After computer analysis of the data, the molecular structure is printed out.

**Figure 11.50** ▲

**Automated X-ray diffractometer** (Top) The single-crystal specimen is mounted on a glass fiber, which is placed on a spindle within the circular assembly of the diffractometer. A new data collection system (left of specimen) reduces data collection time from several days to several hours. (Bottom) The schematic diagram shows the diffracted rays being detected by a photograph. In a modern diffractometer, the final data collection is done with a fixed electronic detector, and the crystal is rotated. The data are collected and analyzed by a computer interfaced with the diffractometer.

## Environment

A CHEMIST Looks at . . .

## Water (A Special Substance for Planet Earth)

Water is the only liquid substance (other than petroleum) to be found on earth in significant amounts. This liquid is also readily convertible under conditions on earth to the solid and gaseous forms. Water has several unusual properties that set it apart from other substances. For example, its solid phase, ice, is less dense than liquid water, whereas for most substances the solid phase is more dense than the liquid. In addition, water has an unusually large heat capacity. These are some of the properties that are important in determining conditions favorable to life. In fact, it is difficult to think of life without water.

The unusual properties of water are largely linked to its ability to form hydrogen bonds. For example, ice is less dense than liquid water because ice has an open, hydrogen-bonded structure (see Figure 11.51). Each oxygen atom in the structure of ice is surrounded tetrahedrally by four hydrogen atoms: two that are close and covalently bonded to give the  $\text{H}_2\text{O}$  molecule, and two others that are farther away and held by hydrogen bonds. The tetrahedral angles give rise to a three-dimensional structure that contains open space. When ice melts, hydrogen bonds break, the ice structure partially disintegrates, and

Figure 11.51 ▲

**The structure of ice** Oxygen atoms are represented by large red spheres; hydrogen atoms, by small blue spheres. Each oxygen atom is tetrahedrally surrounded by four hydrogen atoms. Two are close, giving the  $\text{H}_2\text{O}$  molecule. Two are farther away, held by hydrogen bonding (represented by three dots). The distribution of hydrogen atoms in these two types of positions is random.

the molecules become more compactly arranged, leading to a more dense liquid.

Even liquid water has significant hydrogen bonding. Only about 15% of the hydrogen bonds are broken when ice melts. You might view the liquid as composed of icelike clusters in which hydrogen bonds are continually breaking and forming, so clusters disappear and new ones appear. This is sometimes referred to as the “flickering cluster” model of liquid water.

As the temperature rises from  $0^\circ\text{C}$ , the clusters tend to break down further, giving an even more compact liquid. Thus, the density rises (see Figure 11.52). However, as is normal in any liquid when the temperature rises, the molecules begin to move and vibrate faster, and the space occupied by the average molecule increases. For most other liquids, this results in a continuous decrease in density with temperature increase. In water, this normal effect is countered by the density increase due to breaking of hydrogen bonds, but at  $4^\circ\text{C}$  the normal effect begins to predominate. Water shows a maximum density at  $4^\circ\text{C}$  and becomes less dense at higher temperatures.

The unusually large heat of vaporization of water has an important effect on the earth’s weather. Evaporation of the surface waters absorbs over 30% of the solar energy reaching the earth’s surface. This energy is released when the water vapor condenses, and thunderstorms and hurricanes may result. In the process, the waters of the earth

Figure 11.52 ▲

**Density of water versus temperature** Water has a maximum density at  $4^\circ\text{C}$ .

(continued)

## A CHEMIST Looks at . . . Water (A Special Substance for Planet Earth) *(continued)*

are circulated and the freshwater sources are replenished. This natural cycle of water from the oceans to freshwater sources and its return to the ocean is called the *hydrologic cycle* (Figure 11.53).

Although evaporation and condensation of water play a dominant role in our weather, other properties are important as well. The exceptionally large heat capacity of bodies of water has an important moderating effect on the surrounding temperature by warming cold air masses in winter and cooling warm air masses in summer. Worldwide, the oceans are most important, but even inland lakes have a pronounced effect. For example, the Great Lakes give Detroit a more moderate winter than cities somewhat farther south but with no lakes nearby.

The fact that ice is less dense than water means that it forms on top of the liquid when freezing occurs. This has far-reaching effects, both for weather and for aquatic animals. When ice forms on a body of water, it insulates the underlying water from the cold air and limits further freezing. Fish depend on this for winter survival. Consider what

would happen to a lake if ice were more dense than water. The ice would freeze from the bottom of the lake upward. Without the insulating effect at the surface, the lake could well freeze solid, killing the fish. Spring thaw would be prolonged, because the insulating effect of the surface water would make it take much longer for the ice at the bottom of a lake to melt.

The solvent properties of water are also unusual. Water is both a polar substance and a hydrogen-bonding molecule. As a result, water dissolves many substances, including ionic and polar compounds. These properties make water the premier solvent, biologically and industrially.

As a result of the solvent properties of water, the naturally occurring liquid always contains dissolved materials, particularly ionic substances. *Hard water* contains certain metal ions, such as  $\text{Ca}^{2+}$  and  $\text{Mg}^{2+}$ . These ions react with soaps, which are sodium salts of stearic acid and similar organic acids, to produce a curdy precipitate of calcium and magnesium salts. This precipitate adheres to clothing and bathtubs (as bathtub ring). Removing  $\text{Ca}^{2+}$  and  $\text{Mg}^{2+}$  ions from hard water is referred to as *water softening*.

Water is often softened by *ion exchange*. Ion exchange is a process whereby a water solution is passed through a column of a material that replaces one kind of ion in solution with another kind. Home and commercial water softeners contain cation-exchange resins, which are insoluble macromolecular substances (substances consisting of giant molecules) to which negatively charged groups are chemically bonded. The negative charges are counterbalanced by ions such as  $\text{Na}^+$ . When hard water containing the  $\text{Ca}^{2+}$  ion passes through a column of this resin, the  $\text{Na}^+$  ion in the resin is replaced by  $\text{Ca}^{2+}$  ion.

The water passing through the column now contains  $\text{Na}^+$  in place of  $\text{Ca}^{2+}$  and has been softened. Once the resin has been completely converted to the calcium salt, it can be **regenerated** by flushing the column with a concentrated solution of  $\text{NaCl}$  to reverse the previous reaction.

**Figure 11.53** ▲

**The hydrologic cycle** Ocean water evaporates to form clouds. Then, precipitation (rain and snow) from these clouds replenishes freshwater sources. Water from these sources eventually returns to the oceans via rivers, run-off, or groundwater.

■ See Problems 11.131 and 11.132.

You can relate the resulting pattern produced by the diffraction to the structure of the crystal. You can determine the type of unit cell and its size; if the solid is composed of molecules, you can determine the position of each atom in the molecule.

## A Checklist for Review

### Summary of Facts and Concepts

Gases are composed of molecules in constant random motion throughout mostly empty space. This explains why gases are compressible fluids. Liquids are also composed of molecules in constant random motion, but the molecules are more tightly packed. Thus, liquids are incompressible fluids. Solids are composed of atoms, molecules, or ions that are in close contact and oscillate about fixed sites. Thus, solids are incompressible and rigid rather than fluid.

Any state of matter may change to another state. Melting and freezing are examples of such changes of state, or *phase transitions*. Vapor pressure, boiling point, and melting point are properties of substances that involve phase transitions. Vapor pressure increases with temperature; according to the *Clausius–Clapeyron equation*, the logarithm of the vapor pressure varies inversely with the absolute temperature. The conditions under which a given state of a substance exists are graphically summarized in a *phase diagram*.

Like vapor pressure and boiling point, *surface tension* and *viscosity* are important properties of liquids. These properties can be explained in terms of intermolecular forces. The three kinds of attractive intermolecular forces are *dipole–dipole forces*, *London forces*, and *hydrogen bonding*.

London forces are weak attractive forces present in all molecules; London forces tend to increase with increasing molecular weight. Vapor pressure tends to decrease with increasing molecular weight, whereas boiling point, surface tension, and viscosity tend to increase (unless hydrogen bonding is present). Hydrogen bonding occurs in substances containing H atoms bonded to F, O, or N atoms. When hydrogen bonding is present, vapor pressure tends to be lower than otherwise expected, whereas boiling point, surface tension, and viscosity tend to be higher.

Solids can be classified in terms of the type of force between the structural units; there are molecular, metallic, ionic, and covalent network solids. Melting point, hardness, and electrical conductivity are properties that can be related to the structure of the solid.

Solids can be crystalline or amorphous. A crystalline solid has an ordered arrangement of structural units placed at *crystal lattice* points. We may think of a crystal as constructed from *unit cells*. Cubic unit cells are of three kinds: simple cubic, body-centered cubic, and face-centered cubic. One of the most important ways of determining the structure of a crystalline solid is by *x-ray diffraction*.

### Learning Objectives

### Important Terms

#### 11.1 Comparison of Gases, Liquids, and Solids

- Recall the definitions of *gas*, *liquid*, and *solid* given in Section 1.4.
- Compare a gas, a liquid, and a solid using a kinetic-molecular theory description.
- Recall the ideal gas law and the van der Waals equation for gases (there are no similar simple equations for liquids and solids).

#### 11.2 Phase Transitions

- Define *change of state (phase transition)*.
- Define *melting*, *freezing*, *vaporization*, *sublimation*, and *condensation*.
- Define *vapor pressure*.
- Describe the process of reaching a dynamic equilibrium that involves the vaporization of a liquid and condensation of its vapor.
- Define *boiling point*.
- Describe the process of boiling.
- Define *freezing point* and *melting point*.
- Define *heat (enthalpy) of fusion* and *heat (enthalpy) of vaporization*.
- Calculate the heat required for a phase change of a given mass of substance. **Example 11.1**
- Describe the general dependence of the vapor pressure ( $\ln P$ ) on the temperature ( $T$ ).
- State the Clausius–Clapeyron equation (the two-point form).

**change of state (phase transition)**  
**melting**  
**freezing**  
**vaporization**  
**sublimation**  
**condensation**  
**vapor pressure**  
**boiling point**  
**freezing point**  
**melting point**  
**heat of fusion**  
**heat of vaporization**

- Note the common structures (face-centered cubic and body-centered cubic) of metallic solids.
- Describe the three types of cubic structures of ionic solids.
- Describe the covalent network structure of diamond and graphite.

### 11.9 Calculations Involving Unit-Cell Dimensions

- Calculate atomic mass from unit-cell dimension and density. **Example 11.10**
- Calculate unit-cell dimension from unit-cell type and density. **Example 11.11**

### 11.10 Determining Crystal Structure by X-Ray Diffraction

- Describe how constructive and destructive interference give rise to a diffraction pattern.
- Note that diffraction of X rays from a crystal gives information about the positions of atoms in the crystal.

### Key Equation

$$\ln \frac{P_2}{P_1} = \frac{\Delta H_{\text{vap}}}{R} \left( \frac{1}{T_1} - \frac{1}{T_2} \right)$$

## Questions and Problems

### Self-Assessment and Review Questions

**Key:** These questions test your understanding of the ideas you worked with in the chapter. These problems vary in difficulty and often can be used for the basis of discussion.

**11.1** List the different phase transitions that are possible and give examples of each.

**11.2** Describe how you could purify iodine by sublimation.

**11.3** Describe vapor pressure in molecular terms. What do we mean by saying it involves a dynamic equilibrium?

**11.4** Explain why 15 g of steam at 100°C melts more ice than 15 g of liquid water at 100°C.

**11.5** Why is the heat of fusion of a substance smaller than its heat of vaporization?

**11.6** Explain why evaporation leads to cooling of the liquid.

**11.7** Describe the behavior of a liquid and its vapor in a closed vessel as the temperature increases.

**11.8** Gases that cannot be liquefied at room temperature merely by compression are called “permanent” gases. How could you liquefy such a gas?

**11.9** The pressure in a cylinder of nitrogen continuously decreases as gas is released from it. On the other hand, a cylinder of propane maintains a constant pressure as propane is released. Explain this difference in behavior.

**11.10** Why does the vapor pressure of a liquid depend on the intermolecular forces?

**11.11** Explain the surface tension of a liquid in molecular terms. How does the surface tension make a liquid act as though it had a “skin”?

**11.12** Explain the origin of the London force that exists between two molecules.

**11.13** Explain what is meant by hydrogen bonding. Describe the hydrogen bonding between two H<sub>2</sub>O molecules.

**11.14** Why do molecular substances have relatively low melting points?

**11.15** Describe the distinguishing characteristics of a crystalline solid and an amorphous solid.

**11.16** Describe the face-centered cubic unit cell.

**11.17** Describe the structure of thallium(I) iodide, which has the same structure as cesium chloride.

**11.18** What is the coordination number of Cs<sup>+</sup> in CsCl? of Na<sup>+</sup> in NaCl? of Zn<sup>2+</sup> in ZnS?

**11.19** Explain in words how Avogadro’s number could be obtained from the unit-cell edge length of a cubic crystal.

**What other data are required?**

**11.20** Explain the production of an x-ray diffraction pattern by a crystal in terms of the interference of waves.

**11.21** Which of the following would release the most heat? Assume the same mass of H<sub>2</sub>O in each case.

- a** Cooling the H<sub>2</sub>O sample from 20°C to –1.0°C
- b** Heating the H<sub>2</sub>O sample from –15°C to 60°C
- c** Cooling the H<sub>2</sub>O sample from 95°C to 74°C
- d** Cooling the H<sub>2</sub>O sample from 123°C to 101°C
- e** Cooling the H<sub>2</sub>O sample from 105°C to 84°C

**11.22** The triple point of a solid is at 5.2 atm and –57°C. Under typical laboratory conditions of  $P = 0.98$  atm and  $T = 23^\circ\text{C}$ , this solid will

- a** remain solid indefinitely
- b** boil
- c** melt
- d** sublime
- e** condense

**11.23** Under the right conditions, hydrogen gas,  $H_2$ , can be liquefied. Which is the most important intermolecular force that is responsible for allowing hydrogen molecules to be liquefied?

- a hydrogen bonding
- b dipole-dipole interactions
- c London (dispersion) forces
- d covalent bonds
- e ion-dipole forces

**11.24** An element crystallizes with a simple cubic lattice with atoms at all the lattice points. If the radius of the atom is 200. pm, what is the volume of the unit cell?

- a  $8.00 \times 10^6 \text{ pm}^3$
- b  $6.40 \times 10^7 \text{ pm}^3$
- c  $4.00 \times 10^4 \text{ pm}^3$
- d  $1.60 \times 10^5 \text{ pm}^3$
- e  $6.00 \times 10^7 \text{ pm}^3$

## Concept Explorations

**Key:** Concept explorations are comprehensive problems that provide a framework that will enable you to explore and learn many of the critical concepts and ideas in each chapter. If you master the concepts associated with these explorations, you will have a better understanding of many important chemistry ideas and will be more successful in solving all types of chemistry problems. These problems are well suited for group work and for use as in-class activities.

### 11.25 Intermolecular Forces

The following picture represents atoms of hypothetical, nonmetallic, monatomic elements A, B, and C in a container at a temperature of 4 K (the piston maintains the pressure at 1 atm). None of these elements reacts with the others.

- a What is the state (solid, liquid, or gas) of each of the elements represented in the container?
- b Rank the elements in the container from greatest to least, in terms of intermolecular interactions. Explain your answer.
- c What type(s) of intermolecular attractions are present in each of these elements?
- d Explain which element has the greatest atomic mass.
- e One of the elements in the container has a normal boiling point of 2 K. Which element would that be (A, B, or C)? How do you know?
- f One of the elements has a melting point of 50 K. Which element would that be (A, B, or C)? Why?
- g The remaining element (the one you have yet to choose) has a normal boiling point of 25 K. Identify the element. Could this element have a freezing point of 7 K? Explain.

- h If you started heating the sample to 20 K, explain what you would observe with regard to the container and its contents during the heating.
- i Describe the container and its contents at 20 K. Describe (include a drawing) how the container and its contents look at 20 K.
- j Now you increase the temperature of the container to 30 K. Describe (include a drawing) how the container and its contents look at 30 K. Be sure to note any changes in going from 20 K to 30 K.
- k Finally, you heat the container to 60 K. Describe (include a drawing) how the container and its contents look at this temperature. Be sure to note any changes in going from 30 K to 60 K.

### 11.26 Heat and Molecular Behavior

#### Part 1:

- a Is it possible to add heat to a pure substance and not observe a temperature change? If so, provide examples.
- b Describe, on a molecular level, what happens to the heat being added to a substance just before and during melting. Do any of these molecular changes cause a change in temperature?

**Part 2:** Consider two pure substances with equal molar masses: substance A, having very strong intermolecular attractions, and substance B, having relatively weak intermolecular attractions. Draw two separate heating curves for 0.25-mol samples of substance A and substance B in going from the solid to the vapor state. You decide on the freezing point and boiling point for each substance, keeping in mind the information provided in this problem. Here is some additional information for constructing the curves. In both cases, the rate at which you add heat is the same. **Prior to heating**, both substances are at  $-50^\circ\text{C}$ , which is below their freezing points. The heat capacities of A and B are very similar in all states.

- a As you were heating substances A and B, did they melt after equal quantities of heat were added to each substance? Explain how your heating curves support your answer.
- b What were the boiling points you assigned to the substances? Are the boiling points the same? If not, explain how you decided to display them on your curves.
- c According to your heating curves, which substance reached the boiling point first? Justify your answer.
- d Is the quantity of heat added to melt substance A at its melting point the same as the quantity of heat required to convert all of substance A to a gas at its boiling point? Should these quantities be equal? Explain.

## Conceptual Problems

**Key:** These problems are designed to check your understanding of the concepts associated with some of the main topics presented in each chapter. A strong conceptual understanding of chemistry is the foundation for both applying chemical knowledge and solving chemical problems. These problems vary in level of difficulty and often can be used as a basis for group discussion.

**11.27** Shown here is a curve of the distribution of kinetic energies of the molecules in a liquid at an arbitrary temperature  $T$ .

The lines marked A, B, and C represent the point where each of the molecules for three different liquids (liquid A, liquid B, and liquid C) has the minimum kinetic energy to escape into the gas phase (see Figure 11.5 for more information). Write a brief explanation for each of your answers to the following questions.

- Which of the molecules—A, B, or C—would have the majority of the molecules in the gas phase at temperature  $T$ ?
  - Which of the molecules—A, B, or C—has the strongest intermolecular attractions?
  - Which of the molecules would have the lowest vapor pressure at temperature  $T$ ?
- 11.28** Consider a substance X with a  $\Delta H_{\text{vap}} = 20.3 \text{ kJ/mol}$  and  $\Delta H_{\text{fus}} = 9.0 \text{ kJ/mol}$ . The melting point, freezing point, and heat capacities of both the solid and liquid X are identical to those of water.
- If you place one beaker containing 50 g of X at  $-10^\circ\text{C}$  and another beaker with 50 g of  $\text{H}_2\text{O}$  at  $-10^\circ\text{C}$  on a hot plate and start heating them, which material will reach the boiling point first?
  - Which of the materials from part a, X or  $\text{H}_2\text{O}$ , would completely boil away first?
  - On a piece of graph paper, draw the heating curve for  $\text{H}_2\text{O}$  and X. How do the heating curves reflect your answers from parts a and b?

**11.29** Using the information presented in this chapter, explain why farmers spray water above and on their fruit trees on still nights when they know the temperature is going to drop below  $0^\circ\text{C}$ . (*Hint:* Totally frozen fruit is what the farmers are trying to avoid.)

**11.30** You are presented with three bottles, each containing a different liquid: bottle A, bottle B, and bottle C. Bottle A's label states that it is an ionic compound with a boiling point of  $35^\circ\text{C}$ . Bottle B's label states that it is a molecular compound with a boiling point of  $29.2^\circ\text{C}$ . Bottle C's label states that it is a molecular compound with a boiling point of  $67.1^\circ\text{C}$ .

- Which of the compounds is most likely to be incorrectly identified?

- If Bottle A were a molecular compound, which of the compounds has the strongest intermolecular attractions?
  - If Bottle A were a molecular compound, which of the compounds would have the highest vapor pressure?
- 11.31** Shown here is a representation of a unit cell for a crystal. The orange balls are atom A, and the gray balls are atom B.

- What is the chemical formula of the compound that has this unit cell ( $\text{A}_x\text{B}_y$ )?
- Consider the configuration of the A atoms. Is this a cubic unit cell? If so, which type?

**11.32** As a demonstration, an instructor had a block of ice suspended between two chairs. She then hung a wire over the block of ice, with weights attached to the ends of the wire:

Later, at the end of the lecture, she pointed out that the wire was lying on the floor, apparently having cut its way through the block of ice, although the ice block remained intact. Explain, by referring to the phase diagram for water (Figure 11.11), what has happened.

**11.33** If you place water at room temperature in a well-insulated cup and allow some of the water to evaporate, the temperature of the water in the cup will drop lower than room temperature. Come up with an explanation for this observation.

**11.34** The heats of vaporization for water and carbon disulfide are  $40.7 \text{ kJ/mol}$  and  $26.8 \text{ kJ/mol}$ , respectively. A vapor (steam) burn occurs when the concentrated vapor of a substance condenses on your skin. Which of these substances, water or carbon disulfide, will result in the most severe burn if identical quantities of each vapor at a temperature just above their boiling point came in contact with your skin?

**11.35** When hypothetical element X forms a solid, it can crystallize in three ways: with unit cells being either simple cubic, face-centered cubic, or body-centered cubic.

- Which crystalline form of solid X has the highest density?
- Which crystalline form of solid X has the most empty space?

**11.36** Consider two flasks that contain different pure liquids at 20°C.

The liquid in one flask, substance A, has a molar mass of 100 g/mol and has hydrogen bonding. The liquid in the other flask, substance B, has a molar mass of 105 g/mol and has dipole–dipole interactions.

- If the molecular structures of the compounds are very similar, which flask probably contains substance A?
- If you were to increase the temperature of each of the flasks by 15°C, how would the pictures change (assume that you stay below the boiling points of the liquids)?

## Practice Problems

**Key:** These problems are for practice in applying problem-solving skills. They are divided by topic, and some are keyed to exercises (see the ends of the exercises). The problems are arranged in matching pairs; the odd-numbered problem of each pair is listed first, and its answer is given in the back of the book.

### Phase Transitions

**11.37** Identify the phase transition occurring in each of the following.

- The water level in an aquarium tank falls continuously (the tank has no leak).
- A mixture of scrambled eggs placed in a cold vacuum chamber slowly turns to a powdery solid.
- Chlorine gas is passed into a very cold test tube where it turns to a yellow liquid.
- When carbon dioxide gas under pressure exits from a small orifice, it turns to a white “snow.”
- Molten lava from a volcano cools and turns to solid rock.

**11.38** Identify the phase transition occurring in each of the following.

- Mothballs slowly become smaller and eventually disappear.
- Rubbing alcohol spilled on the palm of the hand feels cool as the volume of liquid decreases.
- A black deposit of tungsten metal collects on the inside of a lightbulb whose filament is tungsten metal.
- Raindrops hit a cold metal surface, which becomes covered with ice.
- Candle wax turns to liquid under the heat of the candle flame.

**11.39** Use Figure 11.7 to estimate the boiling point of diethyl ether,  $(C_2H_5)_2O$ , under an external pressure of 470 mmHg.

**11.40** Use Figure 11.7 to estimate the boiling point of carbon tetrachloride,  $CCl_4$ , under an external pressure of 250 mmHg.

**11.41** An electric heater coil provided heat to a 15.5-g sample of iodine,  $I_2$ , at the rate of 3.48 J/s. It took 4.54 min from the time the iodine began to melt until the iodine was completely melted. What is the heat of fusion per mole of iodine?

**11.42** A 35.8-g sample of cadmium metal was melted by an electric heater providing 4.66 J/s of heat. If it took 6.92 min from the time the metal began to melt until it was completely melted, what is the heat of fusion per mole of cadmium?

**11.43** Isopropyl alcohol,  $CH_3CHOHCH_3$ , is used in rubbing alcohol mixtures. Alcohol on the skin cools by

evaporation. How much heat is absorbed by the alcohol if 4.39 g evaporates? The heat of vaporization of isopropyl alcohol is 42.1 kJ/mol.

**11.44** Liquid butane,  $C_4H_{10}$ , is stored in cylinders to be used as a fuel. Suppose 35.5 g of butane gas is removed from a cylinder. How much heat must be provided to vaporize this much gas? The heat of vaporization of butane is 21.3 kJ/mol.

**11.45** Water at 0°C was placed in a dish inside a vessel maintained at low pressure by a vacuum pump. After a quantity of water had evaporated, the remainder froze. If 9.31 g of ice at 0°C was obtained, how much liquid water must have evaporated? The heat of fusion of water is 6.01 kJ/mol and its heat of vaporization is 44.9 kJ/mol at 0°C.

**11.46** A quantity of ice at 0.0°C was added to 33.6 g of water at 21.0°C to give water at 0.0°C. How much ice was added? The heat of fusion of water is 6.01 kJ/mol and the specific heat is 4.18 J/(g·°C).

**11.47** A quantity of ice at 0°C is added to 64.3 g of water in a glass at 55°C. After the ice melted, the temperature of the water in the glass was 15°C. How much ice was added? The heat of fusion of water is 6.01 kJ/mol and the specific heat is 4.18 J/(g·°C).

**11.48** Steam at 100°C was passed into a flask containing 275 g of water at 21°C, where the steam condensed. How many grams of steam must have condensed if the temperature of the water in the flask was raised to 83°C? The heat of vaporization of water at 100°C is 40.7 kJ/mol and the specific heat is 4.18 J/(g·°C).

**11.49** Chloroform,  $CHCl_3$ , a volatile liquid, was once used as an anesthetic but has been replaced by safer compounds. Chloroform boils at 61.7°C and has a heat of vaporization of 31.4 kJ/mol. What is its vapor pressure at 37.2°C?

**11.50** Methanol,  $CH_3OH$ , a colorless, volatile liquid, was formerly known as wood alcohol. It boils at 65.0°C and has a heat of vaporization of 37.4 kJ/mol. What is its vapor pressure at 22.0°C?

**11.51** White phosphorus,  $P_4$ , is normally a white, waxy solid melting at 44°C to a colorless liquid. The liquid has a vapor pressure of 400.0 mmHg at 251.0°C and 760.0 mmHg at 280.0°C. What is the heat of vaporization of this substance?

**11.52** Carbon disulfide,  $CS_2$ , is a volatile, flammable liquid. It has a vapor pressure of 400.0 mmHg at 28.0°C and 760.0 mmHg at 46.5°C. What is the heat of vaporization of this substance?

## Phase Diagrams

**11.53** Shown here is the phase diagram for compound Z. The triple point of Z is  $-5.1^{\circ}\text{C}$  at 3.3 atm and the critical point is  $51^{\circ}\text{C}$  and 99.1 atm.

- What is the state of Z at position A?
- If we increase the temperature of the compound at position A to  $60^{\circ}\text{C}$  while holding the pressure constant, what is the state of Z?
- If we take the compound starting under the conditions of part b and reduce the temperature to  $20^{\circ}\text{C}$  and increase the pressure to 65 atm, what is the state of Z?
- Would it be possible to make the compound a solid by starting with the conditions of part c and increasing just the pressure?

**11.54** Shown here is the phase diagram for compound X. The triple point of X is  $-25.1^{\circ}\text{C}$  at 0.50 atm and the critical point is  $22^{\circ}\text{C}$  and 21.3 atm.

- What is the state of X at position A?
- If we decrease the temperature from the compound at position A to  $-28.2^{\circ}\text{C}$  while holding the pressure constant, what is the state of X?
- If we take the compound starting under the conditions of part b and increase the temperature to  $15.3^{\circ}\text{C}$  and decrease the pressure to 0.002 atm, what is the state of X?
- Would it be possible to make the compound a solid by starting with the conditions of part c and increasing just the pressure?

**11.55** Use graph paper and sketch the phase diagram of oxygen,  $\text{O}_2$ , from the following information: normal melting point,  $-218^{\circ}\text{C}$ ; normal boiling point,  $-183^{\circ}\text{C}$ ; triple point,  $-219^{\circ}\text{C}$ , 1.10 mmHg; critical point,  $-118^{\circ}\text{C}$ , 50.1 atm. Label each phase region on the diagram.

**11.56** Use graph paper and sketch the phase diagram of argon, Ar, from the following information: normal melting point,  $-187^{\circ}\text{C}$ ; normal boiling point,  $-186^{\circ}\text{C}$ ; triple point,  $-189^{\circ}\text{C}$ , 0.68 atm; critical point,  $-122^{\circ}\text{C}$ , 48 atm. Label each phase region on the diagram.

**11.57** Which of the following substances can be liquefied by applying pressure at  $25^{\circ}\text{C}$ ? For those that cannot, describe the conditions under which they *can* be liquefied.

Substance	Critical Temperature	Critical Pressure
Sulfur dioxide, $\text{SO}_2$	$158^{\circ}\text{C}$	78 atm
Acetylene, $\text{C}_2\text{H}_2$	$36^{\circ}\text{C}$	62 atm
Methane, $\text{CH}_4$	$-82^{\circ}\text{C}$	46 atm
Carbon monoxide, CO	$-140^{\circ}\text{C}$	35 atm

**11.58** A tank of gas at  $21^{\circ}\text{C}$  has a pressure of 1.0 atm. Using the data in the table, answer the following questions. Explain your answers.

- If the tank contains carbon tetrafluoride,  $\text{CF}_4$ , is the liquid state also present?
- If the tank contains butane,  $\text{C}_4\text{H}_{10}$ , is the liquid state also present?

Substance	Boiling Point at 1 atm	Critical Temperature	Critical Pressure
$\text{CF}_4$	$-128^{\circ}\text{C}$	$-46^{\circ}\text{C}$	41 atm
$\text{C}_4\text{H}_{10}$	$-0.5^{\circ}\text{C}$	$152^{\circ}\text{C}$	38 atm

**11.59** Bromine,  $\text{Br}_2$ , has a triple point at  $-7.3^{\circ}\text{C}$  and 44 mmHg and a critical point at  $315^{\circ}\text{C}$  and 102 atm. The density of the solid is  $3.4\text{ g/cm}^3$ , and the density of the liquid is  $3.1\text{ g/cm}^3$ . Sketch a rough phase diagram of bromine, labeling all important features. Circle the correct word in each of the following sentences (and explain your answers).

- Bromine vapor at 40 mmHg condenses to the (liquid, solid) when cooled sufficiently.
- Bromine vapor at 400 mmHg condenses to the (liquid, solid) when cooled sufficiently.

**11.60** Krypton, Kr, has a triple point at  $-169^{\circ}\text{C}$  and 133 mmHg and a critical point at  $-63^{\circ}\text{C}$  and 54 atm. The density of the solid is  $2.8\text{ g/cm}^3$ , and the density of the liquid is  $2.4\text{ g/cm}^3$ . Sketch a rough phase diagram of krypton. Circle the correct word in each of the following sentences (and explain your answers).

- Solid krypton at 130 mmHg (melts, sublimates without melting) when the temperature is raised.
- Solid krypton at 760 mmHg (melts, sublimates without melting) when the temperature is raised.

## Intermolecular Forces and Properties of Liquids

**11.61** The heats of vaporization of liquid  $\text{Cl}_2$ , liquid  $\text{H}_2$ , and liquid  $\text{N}_2$  are 20.4 kJ/mol, 0.9 kJ/mol, and 5.6 kJ/mol, respectively. Are the relative values as you would expect? Explain.

**11.62** The heats of vaporization of liquid  $\text{O}_2$ , liquid Ne, and liquid methanol,  $\text{CH}_3\text{OH}$ , are 6.8 kJ/mol, 1.8 kJ/mol, and 34.5 kJ/mol, respectively. Are the relative values as you would expect? Explain.

**11.63** For each of the following substances, list the kinds of intermolecular forces expected.

- b isopropyl alcohol,  $\text{CH}_3\text{CHOHCH}_3$

**c** hydrogen iodide, HI

**d** krypton, Kr

**11.64** Which of the following compounds would you expect to exhibit *only* London forces?

**a** potassium chloride, KCl

**b**

**c** silicon tetrafluoride, SiF<sub>4</sub>

**d** phosphorus pentachloride, PCl<sub>5</sub>

**11.65** Arrange the following substances in order of increasing magnitude of the London forces: SiCl<sub>4</sub>, CCl<sub>4</sub>, GeCl<sub>4</sub>.

**11.66** Arrange the following substances in order of increasing magnitude of the London forces: CH<sub>4</sub>, C<sub>3</sub>H<sub>8</sub>, C<sub>2</sub>H<sub>6</sub>.

**11.67** Methane, CH<sub>4</sub>, reacts with chlorine, Cl<sub>2</sub>, to produce a series of chlorinated hydrocarbons: methyl chloride (CH<sub>3</sub>Cl), methylene chloride (CH<sub>2</sub>Cl<sub>2</sub>), chloroform (CHCl<sub>3</sub>), and carbon tetrachloride (CCl<sub>4</sub>). Which compound has the highest vapor pressure at room temperature? Explain.

**11.68** The halogens form a series of compounds with each other, which are called interhalogens. Examples are bromine chloride (BrCl), iodine bromide (IBr), bromine fluoride (BrF), and chlorine fluoride (ClF). Which compound is expected to have the highest boiling point at any given pressure? Explain.

**11.69** Predict the order of increasing vapor pressure at a given temperature for the following compounds:

**a** FCH<sub>2</sub>CH<sub>2</sub>F   **b** HOCH<sub>2</sub>CH<sub>2</sub>OH   **c** FCH<sub>2</sub>CH<sub>2</sub>OH

Explain why you chose this order.

**11.70** Predict the order of increasing vapor pressure at a given temperature for the following compounds:

**a** CH<sub>3</sub>CH<sub>2</sub>CH<sub>2</sub>CH<sub>2</sub>OH

**b** CH<sub>3</sub>CH<sub>2</sub>OCH<sub>2</sub>CH<sub>3</sub>

**c** HOCH<sub>2</sub>CH<sub>2</sub>CH<sub>2</sub>OH

Explain why you chose this order.

**11.71** List the following substances in order of increasing boiling point.

**11.72** Arrange the following compounds in order of increasing boiling point.

### Types of Solids

**11.73** Classify each of the following by the type of solid it forms: **a** Na; **b** Fe; **c** B; **d** H<sub>2</sub>O; **e** KF.

**11.74** Classify each of the following by the type of solid it forms: **a** F<sub>2</sub>; **b** BaCl<sub>2</sub>; **c** BCl<sub>3</sub>; **d** CCl<sub>4</sub>; **e** CaO.

**11.75** Classify each of the following solid elements as molecular, metallic, ionic, or covalent network.

**a** tin, Sn

**b** germanium, Ge

**c** sulfur, S<sub>8</sub>

**d** iodine, I<sub>2</sub>

**11.76** Which of the following do you expect to be molecular solids?

**a** silicon tetrachloride, SiCl<sub>4</sub>

**b** lithium bromide, LiBr

**c** sodium fluoride, NaF

**d** bromine chloride, BrCl

**11.77** Arrange the following compounds in order of increasing melting point.

**11.78** Arrange the following substances in order of increasing melting point.

**11.79** Associate each type of solid in the left-hand column with two of the properties in the right-hand column. Each property may be used more than once.

a	molecular solid	low-melting
b	ionic solid	high-melting
c	metallic solid	brittle
d	covalent network solid	malleable
		hard
		electrically conducting

**11.80** On the basis of the description given, classify each of the following solids as molecular, metallic, ionic, or covalent network. Explain your answers.

- a a lustrous, yellow solid that conducts electricity
- b a hard, black solid melting at 2350°C to give a nonconducting liquid
- c a nonconducting, pink solid melting at 650°C to give an electrically conducting liquid
- d red crystals having a characteristic odor and melting at 171°C

**11.81** Associate each of the solids Co, LiCl, SiC, and CHI<sub>3</sub> with one of the following sets of properties.

- a A white solid melting at 613°C; the liquid is electrically conducting, although the solid is not.
- b A very hard, blackish solid subliming at 2700°C.
- c A yellow solid with a characteristic odor having a melting point of 120°C.
- d A gray, lustrous solid melting at 1495°C; both the solid and liquid are electrical conductors.

**11.82** Associate each of the solids BN, P<sub>4</sub>S<sub>3</sub>, Pb, and CaCl<sub>2</sub> with one of the following sets of properties.

- a A bluish white, lustrous solid melting at 327°C; the solid is soft and malleable.
- b A white solid melting at 772°C; the solid is an electrical nonconductor but dissolves in water to give a conducting solution.
- c A yellowish green solid melting at 172°C.
- d A very hard, colorless substance melting at about 3000°C.

### Crystal Structure

**11.83** How many atoms are there in a simple cubic unit cell of an atomic crystal in which all atoms are at lattice points?

**11.84** How many atoms are there in a body-centered cubic unit cell of an atomic crystal in which all atoms are at lattice points?

**11.85** Metallic iron has a body-centered cubic lattice with all atoms at lattice points and a unit cell whose edge length

is 286.6 pm. The density of iron is 7.87 g/cm<sup>3</sup>. What is the mass of an iron atom? Compare this value with the value you obtain from the molar mass.

**11.86** Nickel has a face-centered unit cell with all atoms at lattice points and an edge length of 352.4 pm. The density of metallic nickel is 8.91 g/cm<sup>3</sup>. What is the mass of a nickel atom? From the atomic mass, calculate Avogadro's number.

**11.87** Copper metal has a face-centered cubic structure with all atoms at lattice points and a density of 8.93 g/cm<sup>3</sup>. Its atomic mass is 63.5 amu. Calculate the edge length of the unit cell.

**11.88** Barium metal has a body-centered cubic lattice with all atoms at lattice points; its density is 3.51 g/cm<sup>3</sup>. From these data and the atomic weight, calculate the edge length of a unit cell.

**11.89** Gold has cubic crystals whose unit cell has an edge length of 407.9 pm. The density of the metal is 19.3 g/cm<sup>3</sup>. From these data and the atomic mass, calculate the number of gold atoms in a unit cell, assuming all atoms are at lattice points. What type of cubic lattice does gold have?

**11.90** Chromium forms cubic crystals whose unit cell has an edge length of 288.5 pm. The density of the metal is 7.20 g/cm<sup>3</sup>. Use these data and the atomic mass to calculate the number of atoms in a unit cell, assuming all atoms are at lattice points. What type of cubic lattice does chromium have?

**11.91** Assume X has a body-centered cubic lattice with all atoms at the lattice points. The edge length of the unit cell is 379.0 pm. The atomic mass of X is 195.0 amu. Calculate the density of X.

**11.92** Lead has a face-centered cubic lattice with all atoms at lattice points and a unit-cell edge length of 495.0 pm. Its atomic mass is 207.2 amu. What is the density of lead?

**11.93** Metallic scandium has a hexagonal close-packed structure and a density of 2.99 g/cm<sup>3</sup>. Assume scandium atoms to be spheres of radius  $r$ . Because scandium has a close-packed structure, 74.1% of the space is occupied by atoms. Calculate the volume of each atom; then find the atomic radius,  $r$ . The volume of a sphere is equal to  $4\pi r^3/3$ .

**11.94** Metallic barium has a body-centered cubic structure (all atoms at the lattice points) and a density of 3.51 g/cm<sup>3</sup>. Assume barium atoms to be spheres. The spheres in a body-centered array occupy 68.0% of the total space. Find the atomic radius of barium. (See Problem 11.93.)

### General Problems

**Key:** These problems provide more practice but are not divided by topic or keyed to exercises. Each section ends with essay questions, each of which is color coded to refer to the *A Chemist Looks at Daily Life* (orange), *A Chemist Looks at Frontiers* (purple), *A Chemist Looks at Environment* (green), and *Instrumental Methods* (brown) chapter essay on which it is based. Odd-numbered problems and the even-numbered problems that follow are similar; answers to all odd-numbered problems except the essay questions are given in the back of the book.

**11.95** If you leave your car parked outdoors in the winter, you may find frost on the windows in the morning. If you

then start the car and let the heater warm the windows, after some minutes the windows will be dry. Describe all of the phase changes that have occurred.

**11.96** Snow forms in the upper atmosphere in a cold air mass that is supersaturated with water vapor. When the snow later falls through a lower, warm air mass, rain forms. When this rain falls on a sunny spot, the drops evaporate. Describe all of the phase changes that have occurred.

**11.97** The percent relative humidity of a sample of air is found as follows: (partial pressure of water vapor/vapor pressure of water)  $\times$  100. A sample of air at 27°C was

cooled to  $15^{\circ}\text{C}$ , where moisture began to condense as dew. What was the relative humidity of the air at  $27^{\circ}\text{C}$ ?

**11.98** A sample of air at  $21^{\circ}\text{C}$  has a relative humidity of 55%. At what temperature will water begin to condense as dew? (See Problem 11.97.)

**11.99** The vapor pressure of benzene is 100.0 mmHg at  $26.1^{\circ}\text{C}$  and 400.0 mmHg at  $60.6^{\circ}\text{C}$ . What is the boiling point of benzene at 760.0 mmHg?

**11.100** The vapor pressure of water is 17.5 mmHg at  $20.0^{\circ}\text{C}$  and 355.1 mmHg at  $80.0^{\circ}\text{C}$ . Calculate the boiling point of water at 755.0 mmHg.

**11.101** Describe the behavior of carbon dioxide gas when compressed at the following temperatures:

- a**  $20^{\circ}\text{C}$       **b**  $-70^{\circ}\text{C}$       **c**  $40^{\circ}\text{C}$

The triple point of carbon dioxide is  $-57^{\circ}\text{C}$  and 5.1 atm, and the critical point is  $31^{\circ}\text{C}$  and 73 atm.

**11.102** Describe the behavior of iodine vapor when cooled at the following pressures:

- a** 120 atm      **b** 1 atm      **c** 50 mmHg

The triple point of iodine is  $114^{\circ}\text{C}$  and 90.1 mmHg, and the critical point is  $512^{\circ}\text{C}$  and 116 atm.

**11.103** Describe the formation of hydrogen bonds in propanol,  $\text{CH}_3\text{CH}_2\text{CH}_2\text{OH}$ . Represent possible hydrogen bonding structures in propanol by using structural formulas and the conventional notation for a hydrogen bond.

**11.104** Describe the formation of hydrogen bonds in hydrogen peroxide,  $\text{H}_2\text{O}_2$ . Represent possible hydrogen bonding structures in hydrogen peroxide by using structural formulas and the conventional notation for a hydrogen bond.

**11.105** Ethylene glycol ( $\text{CH}_2\text{OHCH}_2\text{OH}$ ) is a slightly viscous liquid that boils at  $198^{\circ}\text{C}$ . Pentane ( $\text{C}_5\text{H}_{12}$ ), which has approximately the same molecular weight as ethylene glycol, is a nonviscous liquid that boils at  $36^{\circ}\text{C}$ . Explain the differences in physical characteristics of these two compounds.

**11.106** Pentylamine,  $\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{NH}_2$ , is a liquid that boils at  $104^{\circ}\text{C}$  and has a viscosity of  $10 \times 10^{-4} \text{ kg}/(\text{m} \cdot \text{s})$ . Triethylamine,  $(\text{CH}_3\text{CH}_2)_3\text{N}$ , is a liquid that boils at  $89^{\circ}\text{C}$  and has a viscosity of about  $4 \times 10^{-4} \text{ kg}/(\text{m} \cdot \text{s})$ . Explain the differences in properties of these two compounds.

**11.107** Consider the elements Al, Si, P, and S from the third row of the periodic table. In each case, identify the type of solid the element would form.

**11.108** The elements in Problem 11.107 form the fluorides  $\text{AlF}_3$ ,  $\text{SiF}_4$ ,  $\text{PF}_3$ , and  $\text{SF}_4$ . In each case, identify the type of solid formed by the fluoride.

**11.109** Decide which substance in each of the following pairs has the lower melting point. Explain how you made each choice.

- a** potassium chloride,  $\text{KCl}$ ; or calcium oxide,  $\text{CaO}$   
**b** carbon tetrachloride,

or hexachloroethane,

**c** zinc,  $\text{Zn}$ ; or chromium,  $\text{Cr}$

**d** acetic acid,  $\text{CH}_3\text{COOH}$ ; or ethyl chloride,  $\text{C}_2\text{H}_5\text{Cl}$

**11.110** Decide which substance in each of the following pairs has the lower melting point. Explain how you made each choice.

**a** magnesium oxide,  $\text{MgO}$ ; or hexane,  $\text{C}_6\text{H}_{14}$

**b** 1-propanol,

or ethylene glycol,

**c** silicon,  $\text{Si}$ ; or sodium,  $\text{Na}$

**d** methane,  $\text{CH}_4$ ; or silane,  $\text{SiH}_4$

**11.111** Iridium metal,  $\text{Ir}$ , crystallizes in a face-centered cubic (close-packed) structure. The edge length of the unit cell was found by x-ray diffraction to be 383.9 pm. The density of iridium is  $22.42 \text{ g}/\text{cm}^3$ . Calculate the mass of an iridium atom. Use Avogadro's number to calculate the atomic mass of iridium.

**11.112** The edge length of the unit cell of tantalum metal,  $\text{Ta}$ , is 330.6 pm; the unit cell is body-centered cubic (one atom at each lattice point). Tantalum has a density of  $16.69 \text{ g}/\text{cm}^3$ . What is the mass of a tantalum atom? Use Avogadro's number to calculate the atomic mass of tantalum.

**11.113** Use your answer to Problem 11.87 to calculate the radius of the copper atom. Assume that copper atoms are spheres. Then note that the spheres on any face of a unit cell touch along the diagonal.

**11.114** Rubidium metal has a body-centered cubic structure (with one atom at each lattice point). The density of the metal is  $1.532 \text{ g}/\text{cm}^3$ . From this information and the atomic mass, calculate the edge length of the unit cell. Now assume that rubidium atoms are spheres. Each corner sphere of the unit cell touches the body-centered sphere. Calculate the radius of a rubidium atom.

**11.115** Calculate the percent of volume that is actually occupied by spheres in a body-centered cubic lattice of identical spheres. You can do this by first relating the radius of a sphere,  $r$ , to the length of an edge of a unit cell,  $l$ . (Note that the spheres do not touch along an edge but do touch along a diagonal passing through the body-centered sphere.) Then calculate the volume of a unit cell in terms of  $r$ . The volume occupied by spheres equals the number of spheres per unit cell times the volume of a sphere ( $4\pi r^3/3$ ).

**11.116** Calculate the percent of volume that is actually occupied by spheres in a face-centered cubic lattice of identical spheres. You can do this by first relating the radius of a sphere,  $r$ , to the length of an edge of a unit cell,  $l$ . (Note that the spheres do not touch along an edge but do touch along the diagonal of a face.) Then calculate the volume of a unit cell in terms of  $r$ . The volume occupied by spheres equals the number of spheres per unit cell times the volume of a sphere ( $4\pi r^3/3$ ).

**11.117** For the hydrogen halides and the noble gases, we have the following boiling points:

<i>Halogen Family, °C</i>	<i>Noble Gases, °C</i>
HF, 19	Ne, -246
HCl, -115	Ar, -186
HBr, -67	Kr, -152
HI, -35	Xe, -108

Account for the following:

- a The general trend in the boiling points of the hydrides and the noble gases.
- b The unusual boiling point of hydrogen fluoride.
- c The observation that the hydrogen halides have boiling points that are significantly higher than the noble gases.

**11.118** For the carbon and nitrogen family hydrides, we have the following boiling points:

<i>Carbon Family, °C</i>	<i>Nitrogen Family, °C</i>
CH <sub>4</sub> , -164	NH <sub>3</sub> , -33
SiH <sub>4</sub> , -112	PH <sub>3</sub> , -88
GeH <sub>4</sub> , -88	AsH <sub>3</sub> , -55
SnH <sub>4</sub> , -52	SbH <sub>3</sub> , -17

Account for the following:

- a The general trend in the boiling points of the binary hydrides.
- b The unusual boiling point of ammonia.
- c The observation that the nitrogen family hydrides have boiling points that are notably higher than those of the carbon family.

**11.119** Account for the following observations:

- a Both diamond and silicon carbide are very hard, whereas graphite is both soft and slippery.
- b Carbon dioxide is a gas, whereas silicon dioxide is a high-melting solid.

**11.120** Greater variation exists between the properties of the first and second members of a family in the periodic table than between other members. Discuss this observation for the oxygen family using the following data.

<i>Element</i>	<i>Boiling Point, °C</i>	<i>Compound</i>	<i>Boiling Point, °C</i>
O <sub>2</sub>	-183	H <sub>2</sub> O	100
S <sub>8</sub>	445	H <sub>2</sub> S	-61
Se <sub>8</sub>	685	H <sub>2</sub> Se	-42

**11.121** Use chemical principles to discuss the following observations:

- a CO<sub>2</sub> sublimates at -78°C, whereas SiO<sub>2</sub> boils at 2200°C.
- b HF boils at 19°C, whereas HCl boils at -85°C.
- c CF<sub>4</sub> boils at -128°C, whereas SiF<sub>4</sub> boils at -86°C.

**11.122** Draw Lewis structures of each of the following compounds: LiH, NH<sub>3</sub>, CH<sub>4</sub>, CO<sub>2</sub>. Rank these compounds from lowest to highest boiling point. Explain your reasoning.

■ **11.123** Describe the contents of a carbon dioxide fire extinguisher at 20°C. Then describe it at 35°C. Explain the difference.

■ **11.124** Discuss why supercritical carbon dioxide is a nearly ideal solvent.

■ **11.125** A gecko's toes have been shown to stick to walls through van der Waals forces. Van der Waals forces also exist between your finger and a wall. Why, then, doesn't your finger stick to the wall in the same way as the gecko's toes?

■ **11.126** Although a gecko's toes stick easily to a wall, their toes lift off a surface just as easily. Explain.

■ **11.127** Describe the structure of a nematic liquid crystal. How is it similar to a liquid? How is it similar to a crystalline solid?

■ **11.128** What properties of nematic liquid crystals are employed in LCD displays?

■ **11.129** Briefly describe what it is that the Bragg equation relates?

■ **11.130** How is it possible to obtain the structure of a molecule using x-ray diffraction from the molecular crystal?

■ **11.131** What properties of water are unusual? How does hydrogen bonding explain some of these unusual properties?

■ **11.132** The fact that solid ice is less dense than the liquid water is important to weather and aquatic life. Explain.

## Strategy Problems

**Key:** As noted earlier, all of the practice and general problems are matched pairs. This section is a selection of problems that are not in matched-pair format. These challenging problems require that you employ many of the concepts and strategies that were developed in the chapter. In some cases, you will have to integrate several

concepts and operational skills in order to solve the problem successfully.

**11.133** In an experiment, 20.00 L of dry nitrogen gas, N<sub>2</sub>, at 20.0°C and 750.0 mmHg is slowly bubbled into water in a flask to determine its vapor pressure (see the figure on next page).

The liquid water is weighed before and after the experiment, from which the experimenter determines that it loses 353.6 mg in mass. Answer the following questions.

- How many moles of nitrogen were bubbled into the water?
- The liquid water diminished by how many moles? What happened to the liquid?
- How many moles of gas exit the flask during the experiment? What is the partial pressure of nitrogen gas exiting? The total gas pressure is 750.0 mmHg.
- From these data, calculate the vapor pressure of water at 20°C. Does this agree with what you expect?

**11.134** On a particular summer day, the temperature is 30.0°C and the relative humidity is 80.0% (which means that the partial pressure of water vapor in the ambient air is 80.0% of the equilibrium vapor pressure of water). A sample of this air is placed in a 1.00-L flask, which is then closed and cooled to 5.0°C. What is the mass (in grams) of water that still exists as vapor in the flask? How much liquid water (in grams) condenses out?

**11.135** Look at the phase diagram for sulfur in Figure 11.12b. What states of sulfur would you expect to see at each of the triple points? What solid phase would you expect to freeze out if you cooled liquid sulfur? Is this the phase that you usually see at room temperature? Explain your answers.

**11.136** You may have seen the statement made that the liquid state is the stable state of water below 100°C (but above 0°C), whereas the vapor state is the stable state above 100°C. Yet you also know that a pan of water set out on a table at 20°C will probably evaporate completely in a few days, in which case, liquid water has changed to the vapor state. Explain what is happening here. What is wrong with the simple statement given at the beginning of this problem? Give a better statement.

**11.137** Carbon dioxide is often sold in steel cylinders. Use the data given in Figure 11.12a, to answer the following questions.

- Describe what you would expect to see in the cylinder if it were transparent and at room temperature. Explain.
- Suppose you have attached a pressure gauge to the cylinder to register the pressure within the cylinder. How would you expect the gauge to behave as you continue to use CO<sub>2</sub> from the cylinder until you can no longer obtain any CO<sub>2</sub> gas from it?

**11.138** Consider the following two compounds:

- What are the different types of intermolecular forces that exist in each compound?
- One of these compounds has a normal boiling point of 69°C, and the other has a normal boiling point of 138°C. What is the normal boiling point of hexane? Explain.

- One of these compounds has a viscosity of 0.313 g/(cm · s), and the other has a viscosity of 2.987 g/(cm · s). Assign viscosities to 1-pentanol and to hexane.
- Consider the compound CH<sub>3</sub>CH<sub>2</sub>CH<sub>2</sub>CH<sub>2</sub>CH<sub>2</sub>Cl. Where do you think the boiling point of this compound might lie: above both 1-pentanol and hexane, intermediate between these two compounds, or below both of these two compounds?

**11.139** Consider the following three compounds:

- Describe the types of intermolecular forces that you expect to see in each. Explain how you arrived at these types.
- The heats of vaporization of these compounds are (in no particular order): 25.8 kJ/mol, 38.6 kJ/mol, and 19.0 kJ/mol. What is the heat of vaporization of CH<sub>3</sub>CHO?
- If the normal boiling point of CH<sub>3</sub>CHO is 21°C, what is its vapor pressure at 15°C?

**11.140** Here is some information about a compound. It has a melting point of 33°C, a normal boiling point of 81°C, a heat of fusion of 11 kJ/mol, and a heat of vaporization of 32 kJ/mol. What is its vapor pressure at 15°C?

**11.141** Rhenium forms a series of solid oxides: Re<sub>2</sub>O<sub>7</sub> (yellow), ReO<sub>3</sub> (red), Re<sub>2</sub>O<sub>5</sub> (blue), and ReO<sub>2</sub> (brown). One of them has a crystal structure with the following unit cell:

- How many rhenium atoms (gray spheres) are there in a unit cell? How many oxygen atoms are there in a unit cell?
- What is the color of the compound? Explain.

**11.142** Shown below is the cubic unit cell of an ionic compound. Answer the questions by referring to this structure. Be careful to note that some atoms are hidden by those in front.

- One of the spheres (red or green) represents a monatomic, metallic ion. The other color sphere represents a monatomic, nonmetal ion. Which spheres probably represent the metal ion? Explain.
- How many red spheres are there in the unit cell? How many green ones?

- c** From the information you have, deduce the general formula of the compound, using M for the metallic element and X for the nonmetallic element. What are the formulas of the ions?
- d** Give an example of a compound that might have this structure. Explain why you think this compound might have this structure. Which ion of this compound would be represented by the red spheres?

**11.143** Two pure solid substances, substance A and substance B, are heated until a small amount of liquid begins to appear. After the appearance of the liquid, the two samples are heated at a rate of 5 kJ/min. After 10 minutes of applying heat, 10 mL of liquid A and 5 mL of liquid B have formed. In both samples there is still solid present.

- a** Which substance has stronger intermolecular attractions?
- b** Which substance has a smaller heat of fusion?
- c** Which substance would you expect to boil at a higher temperature?

**11.144** Strontium crystallizes as a face-centered cubic cell. What is the mass of a single unit cell of Sr?

**11.145** A puddle in the street has a volume of 11.5 L. Over the course of 5 days, the puddle freezes at night and then thaws during the day. The puddle reaches a low temperature of  $-4.5^{\circ}\text{C}$  during each night and a high temperature of  $3.4^{\circ}\text{C}$  during each day.

- a** When does energy transfer from the puddle to the street occur (day or night)? Justify your answer.
- b** What is the net energy flow between the puddle and the surroundings during a 3-day/night period beginning the second evening at sunset? Assume that the puddle is at its highest temperature at sunset. (*Hint:* No calculations are required to answer this question.)
- c** What is the net energy flow between the puddle and the surroundings during a 3-day/night period beginning the second morning at sunrise?

**11.146** Describe how you would adjust the temperature and pressure of a gas to convert it to the liquid state.

**11.147** Compare the quantities of heat required for each of the following pairings. Justify your answers without performing calculations.

- a** Evaporating a 1.00-g sample of liquid water at  $100^{\circ}\text{C}$  or subliming a 1.00 g sample of water at  $-10^{\circ}\text{C}$ ?
- b** Condensing a 0.5-g sample of water vapor at  $60^{\circ}\text{C}$  or melting a 0.5-g sample of water at  $0^{\circ}\text{C}$ .
- c** Vaporizing a 50-g sample of liquid water placed into an oven set at  $200^{\circ}\text{C}$  or vaporizing a 100-g sample of liquid water placed into an oven set at  $100^{\circ}\text{C}$ . Both water samples are at  $100^{\circ}\text{C}$  when they are placed in the ovens.

**11.148** A cubic unit cell is found to have calcium ions at the corners, a titanium atom in the center of the cell, and oxide ions at the center of each face. What is the empirical formula of this compound?

## Capstone Problems

**Key:** The problems under this heading combine skills, strategies, and concepts learned in previous chapters with those introduced in the current one

**11.149** The vapor pressure of a volatile liquid can be determined by slowly bubbling a known volume of gas through the liquid at a given temperature and pressure. In an experiment, a 5.40-L sample of nitrogen gas,  $\text{N}_2$ , at  $20.0^{\circ}\text{C}$  and 745 mmHg is bubbled through liquid isopropyl alcohol,  $\text{C}_3\text{H}_8\text{O}$ , at  $20.0^{\circ}\text{C}$ . Nitrogen containing the vapor of  $\text{C}_3\text{H}_8\text{O}$  at its vapor pressure leaves the vessel at  $20.0^{\circ}\text{C}$  and 745 mmHg. It is found that 0.6149 g  $\text{C}_3\text{H}_8\text{O}$  has evaporated. How many moles of  $\text{N}_2$  are in the gas leaving the liquid? How many moles of alcohol are in this gaseous mixture? What is the mole fraction of alcohol vapor in the gaseous mixture? What is the partial pressure of the alcohol in the gaseous mixture? What is the vapor pressure of  $\text{C}_3\text{H}_8\text{O}$  at  $20.0^{\circ}\text{C}$ ?

**11.150** In an experiment, a sample of 6.35 L of nitrogen at  $25.0^{\circ}\text{C}$  and 768 mmHg is bubbled through liquid acetone,  $\text{C}_3\text{H}_6\text{O}$ . The gas plus vapor at its equilibrium partial pressure leaves the liquid at the same temperature and pressure. If 6.550 g of acetone has evaporated, what is the vapor pressure of acetone at  $25.0^{\circ}\text{C}$ ? See Problem 11.149.

**11.151** How much heat is needed to vaporize 39.6 mL of liquid hydrogen cyanide,  $\text{HCN}$ , at  $25.0^{\circ}\text{C}$ ? The density of the liquid is 0.687 g/mL. Use standard heats of formation, which are given in Appendix C.

**11.152** How much heat is needed to vaporize 25.0 mL of liquid methanol,  $\text{CH}_3\text{OH}$ , at  $25.0^{\circ}\text{C}$ ? The density of the liquid is 0.787 g/mL. Use standard heats of formation, which are given in Appendix C.

**11.153** How much heat must be added to 28.0 g of solid white phosphorus,  $\text{P}_4$ , at  $24.0^{\circ}\text{C}$  to give the liquid at its melting point,  $44.1^{\circ}\text{C}$ ? The heat capacity of solid white phosphorus is  $95.4 \text{ J}/(\text{K} \cdot \text{mol})$ ; its heat of fusion is 2.63 kJ/mol.

**11.154** How much heat must be added to 50.0 g of solid sodium,  $\text{Na}$ , at  $25.0^{\circ}\text{C}$  to give the liquid at its melting point,  $97.8^{\circ}\text{C}$ ? The heat capacity of solid sodium is  $28.2 \text{ J}/(\text{K} \cdot \text{mol})$ , and its heat of fusion is 2.60 kJ/mol.

**11.155** Acetic acid,  $\text{CH}_3\text{COOH}$ , forms stable pairs of molecules held together by two hydrogen bonds.

Such molecules—themselves formed by the association of two simpler molecules—are called dimers. The vapor over liquid acetic acid consists of a mixture of monomers (single acetic acid molecules) and dimers. At  $100.6^{\circ}\text{C}$  the total pressure of vapor over liquid acetic acid is 436 mmHg. If the vapor consists of 0.630 mole fraction of the dimer, what are the masses of monomer and dimer in 1.000 L of the vapor? What is the density of the vapor?

**11.156** The total pressure of vapor over liquid acetic acid at  $71.38^{\circ}\text{C}$  is 146 mmHg. If the density of the vapor is 0.702 g/L, what is the mole fraction of dimer in the vapor? See Problem 11.155.

**11.157** Nanotechnology, or technology utilizing 1–100 nm sized particles, has rapidly expanded in the past few decades, with potential applications ranging across far-reaching fields such as electronics, medicine, biomaterials, and consumer products, to name a few. One of the primary advantages of nanoparticles is the presence of large surface/mass ratios, resulting in enhanced surface activities compared to bulk materials.

**a** Use the density of silver ( $10.49\text{ g/cm}^3$ ) to determine the number of Ag atoms in a spherical 20.-nm silver particle.

**b** In the crystalline metallic environment, the measured radii of silver atoms has been measured to be 144 pm. Use this to calculate the atomic packing fraction of a 20.-nm silver particle. In other words, calculate the ratio of the volume taken up by Ag atoms to the volume of the entire nanoparticle.

**c** Based on the result of part (b), silver conforms to which type of cubic crystal lattice?

**A** simple cubic

**B** body-centered cubic

**C** face-centered cubic

**d** A cubic Ag ingot having a mass of 5.0-g is processed to form a batch of 20.-nm Ag nanoparticles. Calculate the ratio of the surface area provided by the batch of nanoparticles to the surface area of the initial cube of Ag.

## 12

## Solutions

Light is scattered as it passes through a solution that contains dispersed particles. This type of solution is a colloid. Fog is an example of a colloid where we observe small water droplets dispersed in air scattering light.

## CONTENTS AND CONCEPTS

**Solution Formation**

Here you will have the opportunity to develop a more thorough understanding of the solution process and of what constitutes a solution.

**12.1** Types of Solutions

**12.2** Solubility and the Solution Process

**12.3** Effects of Temperature and Pressure on Solubility

**Colligative Properties**

We will explore how properties of solutions are affected by changes in concentration. You will also be introduced to several ways of expressing concentration.

**12.4** Ways of Expressing Concentration

**12.5** Vapor Pressure of a Solution

**12.6** Boiling-Point Elevation and Freezing-Point Depression

**12.7** Osmosis

**12.8** Colligative Properties of Ionic Solutions

**Colloid Formation**

When relatively large particles of a substance disperse throughout another substance, the result is called a colloid.

**12.9** Colloids

There are various practical reasons for preparing solutions. For instance, most chemical reactions are run in solution. Also, solutions have particular properties that are useful. When gold is used for jewelry, it is mixed, or alloyed, with a small amount of silver. Gold–silver alloys are not only harder than pure gold, but they also melt at lower temperatures and are therefore easier to cast.

Solubility, the amount of one substance that dissolves in another, varies with temperature and, in some cases, with pressure. The variation of solubility with pressure can be a useful property. Acetylene gas,  $C_2H_2$ , for example, is used as a fuel in welding torches. It can be transported safely under pressure in cylinders as a solution in acetone,  $CH_3COCH_3$ . Acetone is a liquid, and at 1 atm pressure 1 L of the liquid dissolves 27 g of acetylene. But at 12 atm, the pressure in a full cylinder, the same quantity of acetone dissolves 320 g of acetylene, so more can be transported. When the valve on a cylinder is opened, reducing the pressure, acetylene gas comes out of solution.

Another useful property of solutions is their lower melting, or freezing, points compared with those of the major component. We have already mentioned the lowering of the melting point of gold when a small amount of silver is added. The use of ethylene glycol,  $CH_2OHCH_2OH$ , as an automobile antifreeze depends on the same property. Water containing ethylene glycol freezes at temperatures below the freezing point of pure water.

What determines how much the freezing point of a solution is lowered? How does the solubility of a substance change when conditions such as pressure and temperature change? These are some of the questions we will address in this chapter.

## ► Solution Formation

When sodium chloride dissolves in water, the resulting uniform dispersion of ions in water is called a solution. In general, a *solution* is a homogeneous mixture of two or more substances, consisting of ions or molecules. A *colloid* is similar in that it appears to be homogeneous like a solution. In fact, it consists of comparatively large particles of one substance dispersed throughout another substance or solution.

From the examples of solutions mentioned in the chapter opening, you see that they may be quite varied in their characteristics. To begin our discussion, let us look at the different types of solutions we might encounter. We will discuss colloids at the end of the chapter.

### 12.1 Types of Solutions

Solutions may exist in any of the three states of matter; that is, they may be gases, liquids, or solids. Some examples are listed in Table 12.1. The terms *solute* and *solvent* refer to the components of a solution. The **solute**, in the case of a solution of a gas or solid dissolved in a liquid, is the gas or solid; in other cases, the solute is the component in smaller amount. The **solvent**, in a solution of a gas or solid dissolved in a liquid, is the liquid; in other cases, the solvent is the component in greater amount. Thus, when sodium chloride is dissolved in water, we have created a solution in which sodium chloride is the solute and water the solvent.

#### Gaseous Solutions

In general, nonreactive gases or vapors can mix in all proportions to give a gaseous mixture. *Fluids that mix with or dissolve in each other in all proportions* are said to be **miscible fluids**. Gases are thus miscible. (If two fluids do not mix but, rather, form two layers, they are said to be *immiscible*.) Air, which is a mixture of oxygen, nitrogen, and smaller amounts of other gases, is an example of a gaseous solution.

Solution	State of Matter	Description
Air	Gas	Homogeneous mixture of gases ( $O_2$ , $N_2$ , others)
Soda water	Liquid	Gas ( $CO_2$ ) dissolved in a liquid ( $H_2O$ )
Ethanol in water	Liquid	Liquid solution of two completely miscible liquids
Brine	Liquid	Solid ( $NaCl$ ) dissolved in a liquid ( $H_2O$ )
Potassium–sodium alloy	Liquid	Solution of two solids ( $K + Na$ )
Dental-filling alloy	Solid	Solution of a liquid ( $Hg$ ) in a solid ( $Ag$ plus other metals)
Gold–silver alloy	Solid	Solution of two solids ( $Au + Ag$ )

### Liquid Solutions

Most liquid solutions are obtained by dissolving a gas, liquid, or solid in some liquid. Soda water, for example, consists of a solution of carbon dioxide gas in water. Acetone,  $C_3H_6O$ , in water is an example of a liquid–liquid solution. (Immiscible and miscible liquids are shown in Figure 12.1.) Brine is water with sodium chloride (a solid) dissolved in it. Seawater contains both dissolved gases (from air) and solids (mostly sodium chloride).

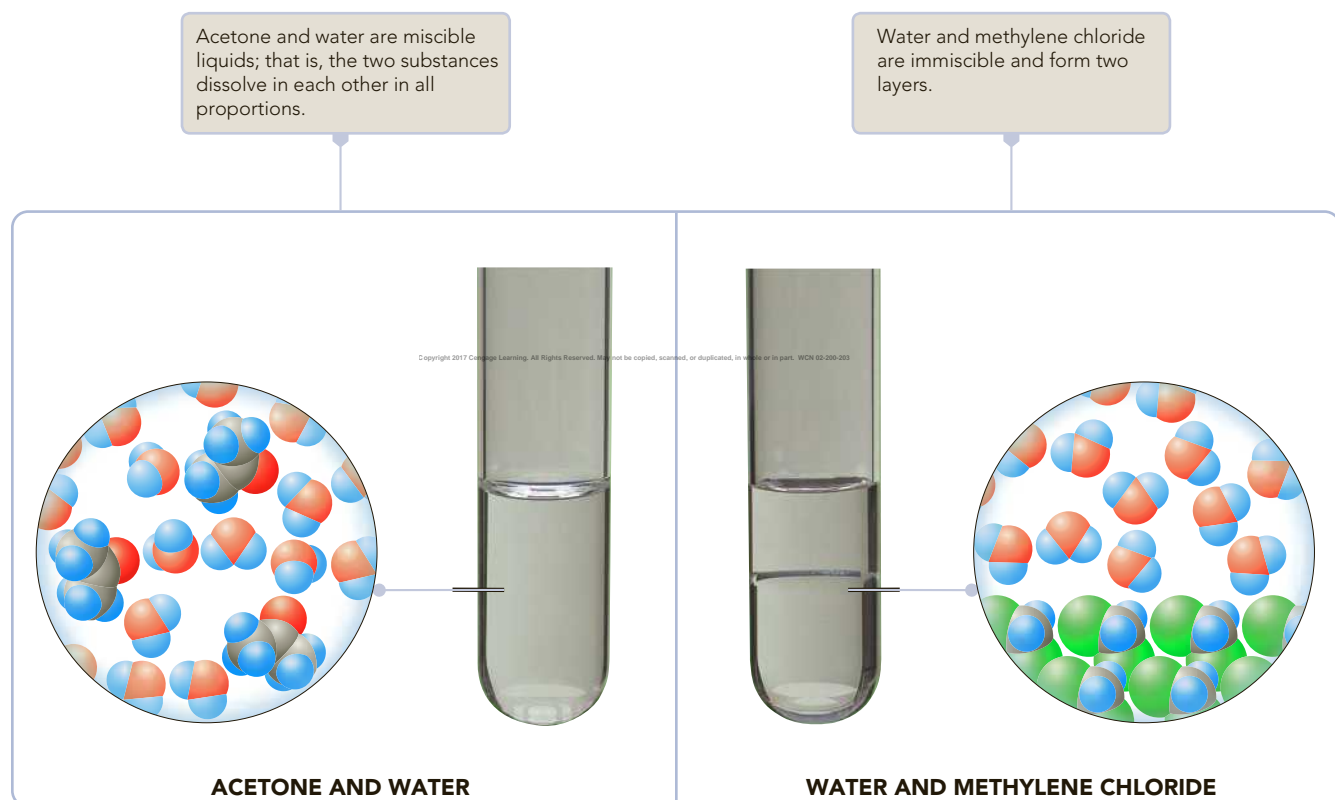

It is also possible to make a liquid solution by mixing two solids together. Consider a potassium–sodium alloy. Both potassium and sodium are solid at room temperature, but a liquid solution results when the mixture contains 10% to 50% sodium. ▶

### Solid Solutions

Solid solutions are also possible. In the chapter opening, we mentioned gold–silver alloys. Dental-filling alloy is a solution of mercury (a liquid) in silver (a solid), with small amounts of other metals.

Sodium metal melts at  $98^\circ C$  and potassium metal melts at  $63^\circ C$ . When the two metals are mixed to give a solution that is 20% sodium, for example, the melting point is lowered to  $-10^\circ C$ . This is another example of the lowering of the freezing, or melting, point of solutions, which we will discuss later in the chapter. Potassium–sodium alloy is used as a heat-transfer medium in nuclear reactors.

Figure 12.1 ▼  
Immiscible and miscible liquids

**Exercise 12.1** Give an example of a solid solution prepared from a liquid and a solid.

See Problems 12.37 and 12.38.

### CONCEPT CHECK 12.1

Identify the solute(s) and solvent(s) in the following solutions.

- a** 80 g of Cr and 5 g of Mo
- b** 5 g of  $\text{MgCl}_2$  dissolved in 1000 g of  $\text{H}_2\text{O}$
- c** 39%  $\text{N}_2$ , 41% Ar, and the rest  $\text{O}_2$

## 12.2 Solubility and the Solution Process

The amount of substance that will dissolve in a solvent depends on both the substance and the solvent. We describe the amount that dissolves in terms of solubility.

### Solubility; Saturated Solutions

To understand the concept of solubility, consider the process of dissolving sodium chloride in water. Sodium chloride is an ionic substance, and it dissolves in water as  $\text{Na}^+$  and  $\text{Cl}^-$  ions. If you could view the dissolving of sodium chloride at the level of ions, you would see a dynamic process. Suppose you stir 40.0 g of sodium chloride crystals into 100 mL of water at  $20^\circ\text{C}$ . Sodium ions and chloride ions leave the surface of the crystals and enter the solution. The ions move about at random in the solution and may by chance collide with a crystal and stick, thus returning to the crystalline state. As the sodium chloride continues to dissolve, more ions enter the solution, and the rate at which they return to the crystalline state increases (the more ions in solution, the more likely ions are to collide with the crystals and stick). Eventually, a *dynamic equilibrium* is reached in which the rate at which ions leave the crystals equals the rate at which ions return to the crystals (see Figure 12.2). You write the dynamic equilibrium this way:

At equilibrium, no more sodium chloride appears to dissolve; 36.0 g has gone into solution, leaving 4.0 g of crystals at the bottom of the vessel. You have a **saturated solution**—that is, a *solution that is in equilibrium with respect to a given dissolved substance*. The solution is saturated with respect to NaCl, and no more NaCl can dissolve. The **solubility** of sodium chloride in water (*the amount that dissolves in a given quantity of water at a given temperature to give a saturated solution*) is 36.0 g/100 mL at  $20^\circ\text{C}$ . Note that if you had mixed 30.0 g of sodium chloride with 100 mL of water, all of the crystals would have dissolved. You would have an **unsaturated solution**, a *solution not in equilibrium with respect to a given dissolved substance and in which more of the substance can dissolve*. (Saturated and unsaturated solutions are compared in Figure 12.3.)

**Figure 12.2** ▲

**Solubility equilibrium** The solid crystalline phase is in dynamic equilibrium with species (ions or molecules) in a saturated solution. The rate at which species leave the crystals equals the rate at which species return to the crystals.

Sometimes it is possible to obtain a **supersaturated solution**, a *solution that contains more dissolved substance than a saturated solution does*. For example, the solubility of sodium thiosulfate,  $\text{Na}_2\text{S}_2\text{O}_3$ , in water at  $100^\circ\text{C}$  is 231 g/100 mL. But at room temperature, the solubility is much less—about 50 g/100 mL. Suppose you prepare a solution saturated with sodium thiosulfate at  $100^\circ\text{C}$ . You might expect that as the water solution was cooled, sodium thiosulfate would crystallize out. In fact, if the solution is slowly cooled to room temperature, this does not occur. Instead the result is a solution in which 231 g of sodium thiosulfate is dissolved in 100 mL of cold water, compared with the 50 g you would normally expect to find dissolved.

Supersaturated solutions are not in equilibrium with the solid substance. If a small crystal of sodium thiosulfate is added to a supersaturated solution, the excess immediately crystallizes out. Crystallization from a supersaturated solution is usually quite fast and dramatic (see Figure 12.4).

Figure 12.3 ◀

**Comparison of unsaturated and saturated solutions**

Figure 12.4 ◀

**Crystallization from a supersaturated solution of sodium acetate**

### Factors in Explaining Solubility

The solubilities of substances in one another vary widely. You might find a substance miscible in one solvent but nearly insoluble in another. As a general rule, “like dissolves like.” That is, similar substances dissolve one another. Oil is miscible in gasoline. Both are mixtures of hydrocarbon substances (compounds of hydrogen and carbon only). On the other hand, oil does not mix with water. Water is a polar substance, whereas hydrocarbons are not. Why do similar substances dissolve in one another to greater extents than do dissimilar substances? What factors are involved in solubility?

The solubility of one substance in another can be explained in terms of two factors. One is the natural tendency of substances to mix. This is sometimes also referred to as the natural tendency toward disorder. Figure 12.5a shows a vessel

Figure 12.5 ▶

## The mixing of gas molecules

divided into two parts, with oxygen gas on the left and nitrogen gas on the right. If you remove the partition, the molecules of the two gases begin to mix. Ultimately, the molecules become thoroughly mixed through their random motions (Figure 12.5b). You might expect a similar mixing of molecules or ions in other types of solutions.

If the process of dissolving one substance in another involved nothing more than simple mixing, you would expect all substances to be completely soluble in one another; that is, you would expect substances to be miscible. You know that this is only sometimes the case. Usually, substances have limited solubility in one another. A factor that can limit solubility is the relative forces of attraction between species (molecules or ions). Suppose there are strong attractions between solute species and strong attractions between solvent species, but weak attractions between solute and solvent species. In that case, the strongest attractions are maintained so long as the solute and solvent species do not mix. The lowest energy of the solute–solvent system is obtained then also.

The solubility of a solute in a solvent (that is, the extent of the mixing of the solute and solvent species) depends on a balance between the natural tendency for the solute and solvent species to mix and the tendency for a system to have the lowest energy possible.

Figure 12.6 ▲

**The immiscibility of liquids** Suppose an A molecule moves from liquid A into liquid B. If the intermolecular attraction between two A molecules is much stronger than the intermolecular attraction between an A molecule and a B molecule, the net force of attraction tends to pull the A molecule back into liquid A. Thus, liquid A will be immiscible with liquid B.

### Molecular Solutions

The simplest example of a molecular solution is one gas dissolved in another gas. Air, essentially a solution of oxygen and nitrogen, is an example. The intermolecular forces in gases are weak. The only solubility factor of importance is the tendency for molecules to mix (this will be discussed in Chapter 18). Gases are therefore miscible.

Substances may be miscible even when the intermolecular forces are not negligible. Consider the solution of the two similar liquid hydrocarbons heptane,  $C_7H_{16}$ , and octane,  $C_8H_{18}$ , which are components of gasoline. The intermolecular attractions are due to London forces, and those between heptane and octane molecules are nearly equal to those between octane and octane molecules and heptane and heptane molecules. The different intermolecular attractions are about the same strength, so there are no favored attractions. Octane and heptane molecules tend to move freely through one another. Therefore, the tendency of molecules to mix results in miscibility of the substances.

As a counterexample, consider the mixing of octane with water. There are strong hydrogen bonding forces between water molecules. For octane to mix with water, hydrogen bonds must be broken and replaced by much weaker London forces between water and octane. In this case, the maximum forces of attraction among molecules (and therefore the lower energy) result if the octane and water remain unmixed. Therefore, octane and water are nearly immiscible. (See Figure 12.6.)

The statement “like dissolves like” succinctly expresses these observations. That is, substances with similar intermolecular attractions are usually soluble in one another. The two similar hydrocarbons heptane and octane are completely miscible, whereas octane and water (with dissimilar intermolecular attractions) are immiscible.

Name	Formula	Solubility in H <sub>2</sub> O (g/100 g H <sub>2</sub> O at 20°C)
Methanol	CH <sub>3</sub> OH	Miscible
Ethanol	CH <sub>3</sub> CH <sub>2</sub> OH	Miscible
1-Propanol	CH <sub>3</sub> CH <sub>2</sub> CH <sub>2</sub> OH	Miscible
1-Butanol	CH <sub>3</sub> CH <sub>2</sub> CH <sub>2</sub> CH <sub>2</sub> OH	7.9
1-Pentanol	CH <sub>3</sub> CH <sub>2</sub> CH <sub>2</sub> CH <sub>2</sub> CH <sub>2</sub> OH	2.7
1-Hexanol	CH <sub>3</sub> CH <sub>2</sub> CH <sub>2</sub> CH <sub>2</sub> CH <sub>2</sub> CH <sub>2</sub> OH	0.6

For the series of alcohols (organic, or carbon-containing, compounds with an —OH group) listed in Table 12.2, the solubility in water decreases from miscible to slightly soluble. Water and alcohols are alike in having —OH groups through which strong hydrogen bonding attractions arise (see Figure 12.7).

The attraction between a methanol molecule, CH<sub>3</sub>OH, and a water molecule is nearly as strong as that between two methanol molecules or between two water molecules. Methanol and water molecules tend to mix freely. Methanol and water are miscible, as are ethanol and water and 1-propanol and water. However, as the hydrocarbon end, R—, of the alcohol becomes the more prominent portion of the molecule, the alcohol becomes less like water. Now the forces of attraction between alcohol and water molecules are weaker than those between two alcohol molecules or between two water molecules. Therefore, the solubilities of alcohols decrease with increasing length of R.

Figure 12.7 ▲

**Hydrogen bonding between water and ethanol molecules** The dots depict the hydrogen bonding between the oxygen and hydrogen atoms on adjacent molecules.

### ✓ CONCEPT CHECK 12.2

You have two molecular compounds, X and Y. Compound X has stronger intermolecular forces than compound Y. X has no dipole–dipole bonding of any kind, and Y exhibits hydrogen bonding. Predict the relative solubility of compounds X and Y in water and in a nonpolar solvent. Explain your reasoning.

**Exercise 12.2** Which of the following compounds is likely to be more soluble in water: C<sub>4</sub>H<sub>9</sub>OH or C<sub>4</sub>H<sub>9</sub>SH? Explain.

See Problems 12.39, 12.40, 12.41, and 12.42.

## Ionic Solutions

Ionic substances differ markedly in their solubilities in water. For example, sodium chloride, NaCl, has a solubility of 36 g per 100 mL of water at room temperature, whereas calcium phosphate, Ca<sub>3</sub>(PO<sub>4</sub>)<sub>2</sub>, has a solubility of only 0.002 g per 100 mL of water. In most cases, these differences in solubility can be explained in terms of the different energies of attraction between ions in the crystal and between ions and water.

The energy of attraction between an ion and a water molecule is due to an *ion–dipole force*. Water molecules are polar, so they tend to orient with respect to nearby ions. In the case of a positive ion (Li<sup>+</sup>, for example), water molecules orient with their oxygen atoms (the negative ends of the molecular dipoles) toward the ion. In the case of a negative ion (for instance, F<sup>−</sup>), water molecules orient with

Figure 12.8 ▲

**Attraction of water molecules to ions because of the ion-dipole force** The O end of  $\text{H}_2\text{O}$  orients toward the cation, whereas an H atom of  $\text{H}_2\text{O}$  orients toward the anion.

Hydration of ions also occurs in crystalline solids. For example, copper(II) sulfate pentahydrate,  $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ , contains five water molecules for each  $\text{CuSO}_4$  formula unit in the crystal. Substances like this, which are called hydrates, were discussed in Chapter 2.

According to Coulomb's law, the energy of attraction of two ions is proportional to the product of the ion charges and inversely proportional to the distance between the centers of the ions.

Figure 12.10 ▲

**The effects of lattice energy and hydration energy on the solution process of ionic solids** Hydration energy pulls ions apart, whereas the lattice energy keeps the ions together. If the lattice energy is large relative to the hydration energy, the ions are likely to remain together, resulting in an insoluble compound.

Figure 12.9 ▲

**The dissolving of lithium fluoride in water**

Ions on the surface of the crystal can hydrate—that is, associate with water molecules; ions at the corners are especially easy to remove because they are held by fewer lattice forces. Ions are completely hydrated in the aqueous phase and move off into the body of the liquid.

their hydrogen atoms (the positive ends of the molecular dipoles) toward the ion (see Figure 12.8).

The attraction of ions for water molecules is called **hydration**. Hydration of ions favors the dissolving of an ionic solid in water. Figure 12.9 illustrates the hydration of ions in the dissolving of a lithium fluoride crystal. As ions on the surface become partially hydrated, bonds to the crystal weaken to the point the ions break free and subsequently become completely hydrated in solution.

If the hydration of ions were the only factor in the solution process, you would expect all ionic solids to be soluble in water. The ions in a crystal, however, are very strongly attracted to one another. Therefore, the solubility of an ionic solid depends not only on the energy of hydration of ions (energy associated with the attraction between ions and water molecules) but also on *lattice energy*, the energy holding ions

together in the crystal lattice. Lattice energy works against the solution process, so an ionic solid with relatively large lattice energy is usually insoluble (Figure 12.10). ◀

Lattice energies depend on the charges on the ions (as well as on the distance between the centers of neighboring positive and negative ions). The greater the magnitude of ion charge, the greater is the lattice energy. ◀ For this reason, you might expect substances with singly charged ions to be comparatively soluble and those with multiply charged ions to be less soluble. This is borne out by the fact that compounds of the alkali metal ions (such as  $\text{Na}^+$  and  $\text{K}^+$ ) and ammonium ions ( $\text{NH}_4^+$ ) are generally soluble, whereas those of phosphate ions ( $\text{PO}_4^{3-}$ ) combined with multiply-charged cations, for example, are generally insoluble.

Lattice energy is also inversely proportional to the distance between neighboring ions, and this distance depends on the sum of the radii of the ions. For example, the lattice energy of magnesium hydroxide,  $\text{Mg}(\text{OH})_2$ , is inversely proportional to the sum of the radii of  $\text{Mg}^{2+}$  and  $\text{OH}^-$ . In the series of alkaline earth hydroxides— $\text{Mg}(\text{OH})_2$ ,  $\text{Ca}(\text{OH})_2$ ,  $\text{Sr}(\text{OH})_2$ , and  $\text{Ba}(\text{OH})_2$ —the lattice energy decreases as the radius of the alkaline earth ion increases (from  $\text{Mg}^{2+}$  to  $\text{Ba}^{2+}$ ). If the lattice energy alone determines the trend in solubilities, you should expect the solubility to increase from magnesium hydroxide to barium hydroxide: the expected solubility ranking being  $\text{Mg}(\text{OH})_2 < \text{Ca}(\text{OH})_2 < \text{Sr}(\text{OH})_2 < \text{Ba}(\text{OH})_2$ . In fact, this is what you find. Magnesium hydroxide is insoluble in water, and barium hydroxide is soluble. But this is not the whole story. The energy of hydration also depends on ionic radius. A small ion has a concentrated electric charge and a strong electric field that attracts water molecules. Therefore, the energy of hydration is greatest for a small ion such as  $\text{Mg}^{2+}$  and least for a large ion such as  $\text{Ba}^{2+}$ . If the energy of hydration of ions alone determined the trend in solubilities, you would expect the solubilities to decrease from magnesium hydroxide to barium hydroxide, rather than to increase. (We should also add that the energy of hydration increases with the charge on the ion; energy of hydration is greater for  $\text{Mg}^{2+}$  than for  $\text{Na}^+$ . Magnesium ion has a larger charge, and also is a smaller ion than  $\text{Na}^+$ .)

The explanation for the observed solubility trend in the alkaline earth hydroxides is that the lattice energy decreases more rapidly in the series  $\text{Mg}(\text{OH})_2$ ,  $\text{Ca}(\text{OH})_2$ ,  $\text{Sr}(\text{OH})_2$ , and  $\text{Ba}(\text{OH})_2$  than does the energy of hydration in the series of ions  $\text{Mg}^{2+}$ ,  $\text{Ca}^{2+}$ ,  $\text{Sr}^{2+}$ , and  $\text{Ba}^{2+}$ . For this reason, the lattice-energy factor dominates this solubility trend.

A CHEMIST Looks at . . .

## Hemoglobin Solubility and Sickle-Cell Anemia

Sickle-cell anemia was the first inherited disease shown to have a specific molecular basis. In people with the disease, the red blood cells tend to become elongated (sickle-shaped) when the concentration of oxygen ( $O_2$ ) is low, as it is, for example, in the venous blood supply (see Figure 12.11). Once the red blood cells have sickled, they can no longer function in their normal capacity as oxygen carriers, and they often break apart. Moreover, the sickled cells clog capillaries, interfering with the blood supply to vital organs.

In 1949, Linus Pauling showed that people with sickle-cell anemia have abnormal hemoglobin. Hemoglobin is the substance in red blood cells that carries oxygen. Hemoglobin is normally present in solution within the red blood cells. But in people with sickle-cell anemia, the unoxygenated hemoglobin readily comes out of solution. It produces a fibrous precipitate that deforms the cell, giving it the characteristic sickle shape.

Hemoglobins are large molecules (molecular weight about 64,000 amu) consisting of four protein chains, two of one kind ( $\alpha$  chains) and two of another kind ( $\beta$  chains). Normal and sickle-cell hemoglobins are almost exactly alike,

except that each  $\beta$  chain of the hemoglobin responsible for sickle-cell anemia differs from normal hemoglobin in one place. In this place, the normal hemoglobin has the group

which helps confer water solubility on the molecule because of the polarity of the group and its ability to form hydrogen bonds. The abnormal hemoglobin has the following hydrocarbon group:

Hydrocarbon groups are nonpolar. This small change makes the molecule less water-soluble.

**Figure 12.11** ▲

**Red blood cells** Scanning electron micrographs of normal (*left*) and sickled (*right*) red blood cells. The color is added by computer.

■ See Problems 12.111 and 12.112.

You see the opposite solubility trend when the energy of hydration decreases more rapidly so that it dominates the trend. Consider the alkaline earth sulfates. Here the lattice energy depends on the sum of the radius of the cation and the radius of the sulfate ion. Because the sulfate ion,  $SO_4^{2-}$ , is much larger than the hydroxide ion,  $OH^-$ , the percent change in lattice energy in going through the series of sulfates from  $MgSO_4$  to  $BaSO_4$  is smaller than in the hydroxides. The lattice energy changes less, and the energy of hydration of the cation decreases by

a greater amount. Now the energy of hydration dominates the solubility trend, and the solubility decreases from magnesium sulfate to barium sulfate. Magnesium sulfate is soluble in water, and barium sulfate is insoluble.

**Exercise 12.3** Which ion has the larger hydration energy,  $\text{Na}^+$  or  $\text{K}^+$ ?

See Problems 12.43 and 12.44.

### CONCEPT CHECK 12.3

The hypothetical ionic compound  $\text{AB}_2$  is very soluble in water. Another hypothetical ionic compound,  $\text{CB}_2$ , is only slightly soluble in water. The lattice energies for these compounds are about the same. Provide an explanation for the solubility difference between these compounds.

## 12.3 Effects of Temperature and Pressure on Solubility

In general, the solubility of a substance depends on temperature. For example, the solubility of ammonium nitrate in 100 mL of water is 118 g at  $0^\circ\text{C}$  and 811 g at  $100^\circ\text{C}$ . Pressure may also have an effect on solubility, as you will see.

### Temperature Change

Most gases become less soluble in water at higher temperatures. The first bubbles that appear when tap water is heated are bubbles of air released as the increasing temperature reduces the solubility of air in water. In contrast, most ionic solids become more soluble in water with rising temperature.

The variations of the solubilities of the salts  $\text{KNO}_3$ ,  $\text{CuSO}_4$ ,  $\text{NaCl}$ , and  $\text{Ce}_2(\text{SeO}_4)_3$  are shown in Figure 12.12. Three of the salts show the usual behavior; their solubilities increase with rising temperature. For example, potassium nitrate,  $\text{KNO}_3$ , changes solubility dramatically from 14 g/100 g  $\text{H}_2\text{O}$  at  $0^\circ\text{C}$  to 245 g/100 g  $\text{H}_2\text{O}$  at  $100^\circ\text{C}$ . Copper(II) sulfate,  $\text{CuSO}_4$ , shows a moderate increase in solubility over this temperature interval. Sodium chloride,  $\text{NaCl}$ , increases only slightly in solubility with temperature.

A number of ionic compounds decrease in solubility with increasing temperature. Calcium sulfate,  $\text{CaSO}_4$ , and calcium hydroxide,  $\text{Ca}(\text{OH})_2$ , are common examples. They are slightly soluble compounds that become even less soluble at higher temperatures. Cerium selenate,  $\text{Ce}_2(\text{SeO}_4)_3$ , shown in Figure 12.12, is very soluble at  $0^\circ\text{C}$  but much less soluble at  $100^\circ\text{C}$ .

Heat can be released or absorbed when ionic substances are dissolved in water. In some cases, this *heat of solution* is quite noticeable. When sodium hydroxide is

**Figure 12.12** ▶

**Solubility of some ionic salts at different temperatures** The solubilities of the salts  $\text{NaCl}$ ,  $\text{KNO}_3$ , and  $\text{CuSO}_4$  rise with increasing temperature, as is the case with most ionic solids. The solubility of  $\text{Ce}_2(\text{SeO}_4)_3$ , however, falls with increasing temperature.

Figure 12.13 ◀

Instant hot and cold compress packs

a The inner bag of the instant hot compress contains calcium chloride,  $\text{CaCl}_2$ . When the inner bag is broken, the  $\text{CaCl}_2$  dissolves exothermically in water (heat is released).

b The instant cold compress contains an inner bag of ammonium nitrate,  $\text{NH}_4\text{NO}_3$ , which when broken apart allows the  $\text{NH}_4\text{NO}_3$  to dissolve in the water in the outer bag. The solution process is endothermic (heat is absorbed), so the bag feels cold.

© Cengage Learning

dissolved in water, the solution becomes hot (the solution process is exothermic). On the other hand, when ammonium nitrate is dissolved in water, the solution becomes very cold (the solution process is endothermic). This cooling effect from the dissolving of ammonium nitrate in water is exploited in instant cold packs used in hospitals and elsewhere. An instant cold pack consists of a bag of  $\text{NH}_4\text{NO}_3$  crystals inside a bag of water (Figure 12.13). When the inner bag is broken,  $\text{NH}_4\text{NO}_3$  dissolves in the water. Heat is absorbed, so the bag feels cold. Hot packs, by contrast, containing either  $\text{CaCl}_2$  or  $\text{MgSO}_4$ , dissolve in water with the evolution of heat.

### Pressure Change

In general, pressure change has little effect on the solubility of a liquid or solid in water, but the solubility of a gas is very much affected by pressure. The qualitative effect of a change in pressure on the solubility of a gas can be predicted from Le Châtelier's principle. **Le Châtelier's principle** states that when a system in equilibrium is disturbed by a change of temperature, pressure, or concentration variable, the system shifts in equilibrium composition in a way that tends to counteract this change of variable. Let us see how Le Châtelier's principle can predict the effect of a change in pressure on gas solubility.

Imagine a cylindrical vessel that is fitted with a movable piston and contains carbon dioxide gas over its saturated water solution (Figure 12.14). The equilibrium is

Suppose you increase the partial pressure of  $\text{CO}_2$  gas by pushing the piston down. This change of partial pressure, according to Le Châtelier's principle, shifts the equilibrium composition in a

Figure 12.14 ▲

Effect of pressure on gas solubility

mphilips007/istockphoto.com

way that tends to counteract the pressure increase. From the preceding equation, you see that the partial pressure of  $\text{CO}_2$  gas decreases if more  $\text{CO}_2$  dissolves.

The system comes to a new equilibrium, in which more  $\text{CO}_2$  has dissolved. So you can predict that carbon dioxide is more soluble at higher pressures. Conversely, when the partial pressure of carbon dioxide gas is reduced, its solubility is decreased. A bottle of carbonated beverage fizzes when the cap is removed: as the partial pressure of carbon dioxide is reduced, gas comes out of solution (Figure 12.15). The argument given here for carbon dioxide holds for any gas:

All gases become more soluble in a liquid at a given temperature when the partial pressure of the gas over the solution is increased.

**Figure 12.15** ▲

**Sudden release of pressure from a carbonated beverage** A carbonated beverage is produced by dissolving carbon dioxide in beverage solution under pressure. More carbon dioxide dissolves at the higher pressure than otherwise. When this pressure is suddenly released, carbon dioxide is less soluble, and the excess bubbles from the solution.

### Henry's Law: Relating Pressure to the Solubility of a Gas in a Liquid

The effect of pressure on the solubility of a gas in a liquid can be predicted quantitatively. According to **Henry's law**, *the solubility of a gas is directly proportional to the partial pressure of the gas above the solution*. Expressed mathematically, the law is

$$S = k_{\text{H}}P$$

where  $S$  is the solubility of the gas (expressed as mass of solute per unit volume of solvent),  $k_{\text{H}}$  is Henry's law constant for the gas for a particular liquid at a given temperature, and  $P$  is the partial pressure of the gas. The next example shows how this formula is used.

#### Example 12.1 Applying Henry's Law

##### Gaining Mastery Toolbox

###### Critical Concept 12.1

The solubility of a gas in a liquid (solution) is directly proportional to the partial pressure of the gas above the solution. For example, as the pressure of a gas above a liquid increases, the more gas will dissolve in the liquid. This relationship can be expressed as the equation  $S = k_{\text{H}}P$ , where the term  $k_{\text{H}}$  is Henry's law constant that is specific to a particular liquid at a given temperature.

###### Solution Essentials:

- Henry's law ( $S = k_{\text{H}}P$ )
- Partial pressure

In the chapter opening, we noted that 27 g of acetylene,  $\text{C}_2\text{H}_2$ , dissolves in 1 L of acetone at 1.0 atm pressure. If the partial pressure of acetylene is increased to 12 atm, what is its solubility in acetone?

**Problem Strategy** Because we are trying to determine the solubility of a gas in a liquid, this problem is an application of the Henry's law equation:  $S = k_{\text{H}}P$ . Let  $S_1$  be the solubility of the gas at partial pressure  $P_1$ , and let  $S_2$  be the solubility at partial pressure  $P_2$ . Then you can write Henry's law for both pressures.

$$S_1 = k_{\text{H}}P_1$$

$$S_2 = k_{\text{H}}P_2$$

Dividing the second equation by the first, you get

$$\frac{S_2}{S_1} = \frac{k_{\text{H}}P_2}{k_{\text{H}}P_1} \quad \text{or} \quad \frac{S_2}{S_1} = \frac{P_2}{P_1}$$

You can use this relation to find the solubility at one pressure given the solubility at another.

**Solution** At 1.0 atm partial pressure of acetylene ( $P_1$ ), the solubility  $S_1$  is 27 g  $\text{C}_2\text{H}_2$  per liter of acetone. For a partial pressure of 12 atm ( $P_2$ ),

$$\frac{S_2}{27 \text{ g C}_2\text{H}_2/\text{L acetone}} = \frac{12 \text{ atm}}{1.0 \text{ atm}}$$

(continued)

**Example 12.1** (continued)

Then

$$S_2 = \frac{27 \text{ g C}_2\text{H}_2}{\text{L acetone}} \times \frac{12}{1.0} = \frac{3.2 \times 10^2 \text{ g C}_2\text{H}_2}{\text{L acetone}}$$

At 12 atm partial pressure of acetylene, 1 L of acetone dissolves  $3.2 \times 10^2$  g of acetylene.

**Answer Check** Because the solubility of a gas is directly proportional to the pressure of the gas above the solution, check your answer to make certain that the gas at higher pressure has the greater solubility.

**Exercise 12.4** A liter of water at 25°C dissolves 0.0404 g O<sub>2</sub> when the partial pressure of the oxygen is 1.00 atm. What is the solubility of oxygen from air, in which the partial pressure of O<sub>2</sub> is 159 mmHg?

See Problems 12.47 and 12.48.

**CONCEPT CHECK 12.4**

Most fish have a very difficult time surviving at elevations much above 3500 m. How could Henry's law be used to account for this fact?

**Colligative Properties**

In the chapter opening, we mentioned that the addition of ethylene glycol, CH<sub>2</sub>OHCH<sub>2</sub>OH, to water lowers the freezing point of water below 0°C. For example, if 0.010 mol of ethylene glycol is added to 1 kg of water, the freezing point is lowered to -0.019°C. The magnitude of freezing-point lowering is directly proportional to the number of ethylene glycol molecules added to a quantity of water. Thus, if you add 0.020 (=0.010 × 2) mol of ethylene glycol to 1 kg of water, the freezing point is lowered to -0.038°C (= -0.019°C × 2). The same lowering is observed with the addition of other nonelectrolyte substances. For example, an aqueous solution of 0.020 mol of urea, (NH<sub>2</sub>)<sub>2</sub>CO, in 1 kg of water also freezes at -0.038°C.

Freezing-point lowering is a colligative property. **Colligative properties** of solutions are *properties that depend on the concentration of solute molecules or ions in solution but not on the chemical identity of the solute* (whether it is ethylene glycol or urea, for instance). In the next sections, we will discuss several colligative properties, which are expressed quantitatively in terms of various concentration units. We will first look into ways of expressing the concentration of a solution.

**12.4 Ways of Expressing Concentration**

The *concentration* of a solute is the amount of solute dissolved in a given quantity of solvent or solution. The quantity of solvent or solution can be expressed in terms of volume or in terms of mass or molar amount. Thus, there are several ways of expressing the concentration of a solution.

Recall that the *molarity* of a solution is the moles of solute in a liter of solution. ▶ | Molarity was discussed in Section 4.7.

$$\text{Molarity} = \frac{\text{moles of solute}}{\text{liters of solution}}$$

For example, 0.20 mol of ethylene glycol dissolved in enough water to give 2.0 L of solution has a molarity of

$$\frac{0.20 \text{ mol ethylene glycol}}{2.0 \text{ L solution}} = 0.10 \text{ M ethylene glycol}$$

The solution is 0.10 molar (denoted  $M$ ). This unit is especially useful when you wish to dispense a given amount of solute, because the unit directly relates the amount of solute to the volume of solution.

Some other concentration units are defined in terms of the mass or molar amount of solvent or solution. The most important of these are mass percentage of solute, molality, and mole fraction.

### Mass Percentage of Solute

Solution concentration is sometimes expressed in terms of the **mass percentage of solute**—that is, *the percentage by mass of solute contained in a solution*.

$$\text{Mass percentage of solute} = \frac{\text{mass of solute}}{\text{mass of solution}} \times 100\%$$

For example, an aqueous solution that is 3.5% sodium chloride by mass contains 3.5 g of NaCl in 100.0 g of solution. It could be prepared by dissolving 3.5 g of NaCl in 96.5 g of water ( $100.0 - 3.5 = 96.5$ ).

## Example 12.2 Calculating with Mass Percentage of Solute

### Gaining Mastery Toolbox

#### Critical Concept 12.2

Solution concentration can be expressed as a mass percentage of solute. When expressing solution concentration as a mass percent, the units of mass for the solute and solvent must be the same, for example, *grams* of solute and *grams* of solution. The mass of solution is the sum of the mass(es) of the solute(s) and the solvent.

#### Solution Essentials:

- Mass percentage of solute
- (% mass =  $\frac{\text{mass of solute}}{\text{mass of solution}} \times 100\%$ )
- Solute
- Solution
- Concentration

How would you prepare 425 g of an aqueous solution containing 2.40% by mass of sodium acetate,  $\text{NaC}_2\text{H}_3\text{O}_2$ ?

**Problem Strategy** In order to know how to prepare this solution, we need to know the mass of solute ( $\text{NaC}_2\text{H}_3\text{O}_2$ ) and the mass of solution. The mass percent given in the problem (2.40%) will enable us to determine the mass of solute present in the 425-g sample. Keeping in mind that the total mass of solution equals the sum of the mass of solute and the mass of solvent (mass solution = mass solute + mass solvent), we will be able to determine the mass of  $\text{H}_2\text{O}$  needed to prepare the solution.

**Solution** The mass of sodium acetate (solute) in 425 g of solution is

$$\text{Mass of NaC}_2\text{H}_3\text{O}_2 = 425 \text{ g} \times 0.0240 = 10.2 \text{ g}$$

We have the relationship

$$\text{Mass of solution} = \text{mass NaC}_2\text{H}_3\text{O}_2 + \text{mass H}_2\text{O}$$

Therefore, the quantity of water in the solution is

$$\text{Mass of H}_2\text{O} = \text{mass of solution} - \text{mass of NaC}_2\text{H}_3\text{O}_2 = 425 \text{ g} - 10.2 \text{ g} = 415 \text{ g}$$

**You would prepare the solution by dissolving 10.2 g of sodium acetate in 415 g of water.**

**Answer Check** A quick way to check your work is to substitute the values you determined into the formula for mass percentage of solute; make sure that the calculated value agrees with that given in the problem.

**Exercise 12.5** An experiment calls for 35.0 g of hydrochloric acid that is 20.2% HCl by mass. How many grams of HCl is this? How many grams of water?

See Problems 12.49, 12.50, 12.51, and 12.52.

### Molality

The **molality** of a solution is *the moles of solute per kilogram of solvent*.

$$\text{Molality} = \frac{\text{moles of solute}}{\text{kilograms of solvent}}$$

For example, 0.20 mol of ethylene glycol dissolved in  $2.0 \times 10^3$  g (=2.0 kg) of water has a molality of

$$\frac{0.20 \text{ mol ethylene glycol}}{2.0 \text{ kg solvent}} = 0.10 \text{ } m \text{ ethylene glycol}$$

That is, the solution is 0.10 molal (denoted  $m$ ). The units of molality and molarity are sometimes confused. Note that molality is defined in terms of *mass of solvent*, and molarity is defined in terms of *volume of solution*.

### Example 12.3 Calculating the Molality of Solute

#### Gaining Mastery Toolbox

##### Critical Concept 12.3

Solution concentration can be expressed as the ratio of the moles of solute to the mass of solvent: molality ( $m$ ). When calculating solution molality, the mass of solute must be expressed in kg.

##### Solution Essentials:

- Molality  

$$\left( m = \frac{\text{moles of solute}}{\text{kg of solvent}} \right)$$
- Solute
- Solvent
- Concentration

Glucose,  $\text{C}_6\text{H}_{12}\text{O}_6$ , is a sugar that occurs in fruits. It is also known as “blood sugar” because it is found in blood and is the body’s main source of energy (see Figure 12.16). What is the molality of a solution containing 5.67 g of glucose dissolved in 25.2 g of water?

**Problem Strategy** Recall that the definition of *molality* is moles of solute per kilogram of solvent. Therefore, we need to determine these two quantities to solve this problem. Start by converting mass of solute (glucose) to moles, and next determine the mass of solvent (water) in kilograms. Then use these quantities to calculate the solution molality.

**Solution** The moles of glucose (MM = 180.2 amu) in 5.67 g are found as follows:

$$5.67 \text{ g } \text{C}_6\text{H}_{12}\text{O}_6 \times \frac{1 \text{ mol } \text{C}_6\text{H}_{12}\text{O}_6}{180.2 \text{ g } \text{C}_6\text{H}_{12}\text{O}_6} = 0.0315 \text{ mol } \text{C}_6\text{H}_{12}\text{O}_6$$

The mass of water is 25.2 g, or  $25.2 \times 10^{-3}$  kg.

$$\text{Molality} = \frac{0.0315 \text{ mol } \text{C}_6\text{H}_{12}\text{O}_6}{25.2 \times 10^{-3} \text{ kg solvent}} = 1.25 \text{ } m \text{ } \text{C}_6\text{H}_{12}\text{O}_6$$

**Answer Check** Any time you calculate a molality that is greater than about 15  $m$ , unless it is a very concentrated solution or a pure solvent, you probably made an error.

Figure 12.16 ▲

**Intravenous feeding of glucose** Glucose,  $\text{C}_6\text{H}_{12}\text{O}_6$ , is the principal energy substance of the body and is transported to various cells by the blood. Here a glucose solution is being prepared for administration to a patient.

**Exercise 12.6** Toluene,  $\text{C}_6\text{H}_5\text{CH}_3$ , is a liquid compound similar to benzene,  $\text{C}_6\text{H}_6$ . It is the starting material for other substances, including trinitrotoluene (TNT). Find the molality of toluene in a solution that contains 35.6 g of toluene and 125 g of benzene.

See Problems 12.53, 12.54, 12.55, and 12.56.

### Mole Fraction

The **mole fraction** of a component substance  $A$  ( $X_A$ ) in a solution is defined as *the moles of component substance divided by the total moles of solution* (that is, moles of solute plus solvent).

$$X_A = \frac{\text{moles of substance } A}{\text{total moles of solution}}$$

For example, if a solution is made up of 1 mol of ethylene glycol and 9 mol of water, the total moles of solution are 1 mol + 9 mol = 10 mol. The mole fraction of ethylene glycol is  $1/10 = 0.1$ , and the mole fraction of water is  $9/10 = 0.9$ . Multiplying mole fractions by 100 gives *mole percent*. Hence, this solution is 10 mole percent ethylene glycol and 90 mole percent water. You can also say that 10% of the molecules in the solution are ethylene glycol and 90% are water. The sum of the mole fractions of all the components of a solution equals 1.

#### Example 12.4 Calculating the Mole Fractions of Components

##### Gaining Mastery Toolbox

##### Critical Concept 12.4

Solution concentration can be expressed as the ratio of the moles of one of the substances in the solution to the total number of moles of all substances that comprise the solution, that is, the mole fraction. Both solute and solvent concentration can be expressed as a mole fraction. The sum of the mole fractions of all the components that make up a solution must be equal to 1.

##### Solution Essentials:

- Mole fraction

$$\left( X_A = \frac{\text{moles of substance } A}{\text{total moles of solution}} \right)$$

- Solution

What are the mole fractions of glucose and water in a solution containing 5.67 g of glucose,  $C_6H_{12}O_6$ , dissolved in 25.2 g of water?

**Problem Strategy** The mole fraction of a solution is the moles of the substance of interest divided by the total number of moles of solution. For this problem, the total number of moles of solution is the sum of the moles of glucose and the moles of water. The moles of glucose and water can be calculated directly from their masses. Add these mole quantities together to obtain the total moles of the solution. Divide each substance by the total moles to obtain the mole fractions.

**Solution** This is the glucose solution described in Example 12.3. There you found that 5.67 g of glucose equals 0.0315 mol of glucose. The moles of water in the solution are

$$25.2 \text{ g } H_2O \times \frac{1 \text{ mol } H_2O}{18.0 \text{ g } H_2O} = 1.40 \text{ mol } H_2O$$

Hence, the total moles of solution are

$$1.40 \text{ mol} + 0.0315 \text{ mol} = 1.432 \text{ mol}$$

(You retain an extra figure in the answer for further computation.) Finally, you get

$$\text{Mole fraction glucose} = \frac{0.0315 \text{ mol}}{1.432 \text{ mol}} = \mathbf{0.0220}$$

$$\text{Mole fraction water} = \frac{1.40 \text{ mol}}{1.432 \text{ mol}} = \mathbf{0.978}$$

**Answer Check** Note that the sum of the mole fractions is 1.00. Whenever you calculate mole fractions, you can check your answer by making sure that they sum to 1.

**Exercise 12.7** Calculate the mole fractions of toluene and benzene in the solution described in Exercise 12.6.

See Problems 12.57 and 12.58.

Toluene

Benzene

## Conversion of Concentration Units

It is relatively easy to interconvert concentration units when they are expressed in terms of mass or moles of solute and solvent, as the following examples show.

### Example 12.5 Converting Molality to Mole Fractions

#### Gaining Mastery Toolbox

##### Critical Concept 12.5

The concentration of a solution can be expressed in many different ways. Given the concentration of a solution in one set of units, it is often possible to convert to a different set of units. It is critical to keep track of all of the components that define a solution (solute, solvent, and solution) because the concentration units are defined using these quantities. In order to solve the problem in Example 12.5, we must first determine the moles of solute (glucose), moles of solvent (water), and moles of solution (glucose and water).

##### Solution Essentials:

- Molality  $\left(m = \frac{\text{moles of solute}}{\text{kg of solvent}}\right)$
- Mole fraction  $\left(X_A = \frac{\text{moles of substance A}}{\text{total moles of solution}}\right)$
- Solute
- Solvent
- Solution

An aqueous solution is 0.120 *m* glucose, C<sub>6</sub>H<sub>12</sub>O<sub>6</sub>. What are the mole fractions of each component in the solution?

**Problem Strategy** Because molality is the moles of solute per kilogram of solvent, a 0.120 *m* glucose solution contains 0.120 mol of glucose in 1.00 kg of water. After converting 1.00 kg H<sub>2</sub>O to moles, you can calculate the mole fraction using its definition.

**Solution** The moles of H<sub>2</sub>O in 1.00 kg of water are

$$1.00 \times 10^3 \text{ g-H}_2\text{O} \times \frac{1 \text{ mol H}_2\text{O}}{18.0 \text{ g-H}_2\text{O}} = 55.6 \text{ mol H}_2\text{O}$$

Hence,

$$\text{Mole fraction glucose} = \frac{0.120 \text{ mol}}{(0.120 + 55.6) \text{ mol}} = \mathbf{0.00215}$$

$$\text{Mole fraction water} = \frac{55.6 \text{ mol}}{(0.120 + 55.6) \text{ mol}} = \mathbf{0.998}$$

**Answer Check** Check to see that the mole fractions of each substance sum to 1.

**Exercise 12.8** A solution is 0.120 *m* methanol dissolved in ethanol. Calculate the mole fractions of methanol, CH<sub>3</sub>OH, and ethanol, C<sub>2</sub>H<sub>5</sub>OH, in the solution. See Problems 12.59 and 12.60.

### Example 12.6 Converting Mole Fractions to Molality

#### Gaining Mastery Toolbox

##### Critical Concept 12.6

The concentration of a solution can be expressed in many different ways. Given the concentration of a solution in one set of units, it is often possible to convert to a different set of units. It is critical to keep track of all of the components that define a solution (solute, solvent, and solution) because the concentration units are defined using these quantities. The solution to the problem in Example 12.6 requires that we first determine the moles of solute (glucose) and the mass of solvent (water).

##### Solution Essentials:

- Molality  $\left(m = \frac{\text{moles of solute}}{\text{kg of solvent}}\right)$
- Mole fraction  $\left(X_A = \frac{\text{moles of substance A}}{\text{total moles of solution}}\right)$
- Solute
- Solvent
- Solution

A solution is 0.150 mole fraction glucose, C<sub>6</sub>H<sub>12</sub>O<sub>6</sub>, and 0.850 mole fraction water. What is the molality of glucose in the solution?

**Problem Strategy** The molality of the solution is the moles of solute (glucose) per kilogram of solvent (H<sub>2</sub>O). Given the mole fraction information in the problem, we know that each mole of solution contains 0.150 mol of glucose and 0.850 mol of water. If we convert the moles of water (0.850 mol H<sub>2</sub>O) to mass of water, in kilograms, we can then calculate the molality.

**Solution** The mass of this amount of water is

$$0.850 \text{ mol-H}_2\text{O} \times \frac{18.0 \text{ g H}_2\text{O}}{1 \text{ mol-H}_2\text{O}} = 15.3 \text{ g H}_2\text{O} (= 0.0153 \text{ kg H}_2\text{O}) \quad (\textit{continued})$$

**Example 12.6** (continued)

The molality of glucose,  $C_6H_{12}O_6$ , in the solution is

$$\text{Molality of } C_6H_{12}O_6 = \frac{0.150 \text{ mol } C_6H_{12}O_6}{0.0153 \text{ kg solvent}} = \mathbf{9.80 \text{ } m \text{ } C_6H_{12}O_6}$$

**Answer Check** When calculating molality of solutions, always make certain that the mass of solvent is expressed in kilograms.

**Exercise 12.9** A solution is 0.250 mole fraction methanol,  $CH_3OH$ , and 0.750 mole fraction ethanol,  $C_2H_5OH$ . What is the molality of methanol in the solution?

See Problems 12.61 and 12.62.

To convert molality to molarity, and vice versa, you must know the density of the solution. The calculations are described in the next two examples. As the first example shows, molality and molarity are approximately equal in dilute aqueous solutions.

**Example 12.7** Converting Molality to Molarity**Gaining Mastery Toolbox****Critical Concept 12.7**

The concentration of a solution can be expressed in many different ways. Given the concentration of a solution in one set of units, it is often possible to convert to a different set of units. It is critical to keep track of all of the components that define a solution (solute, solvent, and solution) because the concentration units are defined using these quantities. The solution to the problem in Example 12.7 requires that we first determine the mass of solute (KCl) and the mass of solution (KCl and water).

**Solution Essentials:**

## • Molality

$$\left( m = \frac{\text{moles of solute}}{\text{kg of solvent}} \right)$$

## • Molarity

$$\left( M = \frac{\text{moles of solute}}{\text{L of solution}} \right)$$

- Solute
- Solvent
- Solution

An aqueous solution is 0.273 *m* KCl. What is the molar concentration of potassium chloride, KCl? The density of the solution is  $1.011 \times 10^3 \text{ g/L}$ .

**Problem Strategy** You are asked to determine the molarity of the solution, which is the moles of solute (KCl) per liter of solution (volume of  $H_2O$  and KCl). The molality tells you that the solution contains 0.273 mol KCl in 1 kg of water. If we determine the volume of solution that contains 0.273 mol KCl, we should be able to calculate the molarity. Because the solution is made up of only KCl and water, the solution mass is the mass of 0.273 mol KCl plus the mass of 1.000 kg of water. Knowing the total mass of solution, we then can use the solution density to convert from the mass of solution to the volume of solution. The molarity is obtained by dividing the moles of solute by the volume of solution in liters.

**Solution** The first step in determining the volume of solution is to find the mass of potassium chloride in this quantity of solution:

$$0.273 \text{ mol KCl} \times \frac{74.6 \text{ g KCl}}{1 \text{ mol KCl}} = 20.4 \text{ g KCl}$$

The total mass of the solution equals the mass of water plus the mass of potassium chloride.

$$1.000 \times 10^3 \text{ g} + 20.4 \text{ g} = 1.020 \times 10^3 \text{ g}$$

The volume of the solution can be calculated using the inverse of the density of the solution.

$$\text{Volume of solution} = 1.020 \times 10^3 \text{ g} \times \frac{1 \text{ L}}{1.011 \times 10^3 \text{ g}} = 1.009 \text{ L}$$

There is 0.273 mol KCl in every 1.009 L of solution. Hence, the molarity of the solution is

$$\frac{0.273 \text{ mol KCl}}{1.009 \text{ L solution}} = \mathbf{0.271 \text{ } M \text{ } KCl}$$

Note that the molarity and the molality of this solution are approximately equal. This happens in cases where the solutions are dilute and the density is about 1 g/mL.

**Answer Check** If you are converting between molarity and molality of dilute aqueous solutions, the concentrations expressed either way generally do not differ greatly. You can see that is the case here: 0.271 *M* KCl versus 0.273 *m* KCl. Use this fact to check your answers for this type of problem.

(continued)

**Example 12.7** (continued)

**Exercise 12.10** Urea,  $(\text{NH}_2)_2\text{CO}$ , is used as a fertilizer (see the accompanying molecular model). What is the molar concentration of an aqueous solution that is 3.42 *m* urea? The density of the solution is 1.045 g/mL.

See Problems 12.63 and 12.64.

**Example 12.8** Converting Molarity to Molality**Gaining Mastery Toolbox****Critical Concept 12.8**

The concentration of a solution can be expressed in many different ways. Given the concentration of a solution in one set of units, it is often possible to convert to a different set of units. It is critical to keep track of all of the components that define a solution (solute, solvent, and solution) because the concentration units are defined using these quantities. When solving the problem in Example 12.8, it helps to assume that you have a 1-L sample of the solution.

**Solution Essentials:**

## • Molality

$$\left( m = \frac{\text{moles of solute}}{\text{kg of solvent}} \right)$$

## • Molarity

$$\left( M = \frac{\text{moles of solute}}{\text{L of solution}} \right)$$

## • Solute

## • Solvent

## • Solution

An aqueous solution is 0.907 *M*  $\text{Pb}(\text{NO}_3)_2$ . What is the molality of lead(II) nitrate,  $\text{Pb}(\text{NO}_3)_2$ , in this solution? The density of the solution is 1.252 g/mL.

**Problem Strategy** You are asked to calculate the molality of the solution, which is the moles of solute ( $\text{Pb}(\text{NO}_3)_2$ ) per kilogram of solvent ( $\text{H}_2\text{O}$ ). From the molarity, we know that there are 0.907 mol  $\text{Pb}(\text{NO}_3)_2$  per liter of solution. If we consider a 1-L sample of this solution, we can use the density to determine the mass of solution. Because the mass of solution is the mass of lead(II) nitrate plus the mass of water, you can calculate the mass of lead(II) nitrate by difference (mass  $\text{H}_2\text{O}$  = mass of solution – mass of  $\text{Pb}(\text{NO}_3)_2$ ). Now you can calculate the molality.

**Solution** Assuming 1.000 L ( $1.000 \times 10^3$  mL) of solution,

$$\begin{aligned} \text{Mass of solution} &= \text{density} \times \text{volume} \\ &= 1.252 \text{ g/mL} \times 1.000 \times 10^3 \text{ mL} \\ &= 1.252 \times 10^3 \text{ g} \end{aligned}$$

The mass of lead nitrate is

$$0.907 \text{ mol } \text{Pb}(\text{NO}_3)_2 \times \frac{331.2 \text{ g } \text{Pb}(\text{NO}_3)_2}{1 \text{ mol } \text{Pb}(\text{NO}_3)_2} = 3.00 \times 10^2 \text{ g } \text{Pb}(\text{NO}_3)_2$$

The mass of water in 1.000 L of solution is

$$\begin{aligned} \text{Mass of } \text{H}_2\text{O} &= \text{mass of solution} - \text{mass of } \text{Pb}(\text{NO}_3)_2 \\ &= 1.252 \times 10^3 \text{ g} - 3.00 \times 10^2 \text{ g} \\ &= 9.52 \times 10^2 \text{ g} (= 0.952 \text{ kg } \text{H}_2\text{O}) \end{aligned}$$

Hence, the molality of lead(II) nitrate in this solution is

$$\frac{0.907 \text{ mol } \text{Pb}(\text{NO}_3)_2}{0.952 \text{ kg solvent}} = \mathbf{0.953 \text{ } m \text{ } \text{Pb}(\text{NO}_3)_2}$$

**Answer Check** A very common error that you want to avoid when doing this kind of problem is to forget that the solution density is typically the mass of solute per volume of *solution*, not the mass of solute per volume of solvent.

**Exercise 12.11** An aqueous solution is 2.00 *M* urea. The density of the solution is 1.029 g/mL. What is the molal concentration of urea in the solution?

See Problems 12.65 and 12.66.

## 12.5 Vapor Pressure of a Solution

During the nineteenth century, chemists observed that the vapor pressure of a volatile solvent was lowered by addition of a nonvolatile solute. **Vapor-pressure lowering** of a solvent is a colligative property equal to the vapor pressure of the pure solvent minus the vapor pressure of the solution. For example, water at 20°C has a vapor pressure of 17.54 mmHg. Ethylene glycol,  $\text{CH}_2\text{OHCH}_2\text{OH}$ , is a liquid whose vapor pressure at 20°C is relatively low; it can be considered to be nonvolatile compared with water. An aqueous solution containing 0.0100 mole fraction of ethylene glycol has a vapor pressure of 17.36 mmHg. Thus, the vapor-pressure lowering,  $\Delta P$ , of water is

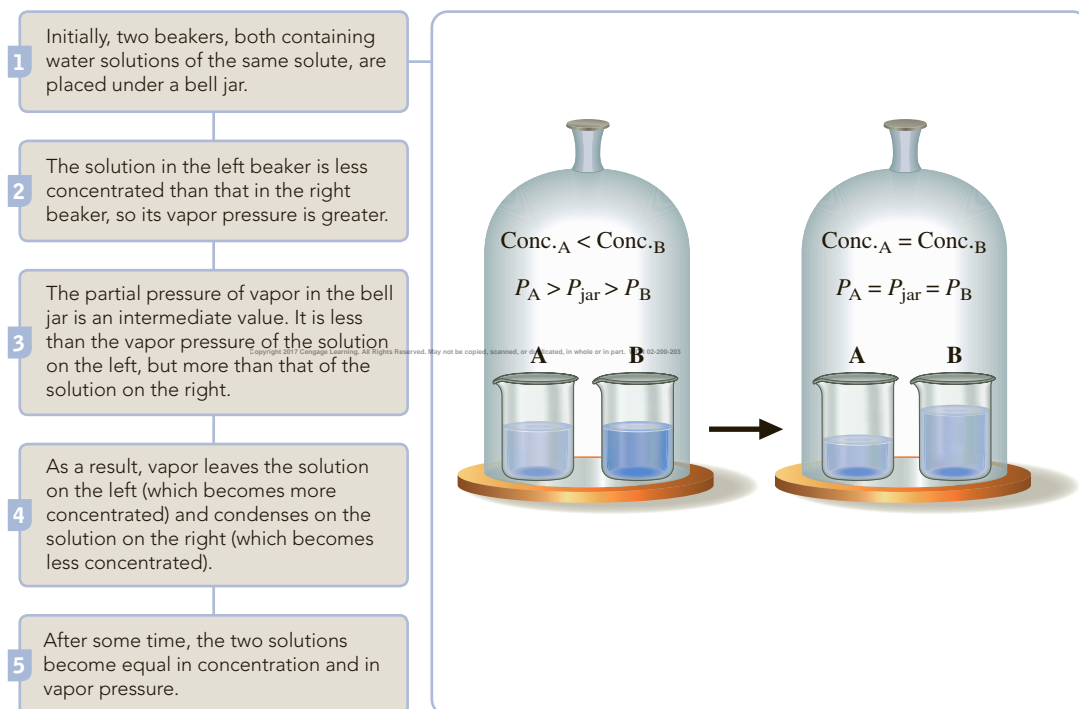

$$\Delta P = 17.54 \text{ mmHg} - 17.36 \text{ mmHg} = 0.18 \text{ mmHg}$$

Figure 12.17 shows a demonstration of vapor-pressure lowering.

In about 1886, the French chemist François Marie Raoult observed that the partial vapor pressure of solvent over a solution of a nonelectrolyte solute depends on the mole fraction of solvent in the solution. Consider a solution of volatile solvent,  $A$ , and nonelectrolyte solute,  $B$ , which may be volatile or nonvolatile. According to **Raoult's law**, the partial pressure of solvent,  $P_A$ , over a solution equals the vapor pressure of the pure solvent,  $P_A^\circ$ , times the mole fraction of solvent,  $X_A$ , in the solution.

$$P_A = P_A^\circ X_A$$

If the solute is nonvolatile,  $P_A$  is the total vapor pressure of the solution. Because the mole fraction of solvent in a solution is always less than 1, the vapor pressure of the solution of a nonvolatile solute is less than that for the pure solvent; the vapor pressure is lowered. In general, Raoult's law is observed to hold for dilute solutions—that is, solutions in which  $X_A$  is close to 1. If the solvent and solute are chemically similar, Raoult's law may hold for all mole fractions. Raoult's law is displayed graphically for two solutions in Figure 12.18.

**Figure 12.17** ▲

Demonstration of Raoult's law of partial vapor pressures

You can obtain an explicit expression for the vapor-pressure lowering of a solvent in a solution, assuming that Raoult's law holds and that the solute is a nonvolatile nonelectrolyte. The vapor-pressure lowering,  $\Delta P$ , is

$$\Delta P = P_A^\circ - P_A$$

Substituting Raoult's law gives

$$\Delta P = P_A^\circ - P_A^\circ X_A = P_A^\circ(1 - X_A)$$

But the sum of the mole fractions of the components of a solution must equal 1; that is,  $X_A + X_B = 1$ . So  $X_B = 1 - X_A$ . Therefore,

$$\Delta P = P_A^\circ X_B$$

From this equation, you can see that the vapor-pressure lowering is a colligative property—one that depends on the concentration, but not on the nature, of the solute. Thus, if the mole fraction of ethylene glycol,  $X_B$ , in an aqueous solution is doubled from 0.010 to 0.020, the vapor-pressure lowering is doubled from 0.18 mmHg to 0.36 mmHg. Also, because the previous equation does not depend on the characteristics of the solute (other than its being nonvolatile and a nonelectrolyte), a solution that is 0.010 mole fraction urea,  $(\text{NH}_2)_2\text{CO}$ , has the same vapor-pressure lowering as one that is 0.010 mole fraction ethylene glycol. The next example illustrates the use of the previous equation.

**Figure 12.18** ▲

**Plot of vapor pressures of solutions showing Raoult's law** Vapor pressures of solvent  $A$  for two solutions have been plotted against mole fraction of solvent. In one case (labeled “ideal solution”), the vapor pressure is proportional to the mole fraction of solvent for all mole fractions; it follows Raoult's law for all concentrations of solute. For the “nonideal solution,” Raoult's law is followed for low solute concentrations (mole fraction of solvent near 1), but the vapor pressure deviates at other concentrations.

### Example 12.9 Calculating Vapor-Pressure Lowering

#### Gaining Mastery Toolbox

##### Critical Concept 12.9

The vapor pressure of a solution is lower than the vapor pressure of the pure solvent. Raoult's law ( $P_A = P_A^\circ X_A$ ) can be used to calculate the vapor pressure of dilute solutions. Raoult's law requires that the solution concentration be expressed as a mole fraction. The vapor pressure lowering of a solution can be expressed as a function of the mole fraction of solute:  $\Delta P = P_A^\circ X_B$ .

##### Solution Essentials:

- Raoult's law ( $P_A = P_A^\circ X_A$ )
- Equation for vapor pressure lowering ( $\Delta P = P_A^\circ X_B$ )
- Mole fraction
- Solute
- Partial pressure
- Vapor pressure

Calculate the vapor-pressure lowering of water when 5.67 g of glucose,  $\text{C}_6\text{H}_{12}\text{O}_6$ , is dissolved in 25.2 g of water at  $25^\circ\text{C}$ . The vapor pressure of water at  $25^\circ\text{C}$  is 23.8 mmHg. What is the vapor pressure of the solution?

**Problem Strategy** In order to calculate the vapor-pressure lowering of the solution described in this problem, we need to determine the amount that the vapor pressure of the pure solvent is changed ( $\Delta P$  of water) with the addition of a solute (glucose). We can use Raoult's law to calculate this quantity, noting that we need to know the mole fraction of the solute (glucose). The vapor pressure of the solution is found by subtracting the vapor-pressure change of the pure solvent from the vapor pressure of the pure solvent.

**Solution** This is the glucose solution described in Example 12.4. According to the calculations performed there, the solution is 0.0220 mole fraction glucose. Therefore, the vapor-pressure lowering is

$$\Delta P = P_A^\circ X_B = 23.8 \text{ mmHg} \times 0.0220 = \mathbf{0.524 \text{ mmHg}}$$

The vapor pressure of the solution is

$$P_A = P_A^\circ - \Delta P = (23.8 - 0.524) \text{ mmHg} = \mathbf{23.3 \text{ mmHg}}$$

**Answer Check** In this type of calculation, a correct answer will always have the vapor pressure of the solution lower than the vapor pressure of the pure solvent.

**Exercise 12.12** Naphthalene,  $\text{C}_{10}\text{H}_8$ , is used to make mothballs. Suppose a solution is made by dissolving 0.515 g of naphthalene in 60.8 g of chloroform,  $\text{CHCl}_3$ . Calculate the vapor-pressure lowering of chloroform at  $20^\circ\text{C}$  from the naphthalene. The vapor pressure of chloroform at  $20^\circ\text{C}$  is 156 mmHg. Naphthalene can be assumed to be nonvolatile compared with chloroform. What is the vapor pressure of the solution?

See Problems 12.67 and 12.68.

**Figure 12.19** ▲

**Molecular models of benzene and toluene** *Top:* Benzene. *Bottom:* Toluene, which differs from benzene, where one hydrogen is replaced by a  $\text{CH}_3$  group.

An *ideal solution* of substances  $A$  and  $B$  is one in which both substances follow Raoult's law for all values of mole fractions. Such solutions occur when the substances are chemically similar so that the intermolecular forces between  $A$  and  $B$  molecules are similar to those between two  $A$  molecules or between two  $B$  molecules. In this case, we are not restricted to the solute being nonvolatile: both the solute and solvent have significant vapor pressure. Therefore, the total vapor pressure over an ideal solution equals the sum of the partial vapor pressures, each of which is given by Raoult's law:

$$P = P_A^\circ X_A + P_B^\circ X_B$$

Solutions of benzene,  $\text{C}_6\text{H}_6$ , and toluene,  $\text{C}_6\text{H}_5\text{CH}_3$ , are ideal. Note the similarity in their structures (see Figure 12.19).

Suppose a solution is 0.70 mole fraction benzene and 0.30 mole fraction toluene. The vapor pressures of pure benzene and pure toluene are 75 mmHg and 22 mmHg, respectively. Hence, the total vapor pressure is

$$P = (75 \text{ mmHg} \times 0.70) + (22 \text{ mmHg} \times 0.30) = 59 \text{ mmHg}$$

You can easily see that the vapor over this solution is richer in the more volatile component (benzene). The partial vapor pressure of benzene over the solution is

$$75 \text{ mmHg} \times 0.70 = 53 \text{ mmHg}$$

Because the total vapor pressure is 59 mmHg, the mole fraction of benzene in the vapor is

$$\frac{53 \text{ mmHg}}{59 \text{ mmHg}} = 0.90$$

The vapor is 0.90 mole fraction benzene, whereas the liquid solution is 0.70 mole fraction benzene. This is a general principle: the vapor over a solution is richer in the more volatile component.

Use is made of this principle to separate a more volatile component from a liquid mixture. If you distill a mixture of benzene and toluene, the vapor and the resulting liquid that distills over (the distillate) will be richer in benzene, the more volatile component. If you then take this distillate and distill it, the vapor and the resulting liquid that comes over will be even richer in benzene. After many such distillations, you can obtain nearly pure benzene. ◀

In practice, instead of actually performing a series of simple distillations to separate the volatile components of a mixture, you perform a single *fractional distillation* using a fractionating column, such as the one shown in Figure 12.20. Vapor from the liquid in the flask condenses on cooler packing material (which might be glass beads) in the lower part of the column. In turn, this liquid (which is slightly richer in benzene) vaporizes and condenses farther up the column, where it is even cooler. The liquid that results is even richer in benzene. The distillation process continues up the column, so the composition of the liquid varies continuously from a mixture of benzene and toluene at the bottom of the column to pure benzene at the top. The temperature also varies continuously up the column, being cooler at the top than at the bottom. The liquid that distills over at first is pure benzene. As the liquid in the distillation flask becomes richer in the less volatile component (toluene), the boiling point of the liquid in the flask increases. Fractional distillation is a common procedure in the laboratory and in industrial processing. For example, it is used to separate the components of petroleum into gasoline, diesel fuel, and so forth. ◀

Simple distillation was discussed in Section 1.4.

Table 23.4 lists the various fractions obtained from petroleum, along with their boiling-point ranges.

**CONCEPT CHECK 12.5**

Suppose you need to boil a water-based solution at a temperature lower than  $100^\circ\text{C}$ . What kind of liquid could you add to the water to make this happen?

Figure 12.20 ◀

**Fractional distillation** This is a typical laboratory apparatus for the fractional distillation of a liquid solution to obtain pure liquid components. The fractionating column contains a packing material, such as glass beads, on which vapor condenses and liquid redistills. The stopper on the receiver is loosely fitted to allow ventilation to the atmosphere.

## 12.6 Boiling-Point Elevation and Freezing-Point Depression

The *normal* boiling point of a liquid is the temperature at which its vapor pressure equals 1 atm. Because the addition of a nonvolatile solute to a liquid reduces its vapor pressure, the temperature must be increased to a value greater than the normal boiling point to achieve a vapor pressure of 1 atm. Figure 12.21 shows the vapor-pressure curve of a solution. The curve is below the vapor-pressure curve of the pure liquid solvent. The **boiling-point elevation**,  $\Delta T_b$ , is a *colligative property of a solution equal to the boiling point of the solution minus the boiling point of the pure solvent*.

The boiling-point elevation,  $\Delta T_b$ , is found to be proportional to the molal concentration,  $c_m$ , of the solution (for dilute solutions).

$$\Delta T_b = K_b c_m$$

The constant of proportionality,  $K_b$  (called the *boiling-point-elevation constant*), depends only on the solvent. Table 12.3 lists values of  $K_b$ , as well as boiling points,

Figure 12.21 ◀

**Phase diagram showing the effect of a nonvolatile solute on freezing point and boiling point** Note that the freezing point ( $T_f$ ) is lowered and the boiling point ( $T_b$ ) is elevated.

Solvent	Formula	Boiling Point (°C)	Freezing Point (°C)	$K_b$ (°C/m)	$K_f$ (°C/m)
Acetic acid	HC <sub>2</sub> H <sub>3</sub> O <sub>2</sub>	118.5	16.60	3.08	3.59
Benzene	C <sub>6</sub> H <sub>6</sub>	80.2	5.455	2.61	5.065

Data are taken from Landolt-Börnstein, 6th ed., *Zahlenwerte und Funktionen aus Physik, Chemie, Astronomie, Geophysik, und Technik*, Vol. II, Part IIa (Heidelberg: © Springer-Verlag, 1960), pp. 844–849 and pp. 918–919.

for some solvents. Benzene, for example, has a boiling-point-elevation constant of  $2.61^\circ\text{C}/m$ . This means that a  $0.100\ m$  solution of a nonvolatile, undissociated solute in benzene boils at  $0.261^\circ\text{C}$  above the boiling point of pure benzene. Pure benzene boils at  $80.2^\circ\text{C}$ , so a  $0.100\ m$  solution boils at  $80.2^\circ\text{C} + 0.261^\circ\text{C} = 80.5^\circ\text{C}$ .

Figure 12.21 also shows the effect of a dissolved solute on the freezing point of a solution. The solution, with a lower vapor pressure than the pure solvent, has a lower freezing point and a higher boiling point than the pure solvent. When freezing occurs, it is usually the pure solvent that freezes out of solution; note how the vapor pressure curve for the solid is unchanged. For example, sea ice, which forms when ocean water freezes, is almost pure water. The **freezing-point depression**,  $\Delta T_f$ , is a colligative property of a solution equal to the freezing point of the pure solvent minus the freezing point of the solution. ( $\Delta T_f$  is shown in Figure 12.21.)

Freezing-point depression,  $\Delta T_f$ , like boiling-point elevation, is proportional to the molal concentration,  $c_m$  (for dilute solutions).

$$\Delta T_f = K_f c_m$$

Here  $K_f$  is the *freezing-point-depression constant* and depends only on the solvent. Table 12.3 gives values of  $K_f$  for some solvents. The freezing-point-depression constant for benzene is  $5.07^\circ\text{C}/m$ . Thus, a  $0.100\ m$  solution freezes at  $0.507^\circ\text{C}$  below the freezing point of pure benzene. Pure benzene freezes at  $5.46^\circ\text{C}$ ; the freezing point of the solution is  $5.46^\circ\text{C} - 0.507^\circ\text{C} = 4.95^\circ\text{C}$ .

### Example 12.10 Calculating Boiling-Point Elevation and Freezing-Point Depression

#### Gaining Mastery Toolbox

##### Critical Concept 12.10

Solutions have higher boiling points and lower freezing points than the pure solvent. The magnitude of the changes in boiling and freezing points of a particular solvent depends on the concentration of the solution: the more concentrated the solution, the more the boiling and freezing points change from their normal values.

An aqueous solution is  $0.0222\ m$  glucose. What are the boiling point and the freezing point of this solution?

**Problem Strategy** In this problem we will need to use the equations for both boiling-point elevation and freezing-point depression. To use these equations, we need solution molality and the appropriate constants. The constants are found in Table 12.3.

**Solution** Table 12.3 gives  $K_b$  and  $K_f$  for water as  $0.512^\circ\text{C}/m$  and  $1.86^\circ\text{C}/m$ , respectively. Therefore,

$$\Delta T_b = K_b c_m = 0.512^\circ\text{C}/m \times 0.0222\ m = 0.0114^\circ\text{C}$$

$$\Delta T_f = K_f c_m = 1.86^\circ\text{C}/m \times 0.0222\ m = 0.0413^\circ\text{C}$$
